also, when such a mixture is introduced into a carbonated water, all the conditions favourable to electrical action. In considering the probable effect of electrical action upon the chemical purification of water, it should not be forgotten that it will decompose many organic bodies which constitute the polluting agents of water. Thus it has been proved by Schlagdenbaufen (*J. Pharm.* [3], xlv. 100) that urea is converted into ammonia and carbonic acid by electrolysis; and it has also been shown by Erlenmeyer (*Zeit. Ch. Pharm.*, 1861, p. 548) that nascent hydrogen appears to convert hippuric acid into glycocine and hydride of benzoyl. If now we

are correct in our view that the chemical purification in coke is produced in the manner above described, then it should be possible to emphasise the purification by introducing a greater quantity of iron into the coke. We put this to the test in the following manner. The coke previously experimented with was treated in a muffle to redness; then cooled, digested for a long time with a concentrated solution of ferric chloride until it was saturated, and dried. It was then introduced into a muffle, and heated to dull redness to reduce the iron. The ferro-coke, as we term it, thus produced, was thoroughly washed, and the filtrations were then made as before. Table B gives the results obtained.

It will be seen that our predictions were fully verified, and that a most marked increase in the purification was accomplished.

water, we digested the coke previously charged with iron with hydrochloric acid, and maintained it at a considerable heat for about 8 hours. This treatment did not remove all the iron, as we subsequently discovered, or we should have treated with nitro-hydrochloric acid and boiled; but it is fairly safe to conclude that all the metallic iron had been extracted, and that the residue was present in the form of pyrites. After digestion, the coke was thoroughly washed, and filtration allowed to proceed as before. Table D gives the results obtained.

It will at once be seen that the chemical activity of the filter has now become almost nil. Hence, seeing that we can increase the amount of purification effected by increasing the ratio of iron to coke, and materially diminish it by decreasing this proportion, we feel that we are justified in concluding that its

We next tried the effect of a dilute solution of ferric chloride upon a new sample of coke, and proceeded exactly as before. Table C gives the results obtained.

The purification, as we had anticipated, was not so great as when the coke was fully charged with iron. It was, nevertheless, very considerable, but exhibited the characteristics common to all filters of this type. The intensity of purifying effect diminished with the deposition of oxide and carbonate.

In order to clinch the question as to whether the iron had anything to do with the purification of the

presence is essential to the purification, and that it is brought about by the contact of the two dissimilar bodies, iron and coke.

Having ascertained this much, we were anxious to see whether we could overcome the obstacles presented to continuous purification by the formation of oxides and carbonates. We reasoned that it would be possible to render the action continuous by introducing our filter of coke and iron into the circuit of an electric current from a Daniell battery. In this way there would be a tendency to depolarisation; but in any case the electric current would be main-

tained, and the oxidation of a greater quantity of iron would be promoted. In order to test this we varied our experiments in the following manner:—

Instead of using a glass tube, we took one of about the same dimensions of wrought-iron. This we filled with powdered coke, taking the usual precautions to prevent any solid matter being introduced mechanically into the filtered water. In the centre of the coke, and firmly embedded in it, we introduced a carbon rod, which we connected by a wire with one pole of a Daniell battery. Around the exterior of the wrought-iron pipe we fastened a wire which was connected with the other pole of the battery. We did not at first make the connection with the battery, but allowed filtration to proceed until the filter had become practically inert. It will be noticed that this occurred in about three days after the commencement of filtration. Of course, during this period the filter was in continuous use night and day. It will be seen that the use of the battery accomplished a remarkable revivification of the filter, as shown in Table E.

From this and other experiments which we have made, we are disposed to regard an electrical battery as a very valuable adjunct to a chemically purifying, as well as to a sterilising filter, and we propose to continue our experiments in this direction.

to the presence of carbonates, which exert a retarding effect in the reduction, and is expedited by the presence of sodic chloride, due no doubt to the fact that the latter body exerts an intensifying effect upon the electrical action of the couple. But whereas he states the couple has "not the least destructive or corrosive action on the organic matter in water" (*ib.* p. 149), we find that it exerts, as we might have expected, a very powerful action upon it when water is filtered through it. Considerable care was exercised in the preparation of our couple, and a large amount of it, about 3 pounds in weight, was introduced into a glass tube about 12 inches long and 2 inches wide. The usual precautions were taken to prevent any solid matter passing into the filtered water, and the rate of filtration was made to correspond with that of the water passing through coke, etc., in the longer tubes. The couple was very energetic, and an abundance of hydrogen was generated in presence of water at a temperature of 19° C. Table F gives the results obtained.

It will be seen that, in the first instance, this couple constitutes a filter of remarkable power; but, in accordance with the observations of Williams with respect to its application to the estimation of nitrates, its intensity diminishes with the gradual accumula-

* Temperature of water maintained at 50° C.

† NaCl added to water.

If, now, we have deduced correct inferences from those experiments to which we have already invited your attention, it should be possible for us to constitute a filter out of the combination of any two dissimilar elements, one of which is subject to oxidation when in contact with water; and the amount of purification should vary directly with the dissimilarity of the bodies constituting the filter. Hence a very powerful purifying agent should be provided in the zinc-copper couple, and we determined, therefore, to experiment with this material. In order to filter water through a considerable thickness of this couple, it was advisable to employ the dry and not the wet couple; and it is well we should say that we have carefully considered the experiments of Williams (*Chem. Soc. Journ.* 1881), and that in most respects our results accord with his. Inasmuch, however, as he has not published complete analyses of the organic constituents of water before and after treatment, it is somewhat difficult to compare our experiments with his; and more especially because he worked with the wet couple, and we have experimented with the dry. In any case, we have found, with him, that the action is completely to convert the nitrogen of the nitrates into ammonia, and that the action is uncertain owing

to the presence of carbonates, which exert a retarding effect in the reduction, and is expedited by the presence of sodic chloride. It is worthy of mention that we could not discover a trace of zinc or copper in solution after the water had been subjected to this method of filtration.

Now, it will be noticed that throughout these experiments the waters, after filtration, have all exhibited a diminution in hardness; and in some cases, more particularly with the zinc-copper couple, the diminution has been very remarkable. It was necessary to ascertain the cause of this, and we proceeded to do so in the following manner:—Distilled water was treated with caustic lime, and, after cooling, carbonic acid was passed into the water to saturation. To a portion of this artificially carbonated water was added pure and freshly precipitated ferric hydrate, and to another portion was added pure zinc hydrate, equally fresh. Both samples were now frequently agitated and strongly aerated. In the first experiments the respective hydrates were allowed to be in contact with the waters for about five minutes; but in the second this was increased to about twelve hours, and in each case there was abundant agitation. The hardness of the carbonated waters was deter-

mined before and after this treatment, with the following results :—

Hardness of artificial water.....	913
" after treatment with ferric hydrate (5 min.)	786
" " " " zincic " (12 hrs.)	886
" " " " ferric " (12 hrs.)	113
" " " " zincic " (12 hrs.)	713

It will thus be seen that ferric and zincic hydrates will decompose the acid carbonate of lime in a manner similar to that effected by Clarke's process ; indeed, the amount of reduction which is effected by ferric hydrate is very great. These experiments satisfactorily explain the reduction in hardness, and show, moreover, why filters of this type (of which so many are in the market) should gradually diminish in purifying intensity with the accumulation of carbonate.

It only remains for us to show that those materials which exert a maximum chemical purifying effect are also the most efficient in producing sterilisation ; and the theory which we advanced at the commencement of this paper will then, we think, be proved.

Samples of water were submitted to plate cultivation, and every precaution was taken to ensure accuracy in accordance with the most recent instructions of Koch, Klein, Bischof and Crookshank, and P. Frankland. We append a table of some of the results obtained by us :—

ORGANISMS IN 1cc. OF WATER (KOCH-FRANKLAND PROCESS).

	A.	B.

We have not thought it necessary to repeat the experiments of Dr. Percy Frankland with respect to the sterilising properties of those bodies, such as spongy iron, animal charcoal, etc., which admittedly influence the chemical composition of the water passing through them, because we are sufficiently convinced of their accuracy. We have as yet confined our attention to what we regard as test cases, and it will, we think, be admitted that we are most fully confirmed in our view that chemical purification of water is accompanied by germ removal. We believe, moreover, that the time is not far distant when the two questions will not be considered except in conjunction with one another. It is our intention to continue our experiments upon this basis, because we are convinced that it is the true one from which to attack the question of filtration. We can but hope that this preliminary statement of some of our results may induce others to take up the work from a similar standpoint ; and in so doing we are convinced that they will materially contribute towards the solution of one of the most pressing and vital of our social problems.

ON RECENT IMPROVEMENTS IN THE TREATMENT OF WATER FOR TECHNICAL PURPOSES.

BY WM. MACNAB AND G. H. BECKETT.

In a great number of cases the water which the manufacturer can command for use in steam boilers and the various processes and operations in his works, is very unsuitable on account of the lime and magnesia salts in solution.

Attention has been frequently drawn to the obvious advantages of softening water before using it in boilers, and for washing purposes ; and, although the chemical treatment to be described has been proposed, we have not found any detailed account of the actual results obtained where the aim has been to remove both the temporary and permanent hardness.

Such a process is now being applied to large quantities of waters from various sources, and the results obtained in practice on the large scale thereby acquire a special interest. This process consists in the use of caustic soda and lime. The use of carbonate and even caustic soda has been practised ; but these reagents had been almost always placed in the boiler itself, in which the precipitation consequently took place. The results we have now to describe have been obtained by treating the water continuously with a mixture of caustic soda and lime water, in such proportions as to reduce the hardness of the water to the lowest attainable point, at the same time avoiding an excess of the reagent.

The treatment is carried on in an apparatus which allows of the separation of the precipitate, and the water which comes away is practically free from lime and other substances which could form a scale in a boiler.

For the sake of convenience we shall first take the consideration of the chemical treatment only, and shall briefly refer to the other methods which have been proposed and tried. The chief of these are :—

(1.) *Carbonate of Soda Method.*—Where this is employed to precipitate lime and magnesia from the water before it is introduced into the boiler, an excess must be used to combine with the free carbonic acid in the water, forming sesquicarbonate, and the treated water then contains excess of alkali, which is objectionable for most purposes, besides which the precipitation is incomplete unless heat be also employed.

(2.) *Lime and Chloride of Barium.*—The chief objection to this method is that the permanent hardness is not removed, the sulphate of lime being simply converted into chloride.

(3.) *Alkaline Oxalates.*—This is expensive, and only lime salts are affected.

(4.) *Magnesia.*—This requires a temperature of 80° C. to complete the reaction.

(5.) *Hydrochloric Acid.*—This is used to decompose the temporary hardness, forming a soluble chloride, but does not remove anything from the water.

(6.) *Lime.*—This removes only the temporary hardness, and of course is excellent so far as it goes.

The lime and caustic soda method removes practically all the hardness, both temporary and permanent, does its work without the aid of heat, and gives a water containing only soluble soda salts and no excess of alkali.

Now, in order to precipitate salts other than the carbonate, it is necessary to employ carbonate of soda, and this is provided by the caustic soda and by the carbonic acid usually present in the water in the free state ; but only so much caustic soda is used as is requisite to decompose the sulphates, chlorides, etc., and lime water is used to remove the carbonic acid which is not required for the caustic soda. To precipitate magnesium salts, caustic and not carbonate of soda is necessary. The following equations exemplify the reactions :—

Caustic soda is preferable to carbonate for this process, for, although the carbonate is causticised by lime, the reaction is not complete in the cold, and the solution made from the carbonate is not so convenient to use in consequence of this. But where the permanent hardness due to lime salts is excessive, or the quantity of free carbonic acid is too small, it becomes necessary to supplement the caustic soda with carbonate of soda in a quantity sufficient to make up the total quantity of alkaline carbonate required to decompose this hardness. In our experience treatment with lime and caustic soda is the most suitable in the majority of cases.

We shall now describe the application of the method, and for this purpose shall take the case of the water supplied by one of the Metropolitan companies. It has the following analysis:—

Grains per Gallon.		Grains per Gallon.	
CaCO ₃	17.46		
CaSO ₄	2.75		
MgSO ₄	1.72	Free CO ₂	7.23
MgCl ₂42	Hardness.....	21.4
NaCl	2.00		
SiO ₂56		
Fe ₂ O ₃ , Al ₂ O ₃			
<hr/>			
24.91			

To neutralise all the free carbonic acid in this water 13lb. of lime or 130gals. of clear lime water would be required for 1000gals. of water; but a part of this carbonic acid is used in combination with soda to decompose the sulphate of lime, so that only 11lb. of lime or 110gals. of lime water will be required. Of caustic soda 0.24lb. will be required for the calcium sulphate, and 0.24lb. for the magnesia salts. If, then, 110gals. of lime water, which contain also .48lb. of caustic soda, be added to 1000gals. of water corresponding to the above analysis, a precipitate will be formed, and if this be allowed to settle the supernatant water will contain only about 3° of hardness, and the following is an analysis of such water as obtained on the large scale:—

Grains per Gallon.		Hardness = 2.6°
CaCO ₃	1.26	
MgCO ₃	1.12	
Na ₂ CO ₃	3.85	
Na ₂ SO ₄	4.83	
NaCl	2.45	
SiO ₂ , Fe ₂ O ₃ , Al ₂ O ₃56	
	<hr/> 14.07	

A few other analyses illustrating the results obtained on the large scale may be also of interest:—

ORIGINAL WATER.		AFTER SOFTENING.

	41.10		23.66
Hardness	28.°	Hardness	5.°
Free CO ₂	8.93		

In this water the reduction was intentionally stopped short of the limit, by using an insufficiency of caustic soda, to avoid the presence of any carbonate of soda; but this latter has not been found to be objectionable in such small quantities as in the first two instances cited above.

Many users of water for boilers have expressed an objection to using caustic soda for softening the water, as they imagined that the water so treated would

enter their boiler charged with caustic soda. It is hardly necessary to state here that the caustic soda, added to the water in regulated quantities, is practically all transformed into the sulphate or chloride, salts which are perfectly harmless for nearly all the technical purposes to which water is applied. An inspection of the foregoing analytical figures will show the ultimate destination of the caustic soda.

It will thus be seen that this process admits of practically all the lime and magnesia, however combined, being removed from such natural hard waters, equivalent quantities of sodium sulphate or chloride being substituted for the corresponding lime and magnesia salts.

It is impossible to entirely remove the lime and magnesia from water by this process, owing to the slight solubility of carbonate of lime and hydrate of magnesia, and in fact the amount of this residual hardness is subject to some variation according to the impurities present, and the time given for the reaction. As far as carbonate of lime is concerned, its solubility seems to be fairly constant, and amounts to about two grains per gallon or one part in 35,000, but the solubility of the magnesia precipitate is liable to variations, which we have endeavoured to investigate.

In this process the magnesia will be precipitated as hydrate or carbonate, according as hydrate or carbonate of soda is used as the precipitant, and of these two magnesia hydrate is the most insoluble. If a solution of a magnesia salt be precipitated with excess of lime water or hydrate of soda, the resulting solution will contain only about one part of magnesia in 50,000 parts of water. But if the caustic soda contained carbonate so as to cause the magnesia hydrate to be mixed with carbonate, a larger quantity of magnesia will remain in solution; and our experiments tend to show that when an excess of caustic soda is used with the view of depriving the precipitate of carbonic acid, the object is only partially attained, and it seems that carbonic acid in solution, even in presence of an excess of caustic soda, will operate by causing more of the magnesia to remain in solution.

Of course these considerations are only of importance when dealing with very dilute solutions of magnesia, as in natural waters.

By the use of lime water the carbonic acid may be removed from the solution, and its solvent effect thereby destroyed; but it is in the difficulty of adjusting the proportion of lime water, so as to avoid an excess over a sufficiency, that the trouble of treating magnesian waters arises, and where a large quantity of magnesium salts is present, it is always difficult to reduce the residual hardness to a minimum.

The difficulty of adjusting the lime and caustic soda so as to obtain the lowest practical result, is illustrated by the following experiment, where the reagents were added in quantities calculated to precipitate all the lime as carbonate, and the magnesia as hydrate. 1gram. MgO and 14gram. CaO per litre in solution as sulphates treated with 265gram. Na₂CO₃, and 200gram. NaHO—that is, equivalent quantities—for 2½ hours in the cold, gave—

CaO unprecipitated	.037gram. per litre = 4.6° hardness
MgO	.054 " " = 9.4 " "
Total	14.0

showing that part of the CO₂ went to the magnesia, with the effect of preventing full precipitation both of the lime and magnesia.

But the use of such treated water will not necessarily give rise to the formation of scale, because a

temperature of from 60—70° C. is sufficient to complete the reaction, giving a full and immediate precipitation of the lime as carbonate, and the magnesia as hydrate, which are then present in the boiler in a state of suspension only, and do not incrust.

The use of water-fully treated with lime and soda has established the fact that practically no incrustation is formed in the boiler, the lime and magnesia which remain in the water to the extent of from two to four degrees of hardness being in a state from which a boiling temperature causes them to be precipitated, so that all that is found in a boiler after say three or six months' work is a small quantity of powder. It seems scarcely necessary to point out that this result is only seen when the experiment is commenced with a really clean boiler. In general it is found that boilers after becoming incrustated with scale during work with ordinary waters are well cleaned only on the upper plates of the centre flues, whilst the underside of the flues and the bottom of the boiler are more or less imperfectly cleaned, and the portions in the narrow spaces between the flues and the shell of the boiler are very seldom cleaned, owing to the great difficulty of reaching these parts with chipping tools. In general, therefore, the treated water has to be used in such a partially cleaned boiler, and in course of time such old deposits of scale become loosened, so that a slight force only is required to detach them, and finally the boiler becomes and remains practically clean. It is worthy of remark that when portions of a boiler contain old scale, the use of softened water will actually show a thin scale on the top of the flue, which is the part generally selected for trying the effect of the method in trials of processes for preventing incrustation. Now this thin scale has its origin in the old scale on other parts of the boiler, which dissolves partially in the boiling soft water, and this on evaporation leaves the dissolved scale again on the top of the flue as new scale. This is particularly the case with calcium sulphate, which predominates in scale formed in this way. It may be noticed here that such scale is very adherent to the iron as long as it is thin, but as soon as the thickness has reached about a sixteenth of an inch it peels away readily, the reason apparently being that its mass gives the stability sufficient to prevent it following the small movements of contraction and expansion of the iron.

That there must be a considerable saving of fuel where the boiler is kept free from incrustation, there is of course a universal agreement, but a reference to figures given by various writers seems to show that the results are obtained more by calculation from small experiments than by actual trials with boilers, and in truth it is very difficult to determine the influence of scale in the work done by a boiler, because of the many attendant sources of error. It might be thought that the temperature of the gases after leaving the boiler would give the necessary data, but this is again modified by the proportion of air admitted through the firebox, and also by the leakage of air into the flues through the brickwork. Perhaps a fair idea might be arrived at by analyses of the issuing gases taken at the same time with the temperature, but this we have not had the opportunity of investigating. It seems to us that evaporation results would not sufficiently exclude the errors introduced in the stoking.

When a water which is to be softened contains organic matter in such quantity and kind as to impart a colour to the water, or at least to impair its brightness, the employment of a soluble salt of alumina (or ferric oxide) is resorted to, and the quantities of lime and soda are so adjusted as to pre-

cipitate the alumina as hydrate as well as to remove the hardness of the water. The use of precipitated alumina has the further result of causing the lime and magnesia precipitate to settle rapidly, which would not always be the case in the absence of the alumina hydrate, for such impure waters have a tendency to remain turbid for a long time after addition of lime or lime and soda; the bulk of the precipitate will settle, but a part remains in suspension. Also if the amount of original hardness in the water is small, the whole precipitate may be so finely divided that it takes a longer time than usual to settle, and in this case, too, the addition of a small quantity of alumina salt will bring about the desired result. The alumina hydrate envelops the finer as well as the larger particles of precipitate and carries the whole down, and where organic matter is present it unites with the alumina to form a lake, and is so removed, as is already sufficiently well known. The quantity of sulphate of alumina required varies from one to seven-tenths of a pound per 1000 gallons, according to the quantity of organic matter present. Where sulphate of alumina is employed, and if the water is to be softened, provision must be made for the saturation of the sulphuric acid by caustic soda, lime being used for this purpose only where a sewage or waste water is to be defecated, and sometimes it is advantageous to employ aluminate of soda. For wool-washing it is, of course, of the utmost importance to have soft water, and in some cases, where the available water contained only from four to five degrees of hardness, and was tinged slightly brown from peaty matter, treatment with a small quantity of sulphate of alumina and caustic or carbonate of soda has effected a very satisfactory improvement, the treated water being clear and colourless, with a hardness of two degrees. The sludge from such a treatment was brown coloured, and had the following composition after having been dried at 135° C. :—

Matter driven off at red heat	45.0%
SiO ₂	11.0
Al ₂ O ₃	16.7
Fe ₂ O ₃	10.3
CaO	8.6
MgO	7.0
CO ₂ , other acids, etc.	1.4
	<hr/> 100.0

The form of apparatus which has become identified with this method of softening water is the invention of Messrs. Gaillet and Huet, of Lille, and is known here as the Stanhope Purifier, for which the English patents are held by The Stanhope Company, Limited (formerly called Corder, Allen & Co.), of 20, Bucklersbury, London, E.C., to whom we are pleased to record our obligations for many facilities afforded in the preparation of this paper. A few words will suffice to render the salient points of this apparatus intelligible. The principle involved is one of subsidence and decantation, which admits of the separation of all kinds of solid matters in suspension, however flocky or gelatinous. In the annexed drawing the same letters refer to the same parts in both figures.

A is a store tank containing caustic soda solution of 27° B. B is a tank receiving the water to be treated, which is maintained at a constant level by means of a valve and float. C and C are two tanks for use alternately, in which the lime water is prepared, a measured quantity of caustic soda being added at each time of charging, this mixture constituting the reagent. D is a small tank for maintaining a constant head of reagent. E is the clarification tank

in which the decantation is accomplished, and which will presently be referred to in detail. F is a large pipe in which the mixture of water and reagent takes place. G is a pipe in connection with cocks for drawing off the sludge as it accumulates in the angular spaces in the clarification tank. At H are the cocks provided with graduated quadrants for conveniently adjusting the quantities of water and reagent. I is the delivery pipe for the softened water.

serves as a safety filter to stop any particles which have escaped subsidence.

The water supplied to the apparatus at B is conveyed by a pipe to H, where it flows into the mixing pipe along with the reagent from C and D, the quantities being regulated by the cocks at H. The mixture of the water and reagent being effected by falling together into the funnel of the pipe F, precipitation at once commences, and the whole travelling down the pipe enters the clarifi-

THE STANHOPE PURIFIER.

The clarification tank E contains a number of thin diaphragms or shelves of a V shape, inclined at an angle of 45° , as shown by the dotted lines; these are rivetted alternately to the two opposite sides of the tank, and their position forces the water to take a serpentine course through the tank. A bed of wood shavings, contained between wire nettings in positions indicated by the two lines of rivets near the top,

cation tank by a branch pipe near the bottom, whence it rises in a serpentine course to the top, whilst the clear and softened water overflows into the delivery pipe at I. The precipitate on settling out finds its way down the inclined shelves to the angular spaces connected with the sludge cocks, by opening of which the mud is removed without interrupting the process. The whole operation is thus a

continuous one, and the labour involved consists in discharging the precipitate by opening the sludge cocks about once a-day, and in the preparation of the reagent at long intervals. In place of the two line tanks, a simple automatic apparatus is sometimes employed for preparing the lime water continuously.

A horizontal form of apparatus designed on similar principles is also made, giving equally good results, and this arrangement is sometimes more suited to the local surroundings or requirements of special cases.

The precipitate from the sludge cocks forms a mud containing about 20 per cent. of solid matter as a maximum, but taking the average of the sludge as obtained by leaving the cocks open until the accumulation of precipitate has all come away, as can easily be seen in practice, the solid matter amounts to four or five per cent. This can be run straight away or allowed to stand for the superfluous water to drain off, leaving the solid matter for more convenient disposal. The solids of the sludge vary of course greatly in composition, according to the nature of the water undergoing treatment. From some waters almost pure carbonate of lime is obtained, others give in addition hydrate of magnesia, and often small quantities of silica and oxide of iron. Organic and coloured matter is sometimes present to a considerable extent, and the alumina and iron salts then employed also modify the composition and appearance of the sludge. As examples of the latter class the following two analyses will serve. Both samples were dried at 135° C. before analysis :—

	I.	II.
Matter driven off at a red heat ...	48.6%	38.8%
SiO ₂	1.2	17.8
Al ₂ O ₃	1.2	21.3
Fe ₂ O ₃	1.5	7.7
CaO	39.1	7.2
MgO	8.0	3.1
CO ₂ , other acids, etc.	4	4.1
	100.0	100.0

This system of collecting a small amount of precipitate from a large volume of liquid by systematic subsidence offers particular advantages where such precipitate is of a light gelatinous nature, by reason of its admixture with hydrate of magnesia or alumina, or gummy and slimy from presence of much organic matter. Excellent results have been obtained with this apparatus in the treatment of waste water from factories and streams polluted with sewage and dyestuffs.

DISCUSSION.

The CHAIRMAN, after alluding to the value of such communications to those who had experienced the effects of foul waters on their boilers, said that he was by no means sure that living organisms were necessarily injurious to health. It was also necessary to consider what effect such powerful filters would have upon the taste of water, for he believed that many people would prefer water of doubtful purity, but pleasant taste, rather than pure water rendered thoroughly insipid.

Dr. PERCY FRANKLAND regretted that he was not present at the beginning of the paper. While admitting that what they had heard made it quite evident that coke was capable of exerting chemical action on the organic matter and nitrates in water, he thought that it was also clear that this action was due to the iron present in the coke. He had not analysed the coke he used in the experiments which he had already brought before the Society, but it was obvious that it could not have contained much iron, for the water

before and after filtration contained much the same amount of organic matter and nitrates. In fact, he had used it purely as a biological filter. The possibility of making coke a chemical as well as a biological filter, and maintaining its efficiency by means of a battery, was of great practical importance; but he was particularly struck by the experiments on the purification of water by a copper-zinc couple. He was glad to see that the authors had submitted their filters to the test of gelatine-plate cultivation, for no filters which failed to remove micro-organisms could properly be considered filters at all. He would like to know how long the various filters alluded to had been in use before the experiments were made. He was not prepared to agree with the theory that sterilisation was always accompanied by chemical action, and *vice versa*, for he knew domestic filters which were efficient in the reduction of chemical organic matter, but which, when submitted to the gelatine test, showed that they were incapable of touching the micro-organisms present. Bischof seemed to take the view that the gelatine process failed to determine the value of filtration, because filters generally regarded as efficient failed to stand this test; or, in other words, the filter was to be the test of the gelatine process, instead of the process testing the filter. With regard to the zinc-copper couple experiment, he would like to know whether the water operated upon was pure or rendered saline, as that fact would have considerable influence on the micro-organisms. Undoubtedly Messrs. Macnab and Beckett's process effected considerable purification, although his own experiments, made at Mr. Newlands's request, had hardly shown the reduction of the hardness in practice to be quite so great as the figures before them would suggest. This was not to be expected; but he should like to hear whether this process had been tried on the hard water from the chalk underlying the London clay, which contained much carbonate of soda, and was distinctly alkaline. This water was very difficult to treat by Clarke's process, and was quite different from the water at Clyde Wharf, which, though derived from the same stratum, was not alkaline.

Mr. BISCHOF agreed with the authors of the paper that biological testing was still in its infancy. When water was required free from iron, they used a test which indicated the presence or absence of iron; and when softness was required, the water was examined to that end. Why, then, should experimenters not adopt the same principle in testing waters for wholesomeness? Yet there were some who attached no importance to these microphytes and their development. As a rule, Dr. Koch's test was restricted to a mere statement of the number of colonies found, which certainly was not Dr. Koch's intention. Microphytes were only partially shown by the gelatine-peptone process. Storage, again, was a most important factor to consider. Storage and consequent multiplication of germs took place in every domestic filter, and they were in a constant dilemma between rapid, and hence inefficient, filtration, and filtration so slow as practically to become storage. He had known New River water increase from 53 to 770,000 colonies in six days while kept in a sterilised flask. One point had been lost sight of—namely, that the suitable temperature for germ development varied within narrow limits—say, 5° C. To this fact regard must be had in preparing the gelatine mixture, lest, on the one hand, development should cease, or, on the other, the test should fail from liquefaction of the plate. Stress had been laid at times on the different kinds of colonies, but little light had been thrown upon them, even by Dr. Koch. The test still fell far short of perfection. Dr. Klein

had given an instance in which Dr. Koch's gelatine-peptone test indicated only 5000 colonies, when another test indicated 150,000. Now, pathogenic organisms failed to grow in gelatine-peptone, so that it was not at all unlikely that among the 145,000 germs not indicated by that process there might be the very pathogenic organisms they were seeking. Dr. Klein had also often added known pathogenic organisms in measured quantities to samples of water, but had never recovered one-half of them, though he knew in each instance what to look for and how to indicate its presence. Surely, then, this was enough to show that the gelatine-peptone method, *per se*, was no test of the wholesomeness of a water.

Mr. THORP said he hardly liked to speak on the subject, because it was so long since he had done any practical work in water analysis. He would, however, like to ask Mr. Salamon whether the ferro-coke which was digested with hydrochloric acid was the same which had been previously used, or a fresh portion which had not been used for filtration. Mr. Salamon laid great stress on the reduction of the total solids and the total hardness, but he could scarcely understand why, for he supposed that it must be from some chemical action of a kind which could be of very little importance in a filter, since it must come to an end. If he understood Mr. Salamon aright, he considered the activity of a filter to be in direct proportion to the dissimilarity of the two constituents. Did he mean electric dissimilarity, or of what kind? Although without any basis of experiment, he should be inclined to agree with Dr. Percy Frankland that there was no necessary relation between the chemical action of a filter and the removal of living organisms. The filter might remove them without chemical action or it might exert chemical action and not remove them. It might do both or neither. It was possible to attach too much importance to the presence of living organisms in a water, yet although they were not necessarily injurious, yet if they were absent they could not do harm. He would like to express his own opinion that it was not desirable to put too much weight on determinations of individual impurities. In water analysis one wanted the opinion of an experienced analyst. If one consulted a medical man, one wanted his advice based on all the symptoms, not on one. If it were possible he thought it would be desirable even to discontinue the publication of numbers obtained in water analysis. If he had no knowledge of the subject, he thought he should prefer to have merely the opinion of a competent man rather than to have a number of figures placed before him which he could not understand. On this subject more weight attached to the name of the analyst than in almost any other department, while the report of a tyro might be valuable or it might be worth no more than the paper on which it was written.

The CHAIRMAN pointed out with regard to the second paper that the object of the process was to prevent the formation of scale in their boilers, and so long as that object was obtained the exact condition of the waters was a matter of indifference.

Mr. NEWLANDS, in reply to Dr. P. Frankland's statement that the water at Clyde Wharf hardly showed as much improvement as the waters referred to in the paper, stated that though it might not be alkaline, nevertheless it contained much organic matter, and was generally more impure than the samples they had before them. The process was a great improvement on those they had tried before, for it was practically continuous, and the cost for chemicals was only about one penny per thousand gallons.

Mr. SPILLER, while recognising the practical value of attempts, such as those of Messrs. Macnab and

Beckett, to soften and purify water for technical purposes by the combined action of soda and lime, could nevertheless have wished to see a greater difference between the quality of the water before and after treatment than appeared to be the case, judging from the figures before them. He was surprised to see as much as 3·85 grms. of sodium carbonate left, equal to about one-third of the total impurity. Surely this pointed to the use of excessive quantities of reagents, for the sodium carbonate was capable of precipitating a further quantity of calcium and magnesium salts.

Mr. MACNAB, in reply, said the paper referred especially to water of the class mentioned by Dr. Percy Frankland. The difficulty of reducing water to the minimum hardness had been touched upon. In regard to the behaviour of magnesia, it was due to the comparatively large quantity of that substance in the Clyde Wharf water that such good results were not obtained as instanced in the paper. With regard to water containing comparatively large quantities of common salt and carbonate of soda from the London district, they had had no experience, but they had in the laboratory treated waters from the coal measures, which generally contained a notable quantity of carbonate of soda in conjunction with sulphate and carbonate of lime, and from that experience he should have no hesitation in saying that the process was capable of dealing with such water. In many cases the carbonate of soda present was quite sufficient to decompose the sulphate of lime, at any rate with the addition of a very small quantity of caustic soda. With regard to Mr. Spiller's remark about there being a needlessly large quantity of carbonate of soda in the analysis, it would certainly have been better if there were less, but those were entirely technical results, and they did vary a little. Anyone who had any experience of working processes on a large scale would know the difficulty of carrying out reactions to theoretical equivalence. In many cases the analyses showed only one grain of carbonate, and in many others there was no carbonate of soda at all. One could not expect a very large diminution in the total solid matter in the water, because the lime was to a large extent replaced by soda salts.

The CHAIRMAN asked if Mr. Salamon had tried any experiments to prove whether fresh colonies appeared in water which had been passed through filters, as in the case of water passed through purely mechanical filters?

Mr. SALAMON, in reply, said that he must share Dr. Percy Frankland's regret that he was not present at the commencement of the paper, because he had missed the point on which he laid particular stress with respect to his experiments. Dr. Frankland stated, at the time he read his paper, that his filtration experiments were made through six inches of coke in a combustion tube. He had referred to that at the commencement of his paper. If a Winchester quart of water were passed through six inches of coke it was hardly so adequate a filtration as those which he had recorded, and indeed could hardly give any definite result at all. But assuming that there was a result obtained, Dr. Percy Frankland said that coke did sterilise water, but omitted to mention that the amount of water which was passed through that coke in order to assure sterilisation was relatively extremely small—probably not more than 5cc.

Dr. PERCY FRANKLAND said he filtered about a litre for twenty-four hours.

Mr. SALAMON said that he took it that Dr. Frankland passed that amount through six inches of coke, submitted that to chemical analysis, and found no difference whatever. After he had done so, he then

put five inches cc. through those six inches of coke and submitted that to plate cultivation. Naturally the 5cc. were able to be chemically affected, whereas the larger quantity would not, and hence he obtained sterilisation in the small sample and no chemical change in the large. It was to be regretted that he did not test the coke for iron, for he himself had always found it present.

Professor BISCHOF said it was generally as sulphide of iron.

Mr. SALAMON said it was iron in some form or other. With regard to the copper-zinc couple, the experiment was not made for drinking or commercial purposes, but was meant to possess a purely theoretical interest and to support their theory. At the same time no zinc or copper was found in the filtered water, and no saline matter was introduced into the water. It was an ordinary sample of water. All the filtrations referred to on the tables were made after the water passed through once—i.e., the filters were not kept for any length of time. In answer to the Chairman, they would extend their investigations to see whether the water was absolutely sterilised by filtration, and if the removal of organic impurities really rendered it incapable of further contamination by germs. With respect to sterilisation taking place without accompanying chemical action, he thought it was a question still to be proved. So far as their experience carried them, those experiments which Dr. Percy Frankland brought forward where he found sterilisation accompanied by purification, they accepted at once; but what required further elucidation, was the statement that micro-organisms might be destroyed without a corresponding chemical purification of the water. In the Pasteur and Chamberland filter all organisms were, no doubt, removed, but there was no proof of their death.

Dr. BISCHOF said it could easily be proved by taking some filtering material, mixing it up with the sterilised water, and then testing it.

Mr. SALAMON said as a matter of fact it was just as correct to assume they were mechanically removed (as in the case of cotton wool) as that they were killed. With respect to the ferro-coke, that which was washed with hydrochloric acid was previously used, and represented that concentrated ferro-coke which gave the excellent purification in the first instance. He must apologise for not having further insisted on that point, because it was the very essence of the experiments that they found purification in the case of ferro-coke when it contained a large amount of iron, and after it was treated with acid and digested for a long time that purifying power ceased. With respect to the hardness, the reason he laid some stress upon that was that the spongy iron experiments effected a very considerable diminution in the hardness. That was noticed also in the experiments with coke, ferro-coke and the copper-zinc couple, and they wanted to find out to what that diminution of hardness was due. They, therefore, purposely made one sample of water artificially strong in temporary hardness, and then added ferric hydrate to it, which produced the remarkable effect shown on the table.

Mr. BISCHOF asked how it acted?

Mr. SALAMON: Probably by decomposing the acid carbonate of lime. Of course ferric hydrate could not exist as such in coke, yet it would be seen on reflection how much it bore on this experiment.

Mr. JOHNSON said that he had made experiments on a large scale with ferric hydrate, and found it to have a strong attraction for lime salts, and when in small quantities it removed them.

University College, Ashton Street.

DR. J. CAMPBELL BROWN IN THE CHAIR.

WOOD AS A PAPER-MAKING MATERIAL.

BY T. ANDERSON REID.

The necessity for crude vegetable fibres for paper-making occasioned by the demand for cheap literature of all kinds has led British paper-makers within recent years to again turn their attention to materials which at one time were considered hardly suitable or too costly to work economically. It is well known to you that formerly rags were the staple raw material of the paper trade. Science and necessity suggested straw, esparto and wood. Esparto is now the chief raw fibre for paper-making, having been introduced for that purpose by Mr. Roulledge thirty-four years ago. It did not come into general use until 1861.

According to Stonhill, the imports of this grass in 1884 amounted to 184,682 tons of a declared value of £1,128,000.

Wood is sharing the same fate as esparto did prior to 1861, and I think it is only a question of time when the paper trade will use it largely. The idea of substituting wood for the other fibres used for paper-making is claimed by several, but I think as far as this country is concerned the credit should be given to Houghton.

In 1856, whilst engaged as a workman boiling esparto grass at a paper mill in Gloucestershire, he had occasion to place a wooden wedge in contact with the alkaline solution in the boiler, and on the boiling being completed he was surprised to find that the wood had become partly disintegrated; subsequently he found that by treating wood with stronger alkaline solution, assisted by increased steam pressure, wood became as tractable as straw or esparto. The process has not met with that consideration in this country which it merits, due in a great measure to our want and appreciation of those scientific principles that are necessary in treating refractory raw material. I may add that quite recently considerable impetus has been given to the question of pulping wood.

For the purpose of the paper-maker, straw, esparto and wood may be structurally assumed to be alike, the three being made up of fibres of cellulose coated more or less with encrusting matters of various kinds.

In straw, silica forms the chief component of the encrusting matter; in wood the fibres are indurated with the material of the fibre wall which has undergone change in the process of growth.

Again, they react with acids and alkalis much the same. For instance, the fibres of straw and esparto may be separated by digesting with solutions of

caustic soda at a steam pressure of 35lb. per square inch, equal to a temperature of 260° F.

Ordinary woods require more soda than the grasses, and pressures varying from 100 to 120lb. per square inch, or in Fahrenheit degrees from 328 to 340. The hardest woods—i.e., sycamore and lignum-vitæ—require, again, very high pressure, 200 to 250lb., but as these are never used for fibre-making, they require no further notice.

Acids have more or less chemical action upon the non-cellulosic constituents of wood, depending upon the nature and strength of the acid used. Nitric acid has been employed industrially for treating wood, but the cost of the acid, and the difficulty of finding plant to withstand its action, have caused it to be discarded; there was also the danger of forming nitro compounds with the cellulose itself.

A solution of sulphur dioxide in water, with or without a sulphite of an alkali or alkaline earth, has, however, found the most favour with chemists. First patented by Tilgmann in 1866, it has since formed the subject of many patents, only differing from the original in matters of detail. It is said that the cellulose obtained by treating wood by any of the various sulphite processes is not nearly so pure as that made by the soda process, and from the nature of things this appears to be quite rational.

For paper-making, wood is treated by two general methods, depending upon what kind of paper it is to be used for: 1st, Mechanical wood-pulp; 2nd, Chemical wood-pulp.

Mechanical wood-pulp is produced by simply rasping wood by suitable machinery in contact with a stream of water. By this means the fibres are teased out and are not deprived of any of the constituents eliminated by chemical treatment. Such pulp comes largely from Sweden and Norway, where the raw material wood abounds, together with an abundance of water. I will here state that mechanical wood-pulp is used only for inferior papers. The material of card-board sample boxes are almost entirely wood-pulp of this description. Many of the Swedish mechanical pulps can hardly be detected by the eye from unbleached chemical pulp; a rough though reliable test consists in igniting a small portion of each pulp and noting the odour of the smoke. Mechanical pulp gives an odour resembling burning wood. Chemical pulp, on the other hand, when treated as above, smells like smouldering cotton wool.

As chemical wood-pulp is the only form in which wood can be applied to the manufacture of the better classes of paper, I will now give you an outline of the various operations involved in the conversion of the wood into pulp by the soda or alkaline process, as this is the only process which up to the present has yielded a nearly pure cellulose from wood, together with the advantage that iron may be used for the boilers, and also that a large percentage of the soda is recoverable.

The question naturally arises, Which are the best woods to use with due regard to quality and yield of fibre? The hard woods, such as beech and birch, yield a higher percentage of fibre than the soft woods. Again, they have the advantage of being denser, consequently a much larger quantity can be worked in a given time, or what is much the same, a boiler will hold a heavier charge. The fibre from them, however, is very short, and where length of fibre is of primary importance, soft woods are preferred; the soft woods generally are found to give also a good percentage of cellulose.

The table below will give an idea of the woods that experience has shown are best adapted to meet the requirements of the pulp maker, and, if care

fully treated, they give a first-class cellulose. A medium fibre may be obtained by working a mixture of two-thirds hard wood and one-third soft wood, or by using poplar; this, although a soft wood, does not possess a long fibre.

WOOD.	Class.	Cellulose or Fibre per cent.	Class of Fibre.
Beech.....	Hard	38.5	Short
Birch	"	42.0	"
Hemlock	Soft	37.5	Long
Poplar	"	41.0	Medium
Scotch Fir	"	39.0	Long
Spruce Fir	"	38.0	"

Before wood can be treated chemically it is requisite that it be broken up, so that the disintegrating fluid may act uniformly upon it. If round timber is being worked, it is necessary to remove every trace of outer bark, as this would make the pulp specky. After barking, the wood is sawn into slabs about the size of ordinary railway sleepers. These, in their turn, are fed obliquely against the "chopper," a heavy revolving wheel, on the periphery of which there are steel cutting knives. The chopped wood is now crushed in a mill constructed after the style of an ordinary coffee-mill, and, by this treatment, the knots get broken, and the wood offers a large surface for the action of the boiling fluid. I may here mention that bamboo canes are also used for making a very high-class fibre. In these, the knotty nodes are cut out preparatory to crushing, as they do not digest well. In preparing wood for the various sulphite processes, I understand that the knots have to be cut out, as they will not soften on boiling. This is a great disadvantage, and must add considerably to the cost of the preliminary preparation, if it does not altogether exclude very knotty wood.

The mechanically-prepared wood is now ready for digesting. The digesters for the alkaline process are mostly vertical wrought-iron cylinders, 20ft. high by 4½ft. diameter, made strong enough to carry 200lb. steam pressure. They have a man-hole at the top for filling, and a sluice valve at the bottom for emptying. About a foot from the bottom, and inside, there is a perforated false bottom, covered with strong iron gauze; there is also a pipe for admitting the alkaline liquor, and another at the lowest point of the digester for blowing off the spent solution. The digesters are generally heated by steam blown in from a separate steam generator. Some digesters are also supplied with a vomit-pipe for vomiting the wood, as it is termed. The vomit-pipe consists of a perforated ring of piping placed underneath the man-hole of the digester. Two vertical pipes are let into the ring, and the free ends of these are placed underneath the false bottom. The steam pipe from the generator comes below the extremity of one of the vertical pipes, and when steam is admitted it forces the liquor up the pipe into the perforated ring, through the holes of which the liquor showers over the wood. As the vomiting takes place during the filling of the digester, it should not be unduly prolonged, otherwise the liquor will be diluted below the boiling strength by the condensed steam. A better arrangement, and one less complicated, consists in fitting the end of the liquor-pipe—which of course should enter the neck of the digester—with a rose, similar to that of an ordinary watering-can. Some woods, particularly the fir tribe, cannot

be vomited, owing to the large amount of resinous matter they contain, which cause them when so treated to froth over.

For digesting wood, there is no doubt that dry heat would be much preferable to live steam. Good results have been obtained by placing a serpentine coil below the false bottom, and allowing steam to circulate through the coil. The condensed water is taken off by an ejector, or valve, placed on the exit end of the coil. There are several advantages attending this mode of heating. 1st. No steam from the generator comes in contact with the contents of digesters, consequently there is no risk of the wood being underboiled by undue dilution of the soda liquor. 2nd. The spent liquor is less dilute, therefore less fuel is required for recovery. 3rd. If the digesters are covered with a good non-conducting medium, the steam may be shut off from the coil when the requisite pressure is attained, and the digestion will proceed without any further application of heat until the close of the operation, as the only heat leaving is what escapes by radiation. 4th. The generator may be turned on to freshly-charged digesters without any risk of the alkaline liquor backing from the digesters into the generator, due to differences of pressure and leaky valves.

Paper-makers seem to be divided in opinion as to which are the best conditions for digesting wood. The majority of them advocate a large excess of caustic soda. Experiment has shown that wood can be completely dissolved by very strong alkaline solutions, aided by high temperature. The idea of a necessity for large excesses of caustic alkali has no doubt arisen from the fact that sometimes the wood is not digested when boiled with apparently the same percentage of soda, but I think the bad boiling-sometimes found could be traced to the causes just mentioned above, where neglect of the workman in attending to the various stages of the boiling would throw the job wholly adrift. For this reason I have advocated the dry-heat method as one which leaves less loopholes for excuse, as a tell-tale gauge would say if the pressure had been sufficient. Again, too little soda or under-pressure does not digest the wood, or only partly so. Economising soda by using extra pressure chars the cellulose, and requires more bleach to bring it up to colour, with the result that the quality of the fibre suffers. Such drastic modes of treatment injure the fibre, and causes the yield to be low. Doubtless this has given rise to the prejudice which is entertained against the soda process by some writers. Assuming that dry heat is decided upon for digesting, 20 per cent. of 70 per cent. caustic on the dry wood, and a pressure of 120lb. per square inch (=340° F.), gives excellent results. The solution of sodium hydrate used for boiling should be as nearly completely caustic as possible. The digester is filled with the mechanically-prepared wood, and this is nearly covered with the alkaline liquor. The cover is put on and bolted down, all other connections being also closed. All being right, steam is turned in, and when the pressure on the digester shows 120lb. it is kept at this for two hours. Steam may then be shut off, and the spent liquor blown out. The wood, if properly digested, should be completely softened, but still retain the form of the original chips.

After the spent liquor is off it is usual to cover the pulp with warm water; the sluice valve at the bottom of the digester is opened, and the stuff washed into wooden drainers with false bottoms of perforated zinc plates.

The next operation consists in washing the pulp free from alkali, and for this purpose the stuff is thrown into an ordinary pulp-washing engine, and a good supply of water kept running until the water

passing through the drum is clear. After this operation the pulp is ready for mixing with other unbleached fibres, such as esparto, straw, or rag fibre, and paper made from the mixture in the usual way. Assuming, however, that the pulp is being made independent of paper-making, after washing, about 20 gallons of bleach solution at 7° Tw. are added to it in the washing engine. This removes the plum-coloured tint common to pulp made from hard wood. Finally it is run from the washing engine over a paper machine and made into sheets, which, in their turn, are packed into bales averaging about 4cwt. each. The baled pulp contains half its weight, or 50 per cent. moisture.

The next important point calling for consideration in the alkaline process is the recovery of the soda from the spent alkaline liquor blown off from the digested wood. The first liquor (that is, the one blown off from the wood) is only worked, as it does not pay for fuel to work the weaker washes obtained. This first liquor averages from 18 to 20° Tw., and represents 90 per cent. of the soda originally employed. It contains about 80 per cent. water, together with matters extracted from the wood, organic and mineral. The process at present pursued is very simple, consisting in boiling down until free from water, and subsequent calcination to burn out organic matters. By this treatment a crude sodium carbonate is obtained, containing from 50 to 53 per cent. alkali Na_2O . There is also present a little free carbon, together with sulphate and sulphide of sodium.

The resulting ash is dissolved in water, and adjusted to about 20° Tw., and causticised with lime in the usual way. The caustic liquor obtained is used for digesting fresh batches of wood, the loss of soda being made up by addition of solid sodium hydrate.

By the foregoing system of recovery, the organic constituents of the spent liquor are lost, being for the most part burnt into carbon dioxide and water. A more rational process would be to run the spent liquor, after being deprived of water, into a retort or still, and distil it destructively at the lowest available temperature. By this means a distillate would be obtained containing acetic acid, methyl alcohol, and the other bodies present from the distillation of woody tissue. It is a point open to experiment if oxalates, and, indirectly, oxalic acid, could not be built up (by proper treatment) from the desiccated liquor. Experiments made in the laboratory upon the destructive distillation of the dry residue from the spent liquor gave promising results.

By the calcination system of recovery, about 80 per cent. of the soda is recovered for use, and this may be set down as reducing the cost of the soda by about 50 per cent. The question of how does wood fibre compare in cost of manufacture with the other crude paper-making fibres, may be answered by putting down the relative cost of pulp made from wood and esparto grass respectively. Wood yields about one third of its weight of fibre. Good esparto is said to yield half its weight.

PULP FROM WOOD.

Basis $\frac{1}{2}$ or 33·3 per cent. yield.

	£	s.	d.
Three tons wood, say 25/- per ton.....	3	15	0
Mechanical treatment, say 7·6 per ton....	1	2	6
Caustic for digesting 25% of 70 . at, say 10s. per cwt.....	7	10	0
Washing and bleaching, say 5/- per ton ..	0	15	0
	13	2	6
Add 20% for exigencies	2	12	6
	15	15	0
Less 50% net of soda used	3	15	0
Cost per ton fibre	£12	0	0

PULP FROM ESPARTO.

	Yield, 30 .	£	s.	d.
Two tons esparto, say £6 per ton		12	0	0
Mechanical treatment, say 5 $\frac{1}{2}$ per ton		0	10	0
Soda as above, 10		2	0	0

It has been already mentioned that aqueous solutions of sulphur dioxide disintegrate wood, liberating the cellulosic tissue. Processes based on this reaction are now receiving a good deal of attention industrially. I will therefore make a few brief remarks on the sulphite or acid process of treating wood. There is no doubt that for certain classes of paper, sulphite pulp forms a valuable addition to the paper stock. Those best qualified to speak—viz., paper-makers of long standing—say that white paper cannot be made from pulp of this kind. Again, published quotations show the prices of soda and sulphite pulps to be much the same.

Practically, the great objection to the employment of acid solutions for disintegrating wood is that iron vessels cannot be used unless well protected internally by some metal upon which the solution has little or no action. Lead is used with more or less success for the above purpose. Copper, by the way, has a low solubility in acid sulphites, even at high temperatures, and a vessel of copper need not be so heavy as one of iron for a given pressure.

The time necessary to pulpify wood by the sulphite process is very much greater than by the soda method, and this must tell against the cost per ton for fuel, labour, etc. The wood, again, as previously mentioned, has to be very carefully prepared mechanically, due regard being paid to the exclusion of knots. In fact, the sulphite process, taken as a whole, is much more complicated in matter of detail than the soda process, and time has yet to show the financial advantages of the acid system of digesting wood over that of the older alkaline process. No doubt experience and experiment will remove many of the difficulties that are now found in connection with the former system.

Before concluding this paper, I may mention a few facts in connection with the utilising of waste wood, such as the chips, etc., produced in Liverpool saw-mills, and that of our Widnes and St. Helens chemical works. Much of the above-named stuff requires no further mechanical preparation than crushing to suit it for making a tolerably good paper fibre. The objection raised to the waste so made might be that any individual mill or works would not form enough to keep a moderate sized pulp plant going. This could be met by collecting the waste to one centre, there to be pulped. If the process were carried on in conjunction with Leblanc alkali making, a further advantage would accrue from the fact that the liquor used for digesting could be obtained direct from the causticiser; consequently the alkali would not cost the same as finished soda ash or caustic. No special recovery plant would be requisite, with the exception of furnace and storage tanks, as the recovered ash could be worked with the Leblanc black-ash into liquor.

In conclusion, I would mention to those who may feel disposed to follow out the problem of pulping wood, that they can obtain a deal of useful knowledge on the subject by perusal of the Prize Essays in Forest Products, published by the Committee of the Edinburgh International Forestry Exhibition.

A NOTE ON MR. WESTMORELAND'S PAPER ON THE WET ASSAY AND COMMERCIAL VALUATION OF COPPER ORES.

BY JOHN INNES,

Member of the Society of Arts, Fellow of the Chemical Society, etc.

HAVING recently read in the February number of the Journal the very interesting and generally accurate paper by Mr. J. W. Westmoreland, I venture to make one or two remarks on the important subject he deals with.

While fully agreeing with the proposition that a wet assay more accurately represents the copper in an ore, I think it is pretty generally admitted that the dry method tells the smelter more nearly what he may expect to get out. The author proposes to assimilate, for the purpose of valuation, the wet and dry produces by introducing a scale of variations, so that one assay might practically give the purchaser both a wet and a dry produce. Thus a pyrites of 3 $\frac{1}{2}$ to 4 per cent. wet would be called 2 $\frac{1}{2}$ to 3 dry, the variation or margin being 1 per cent., which, no doubt, is a fair allowance. There is a serious, if not a fatal, objection to this suggestion. For example, if a sulphide and a chloride each gave 4 per cent. wet, Mr. Westmoreland would equally reduce both to 3 per cent. dry by his process of margins. A dry assay would show the chloride to have a lower percentage than the sulphide; in other words, there would be a loss in the furnace when the chloride was assayed, which would roughly indicate the smelting loss on the bulk. The suggested scheme makes no provision for such a contingency.

In the commercial section of the paper, the reader is told several times that purchases are compared with ore of 8 $\frac{1}{2}$ per cent., that the standard is the standard for 8 $\frac{1}{2}$. As a fact, the standard is always compared or adjusted to 9 per cent. produce.

At Cornish ticketings a standard is certainly made out at a nominal R.C. of 55s., which standard generally appears in the newspapers; but another is always calculated on a R.C. for 9, which varies according to the position of the mines and port of shipment. If the produce of the sale be not 9, the standard is altered by a fixed sum for every produce, which practically is a V.R.C., as stated by Mr. Westmoreland.

The standard at Swansea ticketings is made up at a fixed R.C. for 9, and subsequently adjusted, as in Cornwall, to the produce of the sale, the difference being really an altering of the returning charge.

On page 60 a short paragraph appears in italics, which especially calls for comment:—

"It must be most distinctly understood that the standard is calculated from the prices paid for copper ores, and not the reverse."

Dr. Percy says much the same thing. As a matter of fact, buyers very generally, if not always, base their offers on a certain "standard for 9." At ticketings they vary their successive tickets, up or down, as the evident demand, quality of the ore, etc., indicate. They then deduce an average standard for 9 from the prices of the several lots. Thus, although the standard is calculated from the prices as per Mr. Westmoreland's italicised paragraph, the prices have first been based on the standard. Vivian's scale is now beginning to come into use; the standard is giving way to the "unit." To anyone who has given attention to the "ticketing" system, the wonder is not that it is dying out, but that it has lasted so long.

DISCUSSION.

MR. WESTMORELAND said that the margin referred to by Mr. Innes—namely, 1 per cent. on $3\frac{1}{2}$ to 4 per cent. wet produce—referred to pyrites only; but the difficulty was very easily met, for ores containing chlorides could be calcined, and the wet assay made on the calcined ore. In making dry assays of this class of material, the ore was generally roasted to expel chlorides before the fusion for regulus, for if this was not done most of the copper present as chloride passed into the regulus. He could not agree with Mr. Innes, that it was pretty generally admitted "that the dry assay told the smelter more nearly what he may expect to get out" of the ore, and none of the speakers at the discussion on his (Mr. Westmoreland's) paper had taken that line of defence. It was generally admitted that the smelter did get out more copper than the dry assay indicated; moreover, he had special information which confirmed his statement on this matter. His objections to the dry assay were based on the serious variations of duplicate assays, and the unreliability of the process in the hands of experienced operators, and he would ask which of the undermentioned dry assay products should be taken as "representing to the smelter the yield he may expect to get out":—

					Settled.
(a)	224	33	334	35	344
(b)	59	584	—	—	614
(c)	76	—	764	—	744
(d)	104	—	114	—	12
(e)	694	694	704	—	694

The above results, which were obtained by experienced assayers, were so extremely variable that they could not give any indication of the furnace produce. His suggestion to use the wet assay as a basis would enable exact and accurate results to be used for valuing copper products in place of the rough and unreliable results he had quoted.

Mr. Innes had misunderstood his statement regarding the standard; his reference to $8\frac{3}{4}$ per cent. produce was that 45s. was the R.C. for this produce only, when computing the standard which was used as a basis for the valuation of cupreous pyrites. He agreed with Mr. Innes that the valuation of copper in ores "per unit" was more satisfactory than the ticketing system.

*Meeting held Wednesday, April 7, 1886, at
University College, Ashton Street.*

THE PRESIDENT IN THE CHAIR.

DISCUSSION ON THE PAPER OF MR. J. W.
WESTMORELAND ON "THE DETERMINA-
TION AND VALUATION OF COPPER IN
ORES AND PRODUCTS FOR COMMERCIAL
PURPOSES, WITH SOME REMARKS ON
THE ASSAY OF GOLD IN BAR COPPER."

THE CHAIRMAN said that although the paper had been originally read before the London Section, yet it was of interest to Liverpool, inasmuch as they had there more to do with the purchase and assay of copper than any other place, excepting Swansea. There were really two questions involved in the paper—one, that of practical sampling and moisture estimation; the other, that of chemical analysis. There were many present well qualified to deal with the question from both points of view, and the meeting would be glad to hear their remarks.

DR. WATSON wished that there had been somebody present to say a word in defence of the Cornish assayers, with whom the author had dealt hardly. They had, in his opinion, proved themselves by no means unreliable in the assaying of copper; they had also been the mainstay of the copper trade as regarded buying and selling. Those who had had opportunities of comparing the results of these dry assayers with those obtained in other ways, could all speak strongly as to their reliability. The author has suggested that they should agree to buy copper on the basis of the product by wet assay rather than by dry assay. It would make little difference to copper smelters who understood their business what basis was used, and the time of transition would prove one of great inconvenience, and even loss, to those who had the sale of copper ores. The author had gone some way to point out anomalies in the present methods, but he had hardly made out a case strong enough to induce them to leave the old Cornish system for one based on the actual contents of copper ores. At the same time, he entirely agreed with the author's estimate of the accuracy of the iodide process. It was in daily use in his laboratory for all estimations of copper. He was distinctly opposed to the establishment of standard international methods of analysis. He would leave a choice of methods to the analyst, being assured that the trade would soon determine for itself whether the results had been properly obtained.

Mr. RAWSON said he did not wish to enter into the discussion of the Cornish assay mentioned by Dr. Watson, but to confine himself more especially to the chemical side of the question as regarded the actual wet assays of copper ores, and to compare methods used by himself with those mentioned by Mr. Westmoreland in his valuable paper. As regarded the moisture, though they did not employ such a primitive method as making the ore red hot for a few minutes, whereby arsenic as well as other volatile constituents, together with water, must be driven off, they used to heat the ore, taking 1lb. of it in a pan over a Fletcher's burner with the gas turned down. The pan and its contents were then weighed, and the drying was repeated for a shorter time, and again weighed. If the second weighing agreed closely enough with the first, the difference between the second weighings and the original weight was taken as the moisture. Of course he did not consider that this process was of anything like scientific accuracy, though he did think that it gave results with a sufficiently close approximation to the truth for all ordinary manufacturing purposes. Still, however, there was here room for improvement, and he quite agreed with Mr. Westmoreland that the matter was one worthy of further inquiry. Then, as regarded the method of testing green ores for copper, the cyanide process, in which Mr. Westmoreland was evidently by no means a believer, gave, it seemed to him, very good results, if proper care was taken, the process he used being this: A certain weight of the ore was dissolved in nitric acid and evaporated down with sulphuric acid, and then dissolved in hot water, filtering off any insoluble residue. A solution of sodic thiosulphate was then added, whereby the copper was precipitated as cuprous sulphide; this was filtered off, dried and ignited and dissolved in nitric acid, and the excess of nitric acid got rid of by evaporation. The cupric nitrate was then dissolved in a known volume of hot water, and a known amount of ammonia added. A weighed piece of pure electrolytic copper was then taken, weighing about as much as the copper present in the amount of green ore used for analysis, dissolved in nitric acid, the excess of which was evaporated off and then the same known

volumes of water and ammonia were added. They had then two solutions containing about the same amount of copper, the amount in one being known and the other unknown, and the same volume of water and ammonia in each. It now only remained to titrate the two solutions in such a way that they should both be done at the same time. As the blue colour, on the addition of cyanide, did not at once disappear, but first passed through a pink stage, it was as well to filter a part of each solution, towards the end of the operation, into a test tube, and on looking down through the column of liquid it could be at once seen whether there was any colour remaining. It was especially necessary to have about the same amount of copper, the same volume of water and of ammonia in each, and that the titrations should be completed in the same time, in order to get thoroughly satisfactory results. Any lead present was mainly got rid of by the evaporation with sulphuric acid, and even if it were present at the final titration, Dr. Steinbeck states, and some experiments of his own bore this out, that it had no effect whatever on the amount of cyanide used. The presence of zinc, of course, would be very prejudicial, but then this was not precipitated by the hyposulphite, or rather thio-sulphate of soda; any arsenic was also volatilised by the ignition of the Cu_2S previous to its dissolving in nitric acid. Hence he was inclined to think that the process was quite trustworthy, provided that the precautions already mentioned were carefully followed. If Mr. Westmoreland had used the method with these improvements, which were well known in works, he was surprised that he was not satisfied with it; if, however, he had not done so, he thought he would probably think of it much more highly if he adopted the precautions here indicated. Mr. Westmoreland further stated in his paper that he had come across differences of 25 per cent. between chemists who used this method; he could only say that he was unable to recall to mind such a discrepancy as this, 15 per cent. being about the maximum in his experience, and in most cases the results were far more favourable even than this. Now, as regarded the testing of copper precipitates; as before, the weighed quantity was dissolved in nitric acid and evaporated down twice with sulphuric acid, and then filtered, thio-sulphate was added, and the cuprous sulphide filtered off and dried, and then mixed with sulphur and ignited in a hydrogen crucible in a current of hydrogen, allowed to cool, and weighed. The lead, which was usually from 50 to 100 per cent., was almost all removed by the evaporation with sulphuric acid, but if there should be any left it would be so little as not to exert any appreciable influence on the results. He had used this method many times, and had always found it to be an accurate one. This he had proved by assaying the same sample over more than once, and also by the general run of the numerous analyses which had been made, and which had been checked by this and other methods. He had, however, never been able to make much out of the electro-deposition method: his own results with it he felt could never be thoroughly depended upon, being sometimes too high and sometimes too low for no assignable reason that he could discover. Some little time ago, moreover, before he heard that Mr. Westmoreland was going to read a paper, he caused two students to make some tests, by the electrolytic method, of an ore which had been determined by the cyanide process. The first one got his results as high as 27.77 per cent. copper, whilst the other student, whose work, though he had no special knowledge of this mode of analysis, was usually exceedingly accurate, only found some 21.20 per cent. copper. The cyanide results gave 24.70 per cent. copper, which, as they

would observe, was a very fair mean between the two. As however this method was used in America, and as Mr. Westmoreland approved of it, he should be glad to hear why it had given such indifferent results in his hands. He fancied that in this method, as in so many others, there would be certain conditions which must be strictly acted upon, and without variation, to get consecutive concordant results. He quite agreed with the author when he said that roasting the precipitated copper in a muffle was not a reliable way; estimations which he had made by it himself, and also his own figures by the subsulphide process, compared with those given by the users of this method, had satisfied him that it was not good. Mr. Westmoreland stated that he had known cases where the ore had simply been dissolved in nitric acid and excess of ammonia added, and the ammoniacal liquid titrated there and then with standard cyanide, the results obtained in this way being sent in as accurate assays. He did not see how such a method could give anything but approximate percentages. It was, however, very useful, owing to the speed with which estimations could roughly be made of the amount of copper in it. It would never do, however, to buy or sell on such an analysis, as the results were from about $\frac{1}{4}$ to $\frac{3}{4}$ per cent. too low, according to the amount of copper present in the sample.

Mr. A. G. PHILLIPS said that with regard to the question of moisture, he thought the present method, carried out in a pan, was sufficiently accurate for all practical purposes. It was, however, possible that discrepancies might arise where the assayer dried his sample at a higher or lower temperature than that used in estimating moisture, and it had been suggested—and with regard to more valuable ores, such as silver, the suggestion had been carried out—that four or five samples should be dried, and the dry material actually bottled in the presence of the samplers and forwarded to the assayers to be assayed without further drying. In that case if any water was left in the sample it would be to the advantage of one party, but at the same time the assay would be proportionately in favour of the other party. This seemed to be the only way to get rid of the difficulty which at present existed. Mr. Westmoreland's remarks pointed to a suggestion that some arrangement might be made for drying at a fixed temperature, but he did not think that would do, because some ores required drying at a much higher temperature than others. With regard to the wet processes for the estimation of copper, he thought they might concede that the process Mr. Westmoreland so strongly advocated (the iodide process) was an exceedingly accurate one, as was also the cyanide process for low produce ores, if properly carried out. Then there was the electro-deposition method, and also that of weighing the copper as subsulphide after ignition in a current of hydrogen, so that practically they had three or four accurate methods for estimating copper. The great gist of Mr. Westmoreland's paper seemed to be an attack upon the Cornish method, and he spoke as if it were comparable to the chemical methods for ascertaining the copper in an ore, but it was never intended for that, but was merely a method for ascertaining commercial value, the original idea apparently being to make the assay by carrying out on a small scale in the laboratory, the same operations as would afterwards be employed in smelting the ore. In this way the amount arrived at would be, not the actual contents of any ore, but the amount recoverable by the smelter after allowing for loss in course of working. Mr. Westmoreland seemed to treat the matter as if those buying and selling by the Cornish assay were under the impression that they were buying or selling the

exact amounts indicated by the assay, but this was not the case, as everyone in the trade perfectly understood the differences existing between wet and dry assays: it would be a very difficult thing if they swept away the dry assay to arrive at a scale of allowances which would be satisfactory for ores of various produces. If they began sweeping away all those old land-marks, the best way probably would be to buy on the wet assay, making the necessary allowances by a difference in the price per unit. Mr. Westmoreland had gathered together a number of examples of bad results by the Cornish method, where there had been great discrepancies. Having, however, been for some time assistant to one of the Cornish assayers, Mr. Westmoreland had had every opportunity for collecting such results, and it probably took him a considerable time to collect such a number of unsatisfactory ones. The next portion of the paper was extremely interesting with regard to the calculation of the "standards" and the deduction of prices from them, but that was chiefly of historical value, because the Swansea sales had practically ceased to take place, and he believed it was now almost the invariable custom to buy and sell by private sale at so much per unit, and the old arrangement of the "standard" was practically obsolete.

Dr. HURTER: Mr. Westmoreland said in his concluding remarks that the discrepancies he pointed out were due in most cases to "careless work and the use of inaccurate methods," and in a very minor degree to "errors of sampling." But the only manner in which his employers lost money was not by the discrepancies in the Cornish assays, but by errors of sampling. In days gone by, sampling was carried out in a very careless manner. One man was sent by the seller and one by the buyer. The seller's agent tried to pick the richest and the other the poorest pieces of ore, thus samples were got which did not represent fairly the whole parcel of ore. It appeared to him that Mr. Westmoreland had not taken into consideration the circumstances under which the moisture had to be determined. Samples were taken and moisture determined at the spot where the cargo was discharged, often in places where the accessories of a well-appointed laboratory were not at hand. It would certainly be the simplest plan if the determination of moisture could be abandoned, and the copper determined in the moist sample, as the last speaker (Mr. Phillips) had pointed out. But his experience was that pulverising a sample altered its moisture, and as the assayer had to reduce the sample to a fine powder that plan could not safely be adopted. He heard one gentleman express an opinion that Mr. Westmoreland's paper struck a blow at Professor Lunge's proposition of international methods of sampling and testing. He did not think that was so. On the contrary, it appeared to him that the paper, by pointing out serious discrepancies arising from the uses of different methods, supported Dr. Lunge's position. As regards the Cornish assay, that, of course, would not be looked upon as a scientific method of ascertaining the exact amount of copper a sample contained. It was simply a method of ascertaining the value of a certain ore, and taken in conjunction with the system of "returning charges" it was a method which gave different values to each unit for ores of different percentages, although the standard price of the unit was fixed. The Cornish assay was in the copper trade the same thing as the English degree to the alkali trade. Neither of them represented the theoretical amounts; both of them were only used for the valuation of the articles in question. Otherwise he thought Mr. Westmoreland's paper very valuable and in-

teresting. It would, perhaps, have been better if Mr. Westmoreland had given a few comparisons of the iodide process with the cyanide process, both carried out in the same laboratory, but he had no doubt Mr. Westmoreland had proved the iodide process to be a good one; but he doubted whether the trade would all at once abandon the Cornish assay and substitute the iodide process for it.

Mr. TATE agreed with the last speaker that many of the errors which occurred in reports upon copper were due more to sampling than testing. Sampling was certainly not in so perfect a state as it should be. He had seen tests for moisture made by samplers by simply drying the ore in a vessel like a frying pan or saucepan lid in such a manner that no one could tell whether all the moisture had been driven off or whether the sample had lost something besides water. This practice was still in vogue, for he had himself received samples for analysis, supposed to be dry, which yet contained much moisture, showing that, though some attempt had been made to get at the moisture, yet the estimation had been conducted without reasonable care. Every assayer should take careful note of the moisture present and the method of testing for it. It was therefore necessary, before passing judgment on the different methods of assaying, to ascertain whether their methods of sampling could be improved. Sampling was as much a science as assaying, and well worthy of attention. Whatever might be said in favour of the relative merits of wet and dry assays, much depended on the experience of those who made them; and concordant results could not be expected without constant practice. He was not certain that the old Cornish assay would give concordant results in the hands of different operators and in different laboratories, but what he objected to particularly was its secrecy, and the close way in which it was confined to a few operators. This was a totally wrong principle. On the other hand, he agreed in the main with Dr. Hurter that the Cornish assay had been found by commercial men to give them a reliable indication of the value of ores; and he did not wish to supersede a method said to be a sufficient guide without grave reason. The author had overlooked one aspect of the commercial question when he alleged that the difference between the dry and the wet assay was a measure of the difference between the money values of coppers. This was really not the case, because the buyer had to take into consideration the loss of copper in the smelting operation. It was not exactly a relative difference in value between two assays which would guide him.

Mr. WESTMORELAND said this was a misunderstanding; it was only a difference between wet and dry assays.

Mr. TATE was sorry if he had wrongly interpreted the author, but there was a money value given, and the paper gave him the impression that the figures between the two kinds of assay indicated a certain money value. The real question at issue was whether the dry assay gave figures in fair correspondence with the results obtained on the large scale. His own impression was that, by recent improvements in smelting and refining copper, there was a far larger yield than the dry assay would seem to indicate, and for his part he would be glad to see the dry assay abolished. As regarded the various wet methods, there was first the cyanide process. It had undoubtedly been found useful in works, and in the hands of competent persons gave very concordant results; but he questioned whether it would give equally good results in the hands of different operators working in different laboratories, unless they formulated a definite method of procedure never to be deviated

from. He had not found the electro-deposition process altogether satisfactory; and when they had figures varying from twenty-seven to twenty-one put before them by a careful operator, it indicated what differences could result from its use in various laboratories. Of all the processes mentioned, the iodine method seemed to be the best as being least liable to error, and if any change were to be made and the dry assay given up, then this seemed eminently the one to succeed it. On the whole he agreed with the author's conclusions, but must dissent from the grounds on which he based his arguments in favour of a change from the dry to the wet assay.

The CHAIRMAN was sorry to say it was a long time since he personally tested copper ores, but he had pretty considerable experience in testing it in former times, and also of sampling, and he might say his experience entirely coincided with that of Dr. Hurter, that the great losses they always sustained arose from sampling rather than testing. Twenty years ago he was very much surprised to find that in a cargo of pyrites, of 250 or 300 tons, his firm lost £300. They did not certainly get the copper in the burnt ore, but they paid for it in the raw ore, and when he came to look into the matter he found the loss arose from sampling. Since then the sampling had been conducted in a much more satisfactory manner, and he did not think there were the same objections now that there were in former times. As regarded the testing and analysis of ores, he was rather inclined to agree with Mr. Westmoreland, who had laid down a number of propositions in his paper. First that the moisture in the copper ore should be more clearly defined, and notwithstanding the discussion that evening he quite thought this was the case. He quite saw that with ores so different as sulphur ores and precipitate, they must possibly work at different temperatures, but still it was desirable if they could arrive at some common understanding on the subject. It was desirable that if they determine the moisture, they should determine it at some definite temperature. He thought this was perfectly clear, and he had not the slightest doubt that if the chemists and the manufacturers and the assayers, would put their heads together, they would be able to discover some more satisfactory manner of determining the moisture than was adopted at present.

With regard to Mr. Phillips' suggestion, as to sending the dry sample to the assayer, and assaying the sample in the dried state, he thought it would not be impossible to have the sample pulverised sufficiently fine that it could be used in that state for the assay and determining the test. If that could be done it would overcome that difficulty. Then Mr. Westmoreland said that in wet assays of copper ores he preferred the iodide process, and from the general discussion the iodide process seemed to be accepted as a fairly accurate and rapid one, and that concordant results were obtained. He was surprised to hear that the electro-deposition process was interfered with by the presence of bismuth and silver, when Mr. Claudet, who had enormous experience, wrote to Mr. Phillips and said that of all the processes the electro process was to his mind the most perfect, and as the deposition could take place during the night the assay was practically as rapid as any other. Of course the cyanide process was at first adopted on account of the rapidity with which it could be carried out, and it was still used, when they did not want a very accurate process, because they could carry it out in a rough way very rapidly. But when it was necessary to take great precautions (he remembered the time when it was not considered necessary), they then got most discordant results. Now, apparently, the iodide process could be carried out as rapidly as

the cyanide process, and if they got two processes which could be carried out with equal rapidity, it was better to take the one which was more accurate. As regarded the Cornish process and the dry assay, there was a great difference between the Cornish process as adopted to-day and 20, 30 or 40 years ago. Formerly it seemed to him that it simply meant a buyer's assay and a seller's assay; one got one result and the other another, and then it seemed really a toss up in agreeing to the produce between them, because really the difference was enormous. He hardly ever found two Cornish assayers to agree. The process was perfectly ridiculous from a scientific point of view; but soon after the alkali manufacturers began to receive copper ores and to test them, having competent chemists in their works, and finding these enormous differences, they looked to their Cornish assayers to assay by the wet method, saying at the same time, "We make this ore so much," and it was absolutely impossible that the dry assay could make it above a certain figure. The Cornish assayer now, he believed, used the wet method in order to control the dry assayer. This fight had been going on for the last 20 or 30 years, and as Mr. Phillips said, they were now fairly satisfied with the Cornish assay. Well, he supposed he ought to say that he was fairly satisfied, but would they tell him that it was a method with which chemists ought to be satisfied? He thought there was no chemist who would say that he was satisfied with the Cornish assay. At the same time it worked in a way which was well understood in the trade, and it was very difficult to understand a thing of that kind, still it was not impossible. He had supported Dr. Lunge's international methods of sampling and testing, and he thought, on the whole, Mr. Westmoreland's paper was in favour of that proposal rather than against it. He thought that in some future time they should have some agreement as to the wet assay of copper ores, and that copper ores would be sold by the wet process, as more accurate. Although it was difficult, it was not impossible to come to an agreement about a test. Dr. Hurter remembered the difficulty they had at one time about the determination of the value of the manganese ores, when the Spanish manganese ores first came into the market. They found the oxalic method gave results too high, and at any rate the results were unsatisfactory, as they really paid too high a value for the ore, taking the quantity of chlorine yielded when treated with HCl; and they determined, after discussing the matter, to have a different method of analysis, and they adopted one, after consultation with analytical chemists, which had since given satisfaction.

Mr. WESTMORELAND said, in reply, that with regard to the moisture determinations, he had suggested that dried samples should be forwarded to the assayers, who could re-dry them at a low temperature to expel any hygroscopic moisture which had been absorbed after the determination was made. Although it was true that the moisture in different ores was expelled at varying temperatures, yet the adoption of a definite fixed temperature would prevent the discrepancies which now occurred; for what was required was that the samples should be in the same state of partial or complete dryness when assayed as when the moisture determination was made. The determination could not be safely abandoned, as some speakers had suggested, for some years ago he made experiments, taking the moisture on rough samples of ore, and also on other portions of the sample which had been finely powdered, for analysis, when a serious loss of moisture was found to occur during pulverisation. The discrepancies which have been noted by Mr. Tate between his estimations of moisture

and those stated on bottles containing samples, have been generally observed, and may result from the sample having been exposed or reduced to a finer state of division after the determination was made. Whatever may have been the case formerly, he believed that samples were now, as a rule, taken very carefully, and that the discrepancies in assays which he had pointed out were not due to errors of sampling, but to other causes. Take, for instance, the assays on page 57, where two assays of the same sample gave 33 and 35½ per cent. respectively; it was evident in this case that the method of assay and not the sampling was at fault. He was well acquainted with the details of the process of assay mentioned by Mr. Rawson; but the fact that the necessary precautions were observed in the laboratories from which results of wet assays had been quoted, shows that very discordant results were obtained by operators constantly using the process, and whatever modifications were introduced in different laboratories, concordant results should be obtained if the standardising of the cyanide solution was conducted in the same manner as the tests were made. Some speakers laid stress on the fact that concordant results were obtained by them when using the cyanide process; but concordant results alone were very unreliable indications of the value of a method of analysis. What was required was that the results should express as accurately as possible the absolute amount of valuable matter (in this case copper) in the material under trial, and the method which indicated this most accurately should be used for commercial purposes. The cyanide process as described by Mr. Rawson was quite as troublesome as the iodide method, with the disadvantages that a standard solution very liable to change was employed, and that the end reaction was by no means of a very definite character. On referring to his paper, differences of more than 25 per cent. would be found, and Mr. Rawson acknowledged that errors of 15 per cent. might occur in duplicate assays of the same sample. In his own practice, testing green and burnt ores by the iodide method, using very different weights of ore, say 50–100–150 grams, he should not allow greater differences than 0.4 per cent. to pass without retrial. He was aware that the process by the ignition of cuprous sulphide in a current of hydrogen gas was used for the estimation of copper in green ores and precipitates, but it involved the assumption that no other metals except copper were present, giving sulphides not volatile at a red heat; but samples were often examined containing silver, tin, bismuth, etc., and he had also examined samples of precipitate containing 4 per cent. of lead; in these cases the process would be liable to serious error. Regarding the electro-deposition method, he had not noticed the extreme variations mentioned by Mr. Rawson, and the fact that the iodide method was used to check the results of pyrites assays by electro-deposition, confirmed his statement that the iodide was the more accurate process. Dr. Hurter remarked that the only way in which his employers lost money was by errors of sampling, and not by discrepancies in the dry assays. The difficulty was that when discrepancies occurred it was impossible to obtain authentic portions of the samples operated on, in order to see where the error really occurred. Take, for example, the following assays of pyrites: Works' wet assay, 2.05 per cent.; buyer's and vendor's dry assays, 1¼ and 1⅓ per cent. respectively; referee's return as umpire, 1½ per cent.; margin between settled produce and wet assay, 30 per cent. The referee strongly asserted that his assay was correct, and the unfortunate sampler received all the blame. He could not agree with Dr. Hurter that the dry

assay was in the copper trade the equivalent of the English degree in the alkali trade. The cases were not parallel; for the English degree was obtained by a *well-defined and chemically exact process*, the equivalents only being in error, while the dry copper assay was liable to serious variation even in the hands of experienced operators. The method proposed for copper tests—viz., using an accurate and exact process of wet assay, deducting a margin, and taking the product as an equivalent to the present dry assay for commercial purposes—would be an exact parallel to the English alkali degree. He thought Mr. Tate had misunderstood his remarks regarding money value in cases of discrepancies. In the assays of parcels of similar material—for example, cupreous pyrites—the settled produces should vary to the same extent as the wet assays. Thus, if there was 25 per cent. difference between the wet assays of two parcels, the settled produces dry assays should vary to the same extent. Therefore if the wet assays of one parcel varied by this percentage, which was on one basis of valuation worth 3s. per ton of ore, they might, he thought, say that the difference in value by discordant assays would be equal on a parcel of 240 tons ore to £36. The same rule was followed elsewhere, wet assays being compared with wet assays, and dry assays with dry assays, the differences being calculated into money value on the parcel. Mr. A. G. Phillips had stated that he (Mr. Westmoreland) seemed to think that vendors and purchasers of copper ores were not aware that the dry assays did not give the absolute amount of copper in the sample. He was not aware that he had stated this with regard to copper ores, but Mr. Phillips might perhaps be interested in knowing that several large dealers and brokers of bar-copper were not aware of the fact until it was explained by him. Mr. Phillips was also in error regarding his position in Cornwall. He was not assistant to—but chemist with—a dry copper assayer, and in that capacity he made whatever changes he pleased, and used any methods of analysis, assay, etc., he thought proper, without reference to his employer or any other person. Regarding the method of dry assay, not one of the facts or statements he had made regarding the process had been challenged. Was it true, as several speakers had asserted, that the dry assays were accepted as satisfactory either by vendors or purchasers? Was it not a fact that constant complaints were being made regarding the margin between the "settled produces" and wet assays.

If the dry assay furnished any indication of the yield or quality of the metal produced on the large scale, there would be some reason for its retention, but this was not the case. His proposal to use the iodide method, deducting a margin, as a basis, would enable all the present trade customs to be retained, and would be more satisfactory to both buyers and vendors than the present system.

He considered that his statements regarding the inaccurate and unreliable results of the dry assay had not been disproved, and that he had shown that the iodide method was the most reliable process for the estimation of copper.

MEETINGS, SESSION 1885-86.—First Tuesday in each Month, at 7 P.M.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

SUPPLEMENTARY NOTES ON THE METHODS OF EXAMINING FIXED OILS.

BY ALFRED H. ALLEN.

THE following notes connected with points referred to in the paper I read before this Section at the January meeting:—

Valenta's Acetic Acid Test.—In the table published on page 69 of the *Journal*, owing to the undue extension of a bracket, sperm oil and whale oil are represented as being insoluble in an equal measure of glacial acetic acid, even at the boiling point. This is not the case, and, in order to prevent misconception, I give below the temperatures at which their solutions in glacial acetic acid were observed to become turbid, together with similar results obtained with other oils since my last paper was read. The observations were made at my request by Mr. W. Wright. As before, I have placed in juxtaposition the figures obtained by Valenta with specimens of the same kind of oils.

KIND OF OIL.	Turbidity-temperature, °C.	
	Valenta.	Allen.
Whale Oil, No. 1	—	38
„ No. 2	—	86
Bottlenose Oil	—	102
Sperm Oil	—	98-103
Seal Oil	—	72
—	—	—
Linseed Oil, No. 1	—	57
„ No. 2	—	74
„ No. 3	—	73
Cotton-seed Oil	110	90
Rape Oil	insoluble	insoluble
Blown Rape Oil	—	52
—	—	—
Cocoa-nut Oil	40	75
Palm-nut Oil	48	32
Laurel Oil	26-27	40
Nutmeg Butter	27	39
Cacao Butter	105	insoluble

Of the two samples of whale oil examined, No. 1 contained a proportion of glycerides of volatile fatty acids corresponding to 5.1 per cent. of valeric acid, while No. 2 contained only the equivalent of 1.5 per cent. of that acid. The results furnish another instance of oils containing lower glycerides being comparatively easily soluble in glacial acetic acid. The variations between Valenta's figures and those obtained in the author's laboratory show that too

much reliance must not be placed on the indications of the test, which, however, is capable of very useful application in certain cases. Thus, further most encouraging results have been recently obtained with butter and lutterine, but I reserve a full description of these experiments for a future paper.

Bromine Absorptions of Oils.—In my last paper I gave a table in which the proportion of bromine, found by Dr. E. J. Mills and his coadjutors to be absorbed by various oils, were compared with the corresponding iodine absorptions as determined by Hübl. It is only just to Dr. Mills to state that the value I gave for the bromine absorption of almond oil was that found by Mills for the oil expressed from bitter almonds, whereas the result he obtained for the oil from sweet almonds does not present so strongly the anomaly to which I called attention. Since the publication of my last paper, Mr. T. Maben (*Pharm. J.* [3], xvi. 797) has determined the bromine-absorptions of apricot and peach oils, with the results incorporated in Table A on page 283, together with the iodine-absorption found by R. W. Moore for almond oil.

The difference in the bromine-absorption found by Mills for the oils from sweet and bitter almonds is striking, especially as the *British Pharmacopœia* regards the oils as so similar that the use of the one or other kind of nut is optional. As a matter of fact, however, nearly all the oil of commerce is expressed from bitter almonds, as the mark of these is then available for preparing the essential oil. But a bromine-absorption of only 26, if it really corresponds to the triolein present, points to the presence of fully 50 per cent. of palmitin or other solid fats, a proportion which would give an oil the consistency of lard or tallow. On the other hand, the iodine-absorptions of Hübl and Moore are inexplicably high for a non-drying oil, for (multiplied by the factor 1.152) they represent more than 100 per cent. of triolein.

Determination of Glycerin.—In my last paper I mentioned that I had not succeeded in obtaining methyl alcohol which could, by any reasonably simple method of purification, be rendered suitable for effecting the saponification of fixed oils prior to the determination of the resultant glycerin by the permanganate process. In accordance with a recommendation made during the discussion on my paper, I have since applied to Mr. C. A. Fawsitt, who has kindly supplied me with some methyl alcohol which, after rectification with a little caustic soda, is all that can be desired. By the aid of this purified product, I have made determinations of the glycerol in other samples of saponified oil, and have found that, in the case of oils which have been gravely modified in their characters by oxidation, bodies are developed that yield oxalic acid on treatment with permanganate and alkali, and hence vitiate the determination of glycerine by this process. Thus a sample of genuine steam-boiled linseed oil showed 9.94 per cent. of glycerin by the permanganate process against 8.78 per cent. actually isolated. These results show as near an agreement as might be expected, when the unavoidable loss of glycerin by volatilisation in the latter process is taken into account. On the other hand, when the same oil was allowed to dry completely by exposing it in thin layers on glass plates, at a temperature of 100° C., the product when oxidised with permanganate gave oxalic acid equivalent to the impossible proportion of 15.52 per cent. of glycerol, while the amount of the same substance actually isolated in a moderately pure condition was only 6.4 per cent. The discrepancy is probably due to the formation of soluble oxidation-products capable of yielding oxalic acid on further oxidation. Acids of the acrylic series are

known to have this property, and are said to be produced by the oxidation of linseed oil.

In addition to those already mentioned, I have to acknowledge the zealous assistance of Messrs. W. Chattaway, H. G. Hardy, and W. Barraclough, in carrying out the numerous experiments, the results of which are recorded in this and the foregoing paper.

A FEW FACTS IN THE HISTORY OF SOLID CAUSTIC SODA.

BY P. HART.

IN Dr. G. Lunge's excellent book, "Sulphuric Acid and Alkali," vol. i. p. 592, he says: "It is just possible that solid caustic soda was made somewhere between 1845 and 1851, but the fact that not a single English patent about it was taken out during that time tells against that assumption." The statement may be historically interesting that to my personal knowledge solid caustic soda was made, under the direction of the late Dr. Young, of paraffin oil celebrity, at the Manchester Ardwick Bridge Chemical Works, previous to 1852. Dr., then Mr. Young, left the service of Messrs. Tennants & Co. about August in that year, and during the previous twelve or eighteen months

and his employers failed to see, very legitimately turned his attention to the matter, and, combining the information so obtained with Brown's previous patent (Lunge, vol. ii. p. 592), succeeded in working out his method of producing solid caustic soda from what may be termed soda ash mother-liquor. At all events, the fact of his obtaining a patent for this so immediately afterwards as May, 1853, I think adds great weight to my inference.

ON THE ESTIMATION OF SULPHUR AND IMPURITIES IN COAL GAS.

BY T. FAIRLEY, F.R.S.E.

THE manufacture of coal gas is controlled, as regards purity and quality, by the different Acts of Parliament relating to the districts where the gas is supplied.

In London it is required that the gas shall be free from sulphuretted hydrogen, and that the proportion of sulphur in other sulphur compounds shall not exceed 20 grains in winter nor 17 in summer in 100 cubic feet of gas. It is also required that the ammonia shall not exceed 4 grains, but no limits are specified as regards air or carbonic acid.

TABLE A. (See Mr. Allen's Paper on p. 282).

	BROMINE-ABSORPTION.		IODINE-ABSORPTION.		
	Mills.	Maben.	$\frac{1}{100}$ Br.-absorp.	Hubl.	Moore.
Almond Oil (Bitter)	26.3	—	11.8	97.5 to 98.9	98.91 "

Peach-kernel Oil	—	77.0	122.2	—	—

was busy completing his company's works at Bathgate and producing oils there. As is well known, at one stage of the manufacture of paraffin oils, they are or were treated with sulphuric acid, with an after treatment of caustic soda. Now, whether Mr. Young found this latter article difficult to obtain in his new neighbourhood, or from secretive reasons, or disliking the trouble of erecting plant for the causticising soda ash, I do not know, but the fact remains that during the period named some tons of solid caustic soda were made by boiling down the ordinary commercial liquid caustic soda of 70° Tw. As Mr. Young was the only customer, comparatively small quantities were made, and its manufacture did not last long. A cast-iron pot, 6 feet diameter and 3 feet deep, was employed. As the water evaporated, the solution caustic was dribbled in until a sample taken out would set. At this stage the fire was withdrawn, and the pot baled out on to long iron trays. As it set it was broken up with chisel-ended bars into small pieces, and finally packed into American potash barrels. But another fact lies behind this. During a portion of the period when this was going on, the late Mr. William Gossage was experimenting at Ardwick Bridge with his patent method for concentrating sulphuric acid (Lunge, vol. i. p. 556—7), and as no secret was made of this solid caustic soda, it being only made for Mr. Young's convenience, and probably seemed to have no commercial worth, I think it likely, indeed, that Mr. Gossage, having ample opportunity, saw this process being carried on, and seeing in it a commercial future which Mr. Young

In Leeds the gas committee have for some years sought to obtain something like the same standard of purity as is required in London, especially as regards sulphur compounds, and I have made numerous tests weekly at the three different gas works, and at my own laboratory.

FIG. 1.

These tests have generally been made by the apparatus introduced by the London Gas Referees, shown in Fig. 1. A is a small Bunsen burner with steatite top placed in a perforated cylindrical stand, having a cylindrical channel to receive the glass trumpet B,

between which and the top of the burner are placed about 2 ounces of ammonium sesquicarbonate. The products of combustion pass by the trumpet into the cylinder C, packed with glass balls, and provided above with a long tube D for purposes of draught, etc. At the bottom of the cylinder is a narrow tube to allow the condensed liquid to pass into the beaker E. The gas is thus burnt in an atmosphere more or less charged with ammonia, the flame shows at its edge the pale orange tint shown by the burning ammonia. The same purpose may be effected as shown by Mr. W. C. Young (*Analyst*, 1876, p. 143), by placing crystals of sodium carbonate in the upper part of the cylinder.

In this apparatus the Referees require that the gas should be burnt at a rate not exceeding half a cubic foot per hour, in a room where no other gas is being burnt at the time; and that the tubulures or narrow parts of the trumpet and condenser should have a diameter not less than three-quarter-inch, so as to permit a sufficient excess of air to pass through the apparatus. (This latter condition is very frequently neglected by the makers and dealers in these apparatus.) In measuring the gas, corrections should be made for variations in temperature and pressure. The condensed liquid and washings of the whole apparatus are finally made up to a given volume of which a fraction can be taken for estimation of the sulphur as barium sulphate in the usual manner.

In the estimations of sulphur in coal gas by this method, the following suggestions which I have to make may be useful:—

(a.) If the gas burnt amounts to 2·12 cubic feet, or if the portion of the condensed liquid taken corresponds to 2·12 cubic feet, then the barium sulphate weighed in centigrams gives at once the grains of sulphur per 100 cubic feet of gas *without calculation*. If a multiple of 2·12 cubic feet be taken, then the calculation is of the simplest character.

(b.) In acidifying the liquid with hydrochloric acid before adding the barium chloride, it is well to use hydrochloric acid, charged with free bromine, to secure complete oxidation of any products in the condensed liquid. If the supply of gas be not very perfectly governed, the flame may enlarge, and the products for the time being may be imperfectly oxidised. The tests should not only be made in a room where no other gas is burning, but as free as

experiment made with a similar apparatus, using a small spirit lamp, with its flame surrounded with ammonium carbonate, instead of the gas burner, and adjusted to about the same size of flame, will, when kept burning during the same time, afford the means of making an approximate correction for impurity contained in the air.

The Referees' apparatus and mode of testing was a distinct advance on any other previously in use, such as Letheby's (Fig. 2) or Wright's (Fig. 3), or even Letheby's apparatus with additional cylinders, as proposed by Anderson.

Even with experienced workers, however, the Referees' apparatus sometimes gives wide fluctuations in consecutive tests, and there is a suspicion that these fluctuations do not really exist in the composition of the gas.

In very cold weather the sulphur sometimes drops down considerably, probably from the partial condensation of carbon disulphide or other organic sulphides in the mains or pipes.

FIG. 3.

The American chemists, Messrs. Sadler and Silliman, in 1877 (*Journal of Gas Lighting*, vol. 24, p. 461), proposed a modified form of the Referees' apparatus. They abandon the use of ammonium carbonate, and allow to run in at the top of the condenser standard alkali from a burette. By reading off the volume of standard alkali run in during the combustion of a certain volume of gas, the loss of alkalinity corresponds to the sulphur oxidised from the gas. When this titration method is adopted it is essential that the gas be thoroughly purified from ammonia before passing through the meter. The ammonia apparatus may be fed with standard acid and used as a means of estimating the ammonia in the gas.

The following are the results of tests made by me simultaneously by the Referees' method, and by that of Sadler and Silliman, the sulphur being stated in grains per 100 cubic feet of gas:—

Referees.	S. and S.
16·26	16·59
21·43	21·88
15·06	15·79

The latter method has the advantage that, by changing the receiver without washing out the apparatus, it may be used as a continuous process.

In the *Journal of Gas Lighting* for March 16, 1884, Mr. J. A. Wanklyn described a method in which he used the Referees' apparatus without ammonium carbonate, but placing iodine in the upper part of the condenser above the glass balls. Mr. W. J. Dublin described an extensive series of experiments carried on by the late W. T. Keates in 1877, on the same process. Generally the iodine process gave rather higher results than the ammo-

FIG. 2.

possible from draughts and currents. No carbon disulphide or other volatile sulphur compounds should be permitted in the room. Where oxidation has been complete, the condensed liquid will be colourless, or nearly so. I have calculated that at least twenty volumes of air pass through the apparatus for one of gas. In places where tests must be made in a somewhat impure atmosphere, a blank

mium carbonate process. The following are from simultaneous tests made by me :—

Ammonium Carbonate.	Iodine.	Hydrogen Dioxide.
16.79	17.59	17.66 by titration.
		17.42 by precipitation.

The following is a new process which I began to use some years ago, and which I submit has certain advantages. As there are no solid products, it may readily be used without washing out as a continuous process. It consists in using a very dilute solution of hydrogen dioxide run in at the top of the Referees' apparatus, and the plain flame under the trumpet without ammonium carbonate. The oxidising effect is very complete, even in solutions containing less than one per cent. of real dioxide. The equation is $H_2O_2 + SO_2 = H_2SO_4$, and hence the liquid may either be titrated with standard alkali, or acidified and precipitated with barium solution in the usual manner. The hydrogen dioxide of commerce containing from three to six per cent. of real dioxide, is diluted to about one per cent., and if slightly acid its acidity may be determined, or it may be exactly neutralised before use with decinormal solution of ammonia. Ammonia has much less effect in tending to decompose the dioxide than any other alkali. If the sulphur oxidised from the gas is to be estimated by precipitation, the dioxide should be free from barium in solution, which would precipitate in the condenser as barium sulphate. The gas to be tested should first be freed from ammonia.

The hydrogen dioxide is run in very slowly at the top of the apparatus, by a device adopted by Sadler and Silliman, in running in the standard alkali in their method. About seven inches of fine thermometer tubing is double bent into an inverted Π form, and connected with a burette or bottle containing the liquid. Such fine capillary tubing chokes readily with the slightest sediment deposited from the liquid, but by allowing the liquid to pass upwards into the fine tube, one leg of which is placed in the wide tube above the condenser (Fig. 1), and hangs from it, there is no tendency to choking. By slightly raising the bottle or burette containing the liquid, it is easy to regulate the flow to, say one drop in three minutes, or from two to three cubic centimetres per hour.

This method may be used either intermittently or continuously. In the former case the sulphuric acid in the condensed liquid and washings may be determined either by titration or precipitation, or both, and in the latter, the receiver being changed, the volume of gas required is burnt, and then the sulphuric acid estimated in the liquid collected without disturbing the rest of the apparatus. With a sufficiently large supply of the dilute dioxide in the feeding bottle, a test may be carried on for days continuously, or even a week, and a fractional part of the whole liquid taken, thus enabling one to get a real average from all the gas passing through the pipes during the long experiment. The following are the results of experiments carried on simultaneously, generally on ten cubic feet of gas the sulphur being stated as before in grains per 100 cubic feet :—

Ammonium Carbonate.	Hydrogen Dioxide (precipitation).	Hydrogen Dioxide (titration).
19.21	19.32	19.61
19.42	19.55	19.30
17.98	—	18.20
18.48	18.90	—
16.12	17.03	—
16.41	17.72	—
16.79	17.23	17.66

The estimations of carbonic acid and of ammonia in coal gas are made by processes substantially the same as those described in many text-books.

Where the carbonic acid is over one per cent., approximately accurate results may be obtained by the use of Bunté's gas burette, of which I have two simplified and modified forms on the table. Fig. 4 is the ordinary Bunté gas burette. Fig. 5 is a gas burette without the three-way tap, made from an ordinary burette by joining to it at the top a glass tap and cup. Fig. 6 is an ordinary burette made into a gas burette by means of a perforated caoutchouc stopper very tightly fitted in the top of the burette just above the graduation. The working of these burettes is similar to that of the Bunté, except that the one shown in Fig. 5 has to be filled with the gas when in an inverted position. When the gas has been purified by lime, the carbonic acid may fall under one per cent., and then a standard solution of barium hydrate must be used, contained in an ordinary absorption or wash-bottle apparatus, arranged to give as small bubbles of gas as possible. After passing a measured volume of the gas through a measured quantity of the barium hydrate solution, and allowing the precipitated carbonate to settle, a

FIG. 4. FIG. 5. FIG. 6.

portion of the clear liquid may be titrated, and the loss of alkalinity corresponds to the carbonic acid present in the gas.

When the carbonic acid has been determined in a gas burette by the use of sodium hydrate, a further addition of pyrogallol solution shows by the colour produced if air is present, and if there is any appreciable quantity the oxygen corresponding to the air is absorbed.

Mr. Wanklyn has proposed a method for the estimation of carbonic acid in coal gas (this Journal, 1884, page 12). A clean dry glass bottle, holding about one-tenth of a cubic foot, has fitted to it a stout test tube as a stopper. The bottle is filled with the gas by displacement, and the test tube contains a known quantity of standard barium hydrate solution. On shaking the liquid into intimate contact with the gas in the bottle and then allowing the liquid to settle till clear, the titration of a portion of the clear liquid gives the loss of alkalinity of the solution corresponding to the carbonic acid in the gas taken.

The ammonia in coal gas is estimated by passing it through a wide tube filled with glass beads or

broken glass, which have been previously moistened with a measured quantity of standard acid. The beads or glass used must be tested for alkalinity very carefully, as some kinds are quite unfit for the process. Messrs. Sadler and Silliman suggested passing the gas through an upright tower somewhat similar to the condenser in the Referees' sulphur apparatus, but used in an inverted position and filled with broken glass (*Journal of Gas Lighting*, vol. 24, 461). Standard acid was allowed to run in very slowly at the top from a burette, and ran out by a U-shaped fine tube at the bottom. The loss of alkalinity of the acid gave the proportion of ammonia present. This process they used as a continuous one without washing. I have made some experiments by this process, and generally find that I obtain more ammonia by it when used as a continuous process than by the Referees' ammonia apparatus. On starting the two apparatus the results at first are practically the same.

The following are the results in grains per 100 cubic feet of gas, operating in each experiment on about ten cubic feet of gas:—

	Referees.	S. and S.
I.	0.47	0.49
II.	0.49	1.56
III.	0.44	1.57

I have set up a similar apparatus to the above for the estimation of carbonic acid by a continuous process, using a standard solution of pure sodium hydrate to pass through the scrubber. The liquid in the burette and in the receiving vessel below must be completely protected from the atmospheric carbonic acid. After passing through the apparatus, a measured portion of the sodium hydrate solution, corresponding to a given volume of gas, is mixed with a measured quantity of standard barium hydrate sufficient to more than precipitate all the carbonic acid present. On allowing the barium carbonate to settle, a fractional part of the liquid gives, by titration, the loss of alkalinity corresponding to the carbonic acid absorbed.

I have to thank my assistant, Mr. Walter Leach, for his valuable aid in making many of the estimations required in this investigation.

NOTE ON THE DETECTION OF CERTAIN ADULTERATIONS IN DYESTUFFS.

BY T. FAIRLEY.

SOME time ago I received a sample of archil paste (a preparation of cudbear), which was suspected of being sophisticated with an aniline colour, such as magenta.

I endeavoured to make a separation of the colouring matters, making use of the insolubility of the aniline colour in strong aqueous ammonia. By taking a small quantity of the paste and treating it with successive portions of ammonia, all the natural colour of the dyestuff may be removed. On afterwards adding alcohol, the aniline colour appears in its own proper colour.

Sometimes dyewoods, such as logwood, have been faced with magenta, though I have not met with this lately. The above method would be applicable also in that case.

NOTE ON THE SOLUBILITY OF SILVER CHROMATE IN AMMONIUM NITRATE.

BY R. FORBES CARPENTER.

IN the 12th and 13th Reports of the Chief Inspector under the Alkali Acts, pp. 60, 61, mention is made, under the heading of "Estimation of Hydrochloric Acid," of precautions to be observed as to temperature of solution in using potassium chromate as an indicator, which were communicated by Mr. T. F. Stuart, of Hepburn. It is not there suggested that the solubility of silver chromate in the alkaline nitrate produced in the reaction is one of the causes of the excess of silver solution required to obtain the reaction in hot solutions; but that this will suggest itself as possible has been noticed this year in a paper (extracted in the *Chemical News*, vol. liii. No. 136), by G. Biscaro, "On a Defect in the Volumetric Estimation of Chlorine by Mohr's Process" (*Ann. de Chim. Med. Farm. und Chemische Industrie*). Biscaro notes that "if nitrates, especially those of the alkalis and alkaline earths, are simultaneously present, the precipitation of the red silver chromate often takes place too late, whether because such nitrates form double salts with silver nitrate, which are not precipitated by potassium chromate, so that decided excess of silver becomes necessary, or that the silver chromate already formed is slightly soluble in those waters."

My own experience goes to show that the latter is the true answer. In 1884, in the course of a chimney test for HCl, I accidentally discovered, by the use of a wash-bottle containing ammonia (in washing to add to the filtrate from soot, etc.), that on neutralising with nitric acid and proceeding with Mohr's test in a hot solution, the quantity of silver solution used was enormously in excess of that required by the chlorine present. Both the accidentally introduced ammonia and nitric acid were free from chlorine, and after apparently exhausting all other possibilities, it became clear that the alkaline nitrate in hot solution dissolved the silver chromate as quickly as it was formed. Experiments were carried further, and freshly-precipitated silver chromate was treated with strong ammonium nitrate solution. In the cold, solution of the already formed and not nascent chromate is feeble, though decided, as the solution instantly assumes a bright yellow colour. On warming, the rate of solution rapidly increases up to the boiling-point; on cooling, the silver chromate crystallises out in beautiful needle-shaped crystals.

In reference to Mr. Stuart's experiments, mentioned at the commencement of this note, I would observe that although the test-books recognise that silver chromate is "sparingly soluble" (Miller), and that Mr. Stuart's experiments go to prove that the solubility is greater in hot than cold water—yet that, reasoning from the behaviour of ammonium nitrate in hot solutions, the potassium nitrate formed in the double reaction may exert an influence of equal moment.

	50° F.	210° F.	Grains Silver Chromate dissolved in hot solution.

Some experiments have been made to determine the relative solubility of silver chromate in the nitrates of potassium, sodium, ammonium, and magnesium in cold and hot strong solutions. Fifty grains of each of the above named salts were dissolved in 100cc. of water, and the amount of deci-normal silver nitrate solution taken to obtain the reaction with potassium chromate noted. (See table.)

In the three later cases I have deducted the amount of silver chromate dissolved by the water alone, and have given the amount due to the solvent action of the respective nitrates. From all these the silver chromate crystallises out again on cooling.

NOTE ON SOME CONDITIONS AFFECTING THE OXIDATION OF NITROUS ACID TO NITRIC ACID.

BY R. FORBES CARPENTER.

In the "Alkali Maker's Pocket-book" of Drs. Lunge and Hurter, p. 151, it is stated, as to the use of methyl-orange (Poirrier's orange No. 3) as an indicator in acidimetry, that "in some cases methyl-orange fails to yield good results from causes not yet ascertained—*e.g.*, in chimney testing." On inquiry from Dr. Hurter, I learned that the failure of the indicator had not come within his own personal experience, but had been reported to him by Mr. E. G. Ballard, H.M. Inspector residing at St. Helens.

Now, as the best and most complete comparison of indicators has been made by Mr. Robert T. Thomson, in the papers read by him before the Chemical Section of the Glasgow Philosophical Society, commencing January 22, 1883 (reprinted in the *Chemical News*, vol. 47, pp. 123, 135, etc.), I feel confident, in referring to this exhaustive paper, that I am quoting an authority on the subject treated of. From this I gather that the only mineral acid in the estimation of which methyl-orange distinctly fails is nitrous acid, which, indeed, alters the constitution of the indicator entirely.

My own experience in 1882 had led me also to the conclusion that in the presence of alkaline nitrites methyl-orange is valueless as an indicator; and this brings me to the subject of my note.

On entering upon the duties of inspection under the Alkali, etc., Works Regulation Act of 1881, I devoted some attention to the subject of what were the best and most rapid absorbents for the acid gases of sulphur and nitrogen escaping at the vitriol-chamber exits, and selected for the absorption of the acid gases contained in one cubic foot of acid gases a mixture of 10cc. normal caustic soda, with 5cc. to 10cc. of hydrogen peroxide (10 vol.). Experience soon showed me that under these conditions methyl orange could not be trusted as an indicator, and the cause soon became apparent. My object was to obtain sodium sulphates and nitrates only in solution, and with that in view I added excess of hydrogen peroxide to oxidise up all sulphurous and nitrous acids to sulphuric and nitric acid; but in the presence of an alkali the oxidation of nitrous to nitric acid is by no means complete, it is only partial; nitrite of the alkali will exist in solution in greater or less quantity, according to the varying proportions of sulphurous, sulphuric acids, and oxides of nitrogen present in the exit gases. In many cases the proportion of nitrite is so small as not to affect the working of the indicator; but when the sulphur acids escaping are low, and the acidity is due almost entirely to nitrogen oxides, then the failure of the indicator is frequent.

Under these circumstances, I abandoned the mixture of caustic soda and hydrogen peroxide as an absorbent, and found I could implicitly rely on the latter alone, sulphurous and nitrous acids being immediately and completely oxidised and, as regards the oxides of nitrogen, retained in solution more completely than when caustic soda alone is used. From that time I have never known the indicator to fail, even in solutions containing free sulphurous acid—*i.e.*, where the hydrogen peroxide was insufficient in quantity. As I understand Mr. Ballard uses caustic soda alone as an absorbent, I can readily understand the failure of the indicator in the testing of chimneys into which are draughted the exits of vitriol chambers, of which, under normal conditions, the oxides of nitrogen form a considerable part of the total escape.

I may be asked for further proof of the statements herein made. Direct experiment with sodium nitrite had already proved to me the change in the constitution of the indicator caused by free nitrous acid; but confirmation was desirable, and the usual tests for nitrous acid were inadmissible in the presence of excess of hydrogen peroxide, which produces similar reactions. Recourse was had to metaphenylenediamine, and the Bismarck-brown formation with nitrous acid. Nitrite of sodium in neutral and alkaline solutions mixed with excess of hydrogen peroxide showed that nitrous acid still exists as such, and that even in acid solution the oxidation requires some minutes for its completion.

DISCUSSION.

Mr. THOMSON asked what effect nitrous acid had on the methyl-orange indicator?

Mr. FORBES CARPENTER, in reply, said that instead of the usual change from orange-yellow with alkali to pink with acid, the orange changed to golden-yellow, and the eye could not detect the point of transition. After a time, this golden-yellow faded to a colourless solution. As regarded the nature of the change alluded to by Mr. Thomson, while it was probable that a further azo-compound was formed, yet the bleaching showed that this was by no means permanent. It would be most difficult to ascertain the ultimate constitution of the body formed by the reaction of nitrous acid on methyl-orange—dimethyl-aniline-azobenzene sulphonic acid.

METHOD FOR THE DETECTION OF ROSANILINE SALTS AND SULPHONATED ROSANILINE.

BY A. LIEBMANN AND STUDER.

H. SCHIFF (*Compt. rend.* 64, p. 487) found that by treating dilute aqueous solutions of rosaniline salts with sulphurous anhydride, nearly colourless, or rather pale yellow products are obtained, which he called rosaniline sulphurous acid. He further observed that these bodies when brought in contact with a trace of aldehydes show a very intense violet colouration, distinctly different from the original colour of the rosaniline. S. G. Schmidt (*Ber.* 14, p. 1848), who studied the reaction in late years, confirmed its general application and showed that acetone produced the same reaction. The authors further suggested that this test might be used for the detection of aldehydes or acetone, and some months ago when examining a urine from a case of coma diabeticum for acetone, which Professor Dreschfeld, of the Owens College, was kind enough to let us have, we found this test exceedingly delicate, the

rosaniline sulphurous acid showing at once, even with minute traces of the ketone, a deep violet colour. Only last Friday Professor Dreschfeld, to whom we feel deeply obliged, sent us another urine from a man suffering from the same disease, and the application of the reaction proved again very successful. P. Chantard (*Bull. Soc. Chim.* 45, pp. 83-86) used quite recently this reaction for the same purpose, and we are able to confirm throughout this author's statements. This test is of course only applicable to the discovery of a class of chemical compounds—to ascertain what special member we have to deal with, other experiments have to be made.

But we discovered that this property of the aldehydes and the acetone can be, *vice versa*, applied for the detection of rosaniline salts and sulphonated rosaniline. We have tested dyestuffs, wines, and lozenges in this way, and it might be of interest to state here that if, for instance, cudbear contains only one-fortieth per cent of magenta, it produced, after a certain treatment, a distinct reaction with acetone. To test for magenta or sulphonated magenta in cudbear we proceed in the following manner. One gram. of the dyestuff is boiled with 100cc. of water, and after cooling saturated with sulphurous anhydride. Most of the cudbear is precipitated by sulphur dioxide. The magenta or sulphonated magenta remain, however, entirely in solution—not as such, but in combination with sulphurous acid. If now acetone be added to this solution, and magenta or acid magenta is present, the colour turns after a few minutes' standing into a violet, while genuine cudbear does not show any change of colour. As before mentioned, we were able to show quite distinctly the presence of one-fortieth per cent of magenta; one-tenth per cent. produces quite a deep violet, and though the cudbear solution itself is of a pale red, yet there can be no doubt left about the presence or absence of magenta or acid magenta in it. To determine if cudbear contains a rosaniline salt or the sulphonated compound, we boil the solution after being saturated with sulphur dioxide and the precipitated cudbear being filtered off, dye a piece of cotton in it, mordanted in the ordinary way with tannin and tartar emetic. Only magenta will be fixed to the vegetable fibre, and we can readily ascertain which of the two is present.

In order to examine red wines for these colours we evaporate 100cc. to about one-tenth of their volume, saturate with sulphurous acid, and precipitate the natural colour by means of lead acetate. Acetone is added after filtration, and if the wine contains as little as one miligram. in the litre the test answers admirably. It is not necessary to precipitate the natural colour, for even if it remains the test leaves no doubt about the presence or absence of magenta and sulphonated magenta, but for the sake of a greater accuracy we prefer to proceed in this manner.

In the same way lozenges are tested for these colours, and the result proves that the reaction answers equally well in this case, and that the presence of sugar does not interfere with it, which was, however, made quite certain by S. G. Schmidt's researches on this subject.

Before concluding, we want to make some theoretical remarks about the constitution of these compounds. The constitution of the rosaniline sulphurous acids is probably analogous to that of Pira's thionaphthamic acid (*Ann.* 78, p. 51). In this body one H of the amido group is supposed to be replaced by SO_2H , the free acid decomposes readily into α -naphthylamine and sulphuric acid. The rosaniline sulphurous acid might contain SO_2H instead of H in the amido group; when this compound is boiled the original rosaniline salt is re-formed,

and sulphurous acid is driven off. Now the presence of the residue SO_2H might facilitate the condensation between the rosaniline and aldehydes or acetone. Experiments to prove this assertion will be made, and published at some future day. Schmidt's observations that methyl- and ethylalcohols produce also a very slight reaction, seems to contradict our theory. But then he could only detect a very slight change of colour, and this might be due to some impurities in the alcohols he used, though they had to undergo a very careful purification. We shall repeat his experiments with perfectly pure products. Other colouring matters containing the amido group shall be submitted to the action of SO_2 , and aldehydes and acetone, and we hope to be able at some future day to lay the results of our experiments before you.

DISCUSSION.

Mr. THOMSON said that he had noticed in the last number of the *Journal of the Society of Dyers and Colourists*, a process by Dr. Knecht for the detection and estimation of rosaniline salts when mixed with such colouring matter as cudbear or archil. Dr. Knecht experienced great difficulty at first in finding any process for the detection of rosaniline colours when mixed with archil; but he afterwards devised a process only differing from that described by Mr. Fairley (*see present issue*), in the use of caustic soda in place of ammonia to dissolve out the natural colouring matters of archil. He then treated the residue with acetic or hydrochloric acids to develop the colour of the rosaniline salts. Dr. Knecht subsequently found that this method had already been worked out by Mr. Crossley. He considered the test with dyeing up cloth previously bottomed with chrysamine to be a good, though not very delicate, one for rosaniline colours. Dr. Liebmann's process, however, seemed to be far superior to any of those mentioned for the detection of minute quantities of the colour.

The CHAIRMAN asked if rosaniline and sulphurous acid really formed a chemical compound? The action of aldehydes on this body reminded him of Lauth's reaction, on which about twenty-two years ago the preparation of "aldehyde green" was based.

Dr. LIEBMANN, in reply, said he believed that a combination took place when sulphurous acid acted on rosaniline, and that probably the first stage of preparing "aldehyde green" was analogous to the action of aldehydes on rosaniline sulphurous acid. Further experiments would, however, tend to explain the relation between the two compounds.

Meeting held at Mason College, April 7.

DR. TILDEN IN THE CHAIR.

THE CHEMISTRY OF FOUNDRY IRON.

BY THOMAS TURNER, ASSOC. R.S.M., F.C.S.,

Demonstrator of Chemistry, Mason College, Birmingham.

CAST-IRON is by far the cheapest and most abundant form in which the metal is obtained. It combines with a strength amply sufficient for many applications, the property of being readily manufactured by fusion into any required shape; it also possesses exceptionally high crushing strength, and being protected by a skin, is less liable to rust than either wrought-iron or steel. But it has some well-known disadvantages when compared with iron or steel. It is brittle, deficient in malleability and ductility, and possesses a comparatively small tensile strength. Castings are also liable to be somewhat untrustworthy, owing to unsoundness in the interior, and to irregular contraction during cooling.

Of late years, owing partly to these disadvantages, and largely to reduced prices of iron and steel, cast-iron has been superseded for many purposes, as a constructive material. And it has even been supposed by some that cast-iron will be rapidly replaced by steel for foundry purposes. But this idea is disproved by Mr. Head, in his address delivered at Lincoln last year, as President of the Society of Mechanical Engineers (Proceedings, 1885, p. 325). Mr. Head states that steel castings have the disadvantage not only of increased prime cost of material, but in greater loss during casting and cost of moulds, while the annealing process also involves loss of time and extra expense. On the other hand, good iron castings have fine surfaces, sharp edges, and a pleasing appearance. They are also less liable to contain cavities or blow-holes, and as they do not require annealing, they can, when necessary, be quickly produced to meet a pressing emergency. Mr. Head also states that for wearing surfaces nothing works better than cast-iron upon cast-iron, if only sufficient area be provided; and concludes that the art of iron-founding is in no danger of extinction, or even of serious diminution.

Owing to the attention which has been devoted to the study of steel during the last thirty years, the chemistry of cast-iron has not received the attention it really deserved, and consequently little has been done to elucidate the many problems which are as yet unsolved in this important branch of metallurgy. The present paper is an attempt in some measure to aid in this work. It deals with the determinations of the average strength of pig-iron, and briefly, on what chemical characters that strength depends. An account will be given of the methods usually adopted for increasing the strength, or improving the working qualities of cast-iron, and a description of some special processes which appear to possess certain advantages. An endeavour will be made to indicate how metal of any desired strength and working qualities may be obtained, and how by the application of established facts the cast-iron produced in this country may in many cases be very considerably improved.

THE STRENGTH OF CAST-IRON.

Before an accurate opinion can be formed of the mechanical value of a specimen of cast-iron, it is necessary, at least, that the tensile and crushing strengths, together with the relative hardness, should be known. Unfortunately, however, in the published

researches on this subject we are seldom supplied with the requisite data, and we are obliged to rely in great part upon the tensile strength, which, as was shown in the Report of the American Commission on Metal for Cannon (1856), may usually be taken as an index of the character of the metal.

The average tensile strength of British pig-iron is probably about 7.5 tons per square inch. It is subject to considerable variation, the limits being from 4 to nearly 15 tons. These results are not founded upon recent work, and it may be well to give a brief account of the authorities for the above statement, as the conclusions are of considerable importance in connection with other parts of the present paper. The earliest well-known writer on this subject was Tredgold,* who from the observed transverse strength, *calculated* the tensile strength of cast-iron at from 18 to 22 tons per square inch. It was pointed out, however, by Hodgkinson, in a later edition of this work, that Tredgold's calculation was erroneous, and that he had over-rated the tensile strength (4th Edition, 1860—61, pp. 231 and 285).

The well-known French authority, M. Navier, had also calculated the tensile strength of cast-iron, but upon a somewhat similar assumption to that made by Tredgold, and with little better success. However, in his "*Application de la Mécanique*," Navier published the results of some direct experiments made in 1815 by Minard and Desormes, to determine the tensile strength of cylinders of cast-iron, and these are the earliest experiments of the kind with which I am acquainted. The results obtained, when transferred into tons per square inch by Hodgkinson (Tredgold, 4th Ed. p. 230), agree very well with the average tensile strength observed by later English investigators. Thus, the maximum value obtained was 9.08 tons; the minimum 5.09 tons; and the average 7.19 tons.

In 1837 Messrs. Hodgkinson and Fairbairn published the results of a series of tests upon British irons, and by direct experiment obtained a maximum value of 9.76 tons; minimum 6 tons; average 7.46 tons (B. A. 7th Report, 1837, p. 339). In 1849, further experiments were undertaken in connection with the Iron Commissioners' Report; and, with specimens of increased diameter, Hodgkinson obtained a maximum value of 10.5 tons, and a mean of 6.8 tons (W. Pole: "*Iron as a Material for Construction*," p. 79). In 1858 a valuable report was issued, entitled "*Cast-iron Experiments*," containing the results of tests conducted at Woolwich upon about 70 specimens of British pig-iron. As a result of about 850 tensile tests performed, the maximum value obtained was 15.3 tons; the minimum 4.2 tons; and the average (of 51 samples, including several hundred tests) nearly 10.4 tons. This result is higher than those previously mentioned, and is due, probably, not to any improvement in the quality of pig iron, but to the care exercised in remelting and casting, and also to the fact that the specimens were supplied by the manufacturers in answer to an advertisement which appeared in the public press. It is probable, therefore, that the average tensile strength of about 7.5 tons per square inch, previously suggested, may be taken as a fairly representative value for British pig-iron.

It is of importance that the crushing strength should bear a suitable proportion to the tensile strength, when an iron of good mechanical properties is required. In the Woolwich experiments of 1858, the mean ratio is about 4 : 1, while the mean of Mr. Hodgkinson's experiments give about 6 : 1. The first

* T. Tredgold: "*Practical Essay on the Strength of Cast-iron and other Metals*," 1822.

of these ratios is generally taken by engineers as a fair average value. With a low ratio the metal is weak and soft; with a high ratio it is hard and brittle.

FOUNDRIY MIXTURES.

It must be remembered that in the cases we have hitherto mentioned, certain brands of pig-iron were examined without mixture. Hence these results give only the groundwork upon which to build, since cast-iron is very seldom employed in this state for foundry purposes. It has been found by long practice that certain mixtures of iron produce a better result than any single brand alone. By suitable mixtures it is possible to greatly increase the strength of the material, and to produce iron of a character more or less suited for the purpose in view. For an account of the mixtures of iron employed for foundry purposes by various manufacturers throughout this country, the Report of the Commissioners on Iron for Railway Structures, 1849, p. 418 *et seq.*, should be consulted, where directions are given as to the proportions of different brands of iron to be employed for large and small castings, and it is interesting to notice how little foundry practice has changed during the last 40 years. But it is lamentable how little real knowledge of the constituents present is commonly possessed by those who make these mixtures of iron. Quite recently I was assured at a large foundry that the principles were only to be learned by long experience, and that they worked entirely by "the rule of thumb" in their mixtures. In these times of sharp competition it is certainly important that accurate knowledge should be used in the iron foundry.

In 1846-47 Mr. Robert Stephenson conducted some experiments in connection with the erection of the high-level bridge at Newcastle-on-Tyne. The object was to determine, by the transverse strength of the product, the most suitable mixture of cast-iron for the construction of the girders of the bridge. Among the conclusions arrived at were the following:—

1. That simple samples did not run so solid as mixtures; further, that they are sometimes too hard and sometimes too soft for practical purposes.

2. That mixtures of hot and cold blast together gave a better result than either separately; though hot blast iron alone was not much inferior to cold blast iron alone (W. Pole: "Iron as a Material for Construction," p. 88). But though Stephenson showed that a considerable improvement in the quality of pig-iron might be made by suitable mixtures, he did not succeed in obtaining anything like that maximum value which has since been proved possible. Some of his conclusions also can only be regarded as true under the circumstances of the experiments in question. The most noteworthy example of what may be done in this direction is illustrated in the American Report on Metals for Cannon (1856), which shews that during the 10 years ending 1851, the average tenacity of metal in cast-iron guns was increased by about 60 per cent; and this improvement was obtained, not by adding any new substance to the iron, but by increased care in mixing and founding. At this period, just before cast-iron began to be superseded as a material for the construction of ordnance, the mixing of cast-iron was wonderfully well performed in the American Government foundries. Thus Lieut. Wallack, in his Final Report on the Quality of Cast-iron for Cannon, p. 326, recommends that the *lowest* limit of tensile strength for guns of superior quality should be 24,500 lb. per square inch, or about 11 tons, which is rather higher than the *maximum* tensile strength ever recorded by Mr. Hodgkinson in pig-iron. It should be mentioned that guns were

regularly cast of the desired quality, many of them considerably exceeding this lower limit of about 11 tons, and in one case a tensile strength of 20·5 tons is recorded.* This latter number has been somewhat doubted by certain authorities, but no valid objection can be raised to the result. It must not be compared with British experiments, as the latter have been conducted almost entirely on pig-iron. It is not an isolated result, but the maximum of a number of excellent specimens. I have myself obtained a tensile strength of 15·7 tons, and do not doubt but that with suitable precautions a still higher value could be obtained.

It is evident, therefore, that the iron-founder who aims at obtaining a tensile strength of 15 tons, as measured by a test-bar 1 inch in diameter, is aiming only at that which may, by suitable care, be obtained. And it can be shown, further, that the crushing strength may be increased in a similar proportion, while a metal of fair or good working qualities may be produced. At present the majority of manufacturers are content with a tensile strength of about 9 tons, and to aim at an increase in strength of 66 per cent. may seem bold, but I believe this could certainly be obtained in many cases. It is not to be done by the employment of new and expensive material, but by the proper use of that which we at present possess. Cast-iron should, however, be produced with a due regard to chemical and mechanical principles, and some of these we will proceed to discuss.

CHEMICAL PRINCIPLES.

The mechanical properties of cast-iron are very much influenced by the nature and amount of the various constituents it contains. The most important of these, and the one usually present in the largest proportion, is carbon; and this cannot be regarded as an impurity in cast-iron. The influence of the form in which carbon occurs is very great. Thus, white iron, which contains scarcely any graphite, is hard, brittle, and often unsound; while very grey iron, in which the carbon is almost entirely graphitic, is soft and weak. It has been known, for probably at least a century, that the strongest variety of cast-iron is produced from a material which is close-grained grey, and therefore intermediate between these two extremes. This was the material, especially when rather inclined to mottled, which was formerly so much preferred for gun founding†; while if a little more inclined to white, it possesses the highest crushing strength. If, on the other hand, it is a little more grey, it is a good working iron, though perhaps weak.

Any of these grades of iron can be produced at will, and with considerable regularity, by careful management of the blast furnace. But it is well known that during remelting, either in the usual method by the cupola, or in an air furnace, the character of the iron is considerably modified. It is occasionally rendered softer by fusion, but more commonly it is hardened, the action depending on the character of the original material, and the chemical changes produced during melting. Further, it is known to practical founders that irons which, as judged by fracture, are of the same grade, often vary considerably in hardness and working qualities. On these accounts it is hopeless for the present at all events, to expect that pig-iron can be made at the blast furnace, so that on remelting it may produce, without mixture, the best class of castings. What may be expected, however, is an iron

* 45,370 lb. per square inch: American Report, p. 279.

† Karsten says that for this purpose "pig-iron should be neither too grey nor too white, either of which is equally injurious."

tolerably near in properties to that which is desired, and which may be rendered harder or softer, tougher or weaker, as may be required. This should be done by mixing upon definite principles, and not simply by "rule of thumb." It is generally considered sufficient, in mixing iron, to say that a certain hard or soft iron, as the case may be, imparts much of its own "nature" to the mixture. But we want to know *more* than this; we want to know *why* a certain iron is hard, and another soft, and upon what chemical principles we should proceed to most readily and surely convert the one into the other. This can only be accomplished by a knowledge of the exact influence of each and all of the constituents present in cast-iron.

INFLUENCE OF OTHER CONSTITUENTS.

The most important constituents of cast-iron, other than carbon, are manganese, phosphorus, silicon and sulphur. Each of these elements, when present together with carbon, has a definite influence on the amount of graphite in the product, tending either to increase or decrease the proportion of combined carbon. They have each, doubtless, in addition, an influence due to their own presence in the material, though we are at present ignorant of the nature of this latter effect. Hence, each element by its presence produces two effects, one due to its influence on the carbon, and a second due to its action on the iron itself; the first of these is known, and is probably the most important, while the second is at present almost unknown.* And, for practical purposes, we may probably regard the influence of each element on the proportion of graphitic carbon, as being in some measure an index to its effect on the properties of the product.

Each of the four elements previously mentioned, when present in considerable proportions, causes the iron to be practically worthless for foundry purposes; but when present in small quantities they fall naturally into two classes, according to their influence on the proportion of graphite.

1st. Manganese, sulphur, and phosphorus, which tend to produce white iron, by reducing the amount of graphitic carbon.

2nd. Silicon, which increases the proportion of graphite, and so produces grey iron.

We shall now consider each of these classes separately.

I.—MANGANESE, SULPHUR, AND PHOSPHORUS.

Though phosphorus has been placed in this class, to which it most probably belongs, evidence is still wanting before its place can be considered as quite definitely fixed; in the case of manganese and of sulphur, however, there is no doubt.

Spiegeleisen is a familiar example of a white iron produced by the presence of manganese; while the works of Percy, Bell, and others contain proof that the addition of sulphur to cast-iron produces white metal. Hence where combined strength and softness are required, it is important that the proportion of these elements should be small. As to the maximum limit in each case, we have at present little evidence, and upon this point I hope to enter into more detail at a future time. But at present I am inclined to recommend that for best qualities of foundry iron the proportion of sulphur should not exceed 0.2 per cent.; phosphorus, 0.5 per cent.; and manganese, 1.0 per cent. In exceptional cases, where other elements

occur in unusual amounts, these values may be modified, but for general purposes they will probably be sufficiently accurate.

In speaking of the production of white iron it is necessary to say a few words regarding chill casting. This, as is well known, diminishes the proportion of graphite, and produces a white iron. There is, however, only a certain class of irons which are subject to this effect, and I have already elsewhere considered the causes for this fact (*J. Chem. Soc.* 1885, p. 913). It must, therefore, be remembered that in the present paper, except where expressly stated otherwise, I am considering iron when cast according to ordinary foundry practice.

II.—SILICON.

Silicon was formerly regarded as a hurtful ingredient in cast-iron, when present in any proportion, great or small. As an exception to this general condemnation, the following remarks from Watt's Dictionary, vol. iii. p. 334, are worthy of note: "It is generally considered that, within the ordinary limits as to the amount of silicon in cast-iron, this substance does not exercise any prejudicial influence upon the quality of the metal." It is somewhat remarkable that this opinion should have been so general, when it was well known that "refined metal" differed from grey pig, chiefly in the absence of silicon, and that in spite of its greater chemical purity it was inferior in mechanical properties in almost every respect.

It had also been shown by Mr. Clarke, in an extensive series of experiments in connection with the suspension bridge across the Danube at Pesth, that Austrian and Hungarian charcoal irons, which are low in silicon, are somewhat deficient in tenacity, as compared with British iron (Mallet, p. 29). And Messrs. Hodgkinson and Fairbairn had compared together the mechanical properties of irons smelted from the *same ores*, but using respectively hot and cold blast. They found very considerable variations in the specimens tested, but the average transverse strength of iron smelted by hot blast, was 2.5 per cent. higher than when cold blast was used; and the average power of hot blast iron to resist impact was 22.63 per cent. greater than that of cold blast. It has since been proved that the chief difference between hot and cold blast iron, is the higher proportion of silicon in the former; and these results, therefore, do not by any means support the popular objection to the presence of silicon in cast-iron.

I have, however, recently shown that silicon, when added to white cast-iron, causes a separation of graphitic carbon, thus producing a soft grey iron.† It follows, therefore, that when present in suitable proportion, silicon produces an improvement in the qualities of the metal; and it is now very doubtful whether silicon, when present in moderate quantity, should be regarded as an impurity in iron intended for foundry purposes. A short account of the effect produced by different proportions of silicon may not be inappropriate here.

1. *White Iron* almost invariably contains under 1 per cent. of silicon, and in very many cases less than 0.5 per cent. In cases, however, where either sulphur or manganese occurs in more than usual quantity, iron may still be white, though it contain upwards of 1 per cent. of silicon.

2. *Mottled Iron* often contains about one per cent. of silicon, though this amount is subject to considerable variation, the more usual limits being from 0.4 to 2 per cent. In this variety of iron the proportion of sulphur appears to be of great importance, very

* There is yet a third effect, due to the influence of the different elements upon each other. At present we have practically no information whatever upon this point; it is probably of comparatively little importance, and so may be neglected.

† T. Turner: *J. Chem. Soc.* 1885, pp. 577, 902; 1886, p. 130. C. Wood: *J. Iron and Steel Inst.* 1885, ii. p. 164.

small variation causing considerable difference in the product.

3. *Grey Iron* is almost exclusively used in the foundry. It may be roughly divided into three classes, according to the properties which are most marked.

(a) *Crushing Strength*.—Irons which possess the maximum crushing strength are usually silvery grey, or very close-grained in texture; they are hard to the tool, and deficient in tenacity, and hence are only suitable for special purposes. For example, it has been shown by tests at Shoeburyness, that cast-iron shot which possesses the greatest crushing strength has also the maximum penetrative power, and it is found that this can be obtained most readily when the proportion of silicon is about 0·8 per cent.; this is also the proportion which produced the maximum crushing strength in my own experiments (*J. Chem. Soc.* 1885, p. 912). For the manufacture of rolls or other very hard castings, about 0·8 to 1 per cent. of silicon is probably best.

(b) *General Strength*.—Irons which possess the greatest general strength are tolerably close-grained, and of uniform texture. They are softer than the class last mentioned, and of smaller crushing strength, but their tenacity is greater. Their ratio of crushing to tensile strength is in good proportion; and they are sufficiently soft to be worked with tolerable facility. They generally contain about 1·4 per cent. of silicon, the usual variations being $\pm 0\cdot5$ per cent., and depending chiefly on the proportions of other elements.

(c) *Softness and Working Qualities*.—It is often more important to obtain a good working iron than to have one possessing considerable strength. Soft irons are darker in colour, and more open in fracture than those previously considered. Their crushing strength is often less than one-half of that of the first-class, though their tenacity is sometimes much greater; but they vary very considerably in strength. Their carbon is almost entirely graphitic, and they usually contain not less than 1·8 per cent. of silicon. The maximum limit for ordinary purposes is probably 3 per cent., though for casting small objects or thin sheets, where fluidity is required, together with a smooth surface, and a grey iron, even this maximum may sometimes be exceeded.

It has been stated above that all the founder may reasonably expect to be produced, by the blast furnace, is an iron tolerably near in properties to that which he desires, and that this product should be softened or strengthened as may be required. It will be obvious that in the majority of cases, this may be readily and economically accomplished by a suitable alteration in the proportion of silicon. Thus an iron which is too soft may be strengthened by reducing the amount of silicon, while an iron that is too hard may be softened by increasing that amount.

This simple statement is in a measure new, because silicon has been hitherto regarded as an element whose presence was undesirable in cast-iron. But while the importance of silicon has thus been theoretically denied, it has been long practically recognised by the experienced founder. For it can be shown that the soft, good-working iron, produced by an experienced founder, usually contains about 2 per cent. of silicon, and little more than a trace of sulphur, and as a result the combined carbon present does not exceed a few tenths per cent.

There are, however, a few well-marked examples of the effects produced by alterations in the proportion

of silicon which are worthy of detailed examination, and which are none the less interesting because the facts upon which the effects depended were generally either misinterpreted or overlooked.

STIRLING'S TOUGHENED CAST IRON.†

The late Mr. J. D. Morris Stirling took out four patents in all, between the years 1846 and 1851 inclusive. They all referred either to metals or metallic alloys, and generally do not appear to have been much applied. In his first patent, however, taken out in 1846, a very important method for the production of "toughened cast-iron" is mentioned. Thus in the specification, p. 3, he says: "For certain purposes, such as shaftings . . . where a metal possessing greater tenacity or strength than ordinary cast-iron is required, and where it is an object to vary the degree of hardness, I made a mixture of wrought and cast-iron. . . . I melt cast-iron . . . and add to it . . . a quantity of malleable iron less than the weight of the cast-iron. . . . This mixture is afterwards to be re-melted as convenient. . . . And I would remark that the cold blast-iron, or iron containing the lesser quantity of carbon, will require a smaller addition of wrought iron than hot blast-iron, or iron containing a larger quantity of carbon; but I find that the addition of 1-3rd to 1-5th of wrought-iron to answer well in the generality of cases where increased strength, toughness, and tenacity are required."[†]

Stirling appears here to be quite clear upon two points—namely, that not more than one-third of wrought-iron should be added, and that this amount would depend, at least to some extent, upon the character of the iron employed. But he does not appear to have been equally clear upon the cause of the undoubtedly good effect which resulted in many cases. It was apparently sufficient to know that cast-iron was of a brittle nature, and wrought-iron tough, so that wrought-iron imparted some of its tough nature to the mixture. The remarks in the specification, as to the difference in carbon, cannot be regarded as more than a statement of a supposed fact, and not as an explanation of it. We now know, however, that practically the only difference between hot and cold blast-iron is that the former is more highly silicious, which accounts for the fact that this class of iron required a larger proportion of wrought-iron to produce the best effect.

Mr. Stirling had two chief objects in view—namely, to increase the strength of soft irons, and to make a uniform product, from the iron of different districts, which should not be under a given strength. The process was, therefore, not applicable to hard irons, which were actually deteriorated by any addition of wrought-iron. It was also found that with soft irons there was a definite limit, depending on the material, which could not safely be exceeded. Thus it was found in one case that on mixing—

100 parts of cast-iron with 10 of wrought, the transverse strength increased 22½%.
100 parts of cast-iron with 20 of wrought, the transverse strength increased 31½%.
100 parts of cast-iron with 30 of wrought, the transverse strength increased 60%.
100 parts of cast-iron with 40 of wrought, the transverse strength increased 33%.

† For fuller details see—Patent 11,262, 1846: "Toughened cast-iron," etc. Report of the Commissioners on Iron for Railway Purposes, 1849, p. 415 *et seq.* Inst. C.E., xi, 1851–2, p. 238; xviii, 1859, p. 339. Inst. M.E., 1853, p. 19 (an important paper by Stirling himself). W. Fairbairn: "Application of Iron to Building Purposes," 1857–8, p. 68. T. Box, "Strength of Materials," 1883, pp. 202, 503, etc.

Some similar experiments were conducted about the same time by Mr. Lillie, of Manchester. Greatly increased strength was obtained, but the experiments appear to have been abandoned after Stirling took out his patent.

It should be explained that the term "general strength" is used to indicate an iron possessing a good transverse strength, combined with fair crushing and tensile strength and moderate hardness; properties which would render it useful for a large number of applications.

Showing that the maximum result was produced with about 30 per cent. of wrought scrap.

Unfortunately I am not aware of any chemical analysis published in connection with Mr. Stirling's work, but a little consideration will make plain the causes of the result obtained. Thus an average hot blast soft foundry iron may be considered to contain about 3·5 per cent. of carbon, and perhaps 2 per cent. of silicon, or probably more. On mixing this with one-third of its weight of wrought-iron, these numbers would be reduced to about 2·6 for carbon, and 1·5 for silicon; and from what has been already stated as to the effect of silicon on cast-iron, it is evident that any further addition of malleable iron would render the metal both white and steely, and hence cause serious deterioration in its properties.

As to the method of applying this process, it was recommended that the mixture should be made at the blast furnace, by placing the metal in the moulds into which the molten cast-iron was to be run. The malleable iron was thus firmly fixed, and when re-melted in the cupola a uniform product was produced. This product appears to have been subjected to very rigorous and impartial tests, and to have yielded very satisfactory results. Thus the experiments of Messrs. Fairbairn, Hodgkinson, etc., give the following mean values * :—

Kind of Strain.	Stirling's Iron.	Ordinary British Iron.	Increase per cent.
Tensile, tons.....	12·46	7·112	74
Crushing „	55·7	43·00	30
Transverse, lb.....	3300	2063	60

The mean result obtained with “toughened cast-iron” was, therefore, considerably above the maximum value obtained by the same experiments with British pig-iron, as noted above.

Very satisfactory results were also obtained by Mr. Owen, the Government Inspector of Metals, who conducted some experiments on the strength of beams. For this purpose 13 beams were made of British irons, either alone or in mixtures, and 11 beams were also constructed, exactly similar, from the same irons, but with addition of wrought scrap. The results obtained were as follows, (Box, p. 202) :—

	Load.	Deflection.
Mean of 13, ordinary iron.....	38·3 tons	1·91
„ „ 11, Stirling's iron	52·3 „	1·81

giving an increase of load equal to about 37 per cent.

It will be seen that these values are considerably greater than those hitherto noticed in this paper, and mark a considerable improvement in the mechanical properties of British cast-iron.

“Toughened cast-iron” met with a considerable application during the lifetime of Stirling. Thus Mr. Slaughter used it for locomotive cylinders on the Great Western Railway, “and found it made very fine, perfect and sound castings, better than he had ever made before.” Among the larger applications may be mentioned Chelsea Bridge, Windsor Bridges, Yarmouth Bridge, and Manchester Viaduct. In the latter case Stirling says : “By being allowed to reduce the scantling in proportion to the increased strength gained by employing the toughened cast-iron, the contractors for the heavy castings were enabled to profitably fulfil their contract, whereas had they used common iron, and been confined to the specification, they would have been heavy losers.”

In view of these facts, it appears at first sight somewhat surprising that the addition of wrought-iron is

not more generally practised, at present, by iron-founders. The reasons for this are probably as follows :—

1. Cast-iron has been largely superseded by steel and wrought-iron for purposes where considerable strength is required.

2. Special care is necessary in order to secure a uniform and reliable product. Thus Robert Mallet, a founder of large experience, writing in 1856, says : “Want of assured homogeneity, especially in large masses, appears to be the objection to Stirling's patent toughened cast-iron.”—“Construction of Artillery,” p. 30.

3. Owing to the theory of the process being misunderstood, the results obtained were sometimes uncertain, as the effect was ascertained by trial and could not be predicted beforehand.

In spite of these disadvantages, however, it is probable that this process might be profitably employed in many cases. It can be economically applied in the case of cheap weak irons, rich in silicon, for the production of cast-iron possessing special strength. And the chemist should now be able to determine, from the analysis of the pig-iron alone, whether it could be much improved by the addition of wrought-iron scrap.

There are two other methods of strengthening cast-iron which depend upon the same principles as that of Morris Stirling, and which are worthy of a brief reference.

PRICE AND NICHOLSON'S PATENT (No. 2618, 1855).

“This invention relates to the production of a cast-iron of a strength much superior to that now manufactured, and therefore peculiarly applicable to the casting of ordnance, girders, etc. The main object of the invention is to lower the percentage of silicon in cast-iron, whilst the total amount of carbon remains the same” (Specification, p. 3). This object was attained by mixing “refinery metal,” the product of the refinery forge, with soft grey iron in suitable proportion. Although the patentees appear to have regarded silicon as being uniformly injurious, it is evident that practically they showed the contrary, in that they do not recommend the use of refinery metal alone, which in spite of, or rather by virtue of, its special purity, is unfitted for foundry purposes.

The method adopted by Dr. Price would appear to be founded on better chemical principles than that of Stirling, because in the present case it will be noticed that the carbon is kept practically constant, while the proportion of silicon varies. The effect produced by these mixtures would, therefore, doubtless resemble those noticed in my own experiments, except that they are over a smaller range, and in reverse order, since Dr. Price began with grey iron, and gradually added refined metal to it. I am not aware, however, that any regular series of experiments was performed, but the following account of tests by Sir W. Fairbairn is interesting (“Iron Manufacture,” 3rd. Ed. p. 229) :—

“The average strength of cast-iron has been found to be about 7 tons per square inch. But some tests of Dr. Price's compound mixture, used for specimens of cast-iron shot for experiment at Shoburyness, gave tensile strength—

	Tons.
Experiment 1	13·125
„ 2	11·714
„ 3	14·762
„ 4	15·189
Mean ...	13·697

* Box, p. 501.

or an increase of nearly 100 per cent. on ordinary cast-iron." The compression tests gave a mean of 57.37 tons per square inch, an increase of 43 per cent. on the mean of Mr. Hodgkinson's experiments. It will be noticed that the tensile strength observed in these experiments is very nearly double the average strength of pig-iron, and more than half that of wrought-iron (25-26 tons) as found in Kirkaldy's experiments. I believe that these values could be even exceeded by the ironfounder, who desires to obtain a strong iron, if only sufficient attention be paid to mixing.

USE OF STEEL SCRAP.

Steel scrap has been somewhat extensively used during the last few years, in America, as a means of strengthening cast-iron. Thus Samuel M. Carpenter produces strengthened cast-iron by immersing steel in liquid cast-iron (American Patent 173,159, February 8, 1876), claiming that by this method of mixture a better result is obtained. And Mr. Thomas D. West, the author of "American Foundry Practice," and himself an experienced founder, writing recently in the *American Machinist* (May 30 1885, p. 5), gives some directions for the proper use of steel scrap, and speaks favourably of the results obtained. It is employed to give greater strength or hardness, and to increase the depth of chill, being used for wheels, pulleys, and other work where these qualities are required. The process is evidently exactly similar in principle to that originally patented by Stirling, and depending, in a great measure, on changes in the proportion of silicon. It is fully recognised by Mr. West that too much steel has an injurious effect upon the mixture, for he says: "I would not have the reader understand . . . that the more steel or wrought-iron there is mixed with cast-iron the stronger will the mixture be. As far as strength is concerned . . . there is a limit to the percentage which should be mixed with cast-iron, and it greatly depends upon what grades of steel and cast-iron are mixed together. The cast-iron in some cases may not stand more than 3 to 5 per cent. of steel or wrought-iron in order to obtain the greatest strength." It might have been added that hard irons are rendered both harder and weaker by any addition of steel.

The three processes we have discussed, are undoubtedly very important and efficacious methods of strengthening a weak iron. Either wrought-iron, steel scrap, or "refined metal," when added in suitable quantity to a weak iron, will increase both the tensile, crushing, and transverse strength of the metal. And it may be pointed out that at the present prices in South Staffordshire, either wrought-iron or steel scrap might be profitably used where a strong iron is required. Taking "all mine" South Staffordshire foundry iron at £2 12s. 6d. per ton, medium wrought scrap at £2 5s. 0d., and steel scrap at £3, a mixture might be obtained at least equal to the best cold blast or hematite iron at £3, or upwards, with a saving of at least several shillings per ton. (N.B.—Prices are lower since this was written, some months ago.)

There are two methods of strengthening cast-iron, which are sometimes adopted, but which are open to more serious objection than those previously mentioned.

In the first place, remelting has been recommended for this purpose. The influence of this I have recently discussed at some length (*J. Chem. Soc.*, 1886, p. 147), so shall not now consider in detail. The effect produced by remelting is due almost entirely to chemical changes in the material, such as alterations in the amount of silicon and sulphur, and these changes can be more readily and cheaply produced by careful mixing than by continued remelting. Stress

has sometimes been laid upon the use of an air furnace instead of a cupola, for remelting. This involves extra trouble and expense, and the benefit is very doubtful, except in certain special cases. Secondly, the addition of sulphur is sometimes recommended, but I believe the use either of sulphides, or the addition of iron rich in sulphur, is open to several grave objections, which I have not space at present to discuss in detail; I hope, however, to be able to do so shortly.

But though it is important in some cases to be able to produce a very strong iron, in many instances we require a soft iron perfectly uniform in texture. This is of very great importance when the material has to be filed and turned, or otherwise operated upon by the workman. And at the present time it is probably much more important to be able to produce a soft iron from a hard iron, than to increase the strength of a weaker material. It is evident that for this purpose the addition of silicon is of the utmost value, since it is the only element commonly present in cast-iron which produces this effect. So far as I am aware, the fact that the addition of silicon to hard cast-iron produced a soft product, was first noticed in my own experiments (*J. Chem. Soc.*, 1885, p. 577) commenced nearly three years ago. But the fact has been confirmed, and some very interesting observations made in independent experiments by Mr. Charles Wood, of Middlesbro'.

As an example of this effect, I have prepared six specimens made by adding small, but gradually increasing quantities of siliceous iron to South Staffordshire "allmine" white iron, from Mr. Round's furnaces. It will be noticed that the samples pass gradually from white into grey iron as the proportion of silicon increases, becoming ultimately dark grey, and very soft to the tool, being in fact quite suitable for foundry purposes. This will at once suggest an easy and profitable method for the disposal of white iron and "glazed pig," each of which are commonly objectionable varieties of iron, to the smelter. By remelting one part of "glazed pig" with two or three parts of white or hard iron, the product obtained is grey iron, well suited to the use of the founder, and worth quite 5s. per ton more than the materials from which it was made.

In a paper read before the Iron and Steel Institute at its Glasgow meeting in September last, Mr. Wood gave an account of the use of siliceous iron for the purpose of softening hard Cleveland iron. His experiments were conducted on a considerable scale, from sixty to seventy tons being run per day during several months' working. And since the paper was read the use of siliceous iron has been continued with very satisfactory results, and it has also been applied by other founders, who speak favourably of its softening effects. I am indebted to the kindness of Mr. Wood for the following particulars, which have not hitherto been published.

The composition of the siliceous iron employed is as follows, the analysis being by Mr. Stead:—

Combined carbon	0.10
Graphite	3.15
Manganese	0.72
Silicon	4.48
Sulphur	0.01
Phosphorus	1.97

The above material, if used alone, would be hard and weak; it is low in price, and quite unsuited for making foundry castings; it is even less suited for use in the forge. But on mixing together half mottled iron, and half No. 4 foundry iron, with ten per cent. of siliceous pig, a grey iron was produced

which was very soft to the tool, and which gave beautiful castings. The castings contained

Silicon	2.33
Combined carbon	0.107

We see, therefore, that by admixture of three irons, each of inferior quality, and hard, when alone, we obtain a soft material, admirably suited to the founder's use. The mottled and hard foundry irons were hard through a deficiency of silicon, while the siliceous iron was hard for an exactly contrary reason. By suitable mixing a soft product results.

In Mr. Wood's paper an example is given of a mixture consisting of half Cleveland white iron, and half siliceous iron. The white iron contained about one per cent. of silicon and 3.3 per cent. of combined carbon. The siliceous iron closely resembled that I have previously mentioned. The product was analysed by my friend Mr. Walton, the result being as follows:—

Graphite	3.64
Combined carbon	0.14
Silicon	2.71
Phosphorus	1.53
Manganese	0.35
Sulphur	0.08

This iron gave beautifully close-grained castings which were soft, and could be cut easily by any kind of tool. The strength of the material was also increased, as measured by the transverse test on a three-foot bar, with a section of 2" × 1", the following values being obtained:—

Siliceous iron, alone	22.33 cwt.
White iron, alone	25.00 "
Mixture, $\frac{1}{2}$ white, $\frac{1}{2}$ siliceous.	30.33 "

or an increase of 27.7 per cent. on the mean strength of the original irons.

Another interesting use of siliceous iron for foundry purposes is seen in the casting of thin plates. For this purpose a No. 2 or 3 foundry iron is commonly used, and the plates are not unfrequently white even under these circumstances. But Mr. Wood is able to cast plates one-tenth of an inch thick, which are perfectly grey. This result may be obtained by mixing mottled and forge iron, and adding a suitable amount of silicious pig. By this means not only are grey plates capable of being regularly produced, but a cheaper class of iron is employed, and one which, unmixed, would be entirely unsuited for the purpose.

I may, however, remark here that while, when softness is the chief quality required in a specimen of cast-iron, special chemical purity does not appear to be of primary importance, still, when general strength is wanted, it would appear to be necessary not only that graphitic and combined carbon and silicon should bear a suitable proportion to each other, but that the proportion of other elements such as manganese, phosphorus, and sulphur, should be small.

In conclusion, the chief results arrived at in this paper may be briefly summarised as follows:—

1. The average tensile strength of British pig-iron is about 7.5 tons per square inch; but by careful mixing this value may be doubled.

2. The tensile and crushing strengths should be in due proportion, while the metal should not be unusually hard.

3. The proportion of graphitic to combined carbon furnishes an index of the general character of the metal. This proportion can be altered at will by varying the proportion of silicon.

4. Weak irons may be strengthened by adding either wrought-iron, steel, or hard iron of good chemical quality, such as "refinery metal." The use of impure materials is to be avoided.

5. Hard iron may be softened by the addition of silicon in the form of siliceous iron or silicon pig.

From the above facts it is evident that the mechanical properties of cast-iron may be varied at will by the application of definite chemical principles, and that the founder who mixes cast-iron without a knowledge of its composition, can only do so at the risk of producing a hard or weak material, indifferently suited to the purpose in view, and often at the cost of much unnecessary expense and trouble.

DISCUSSION.

The CHAIRMAN strongly recommended members to read the papers which the author had published in the Journal of the Chemical Society, and which contained the results of his experiments carried on during the last two years. Practically, the whole of the work had been conducted in the laboratory of Mason College, and it was to be hoped that the author would pursue his investigations still further. He fully concurred with Mr. Turner in condemning those who still resorted to "rule of thumb" as a guide, and urged, not only chemical manufacturers, but also ironmasters and workers in metal, to support such investigations as likely to yield useful results.

Mr. ROUND said that, in his remarks on the strength of pig-iron, the author had not alluded to the qualities used, or their sources. Irons from different localities varied much in character, each sample possessing certain desirable features, and it was quite possible to obtain an iron possessing a combination of these qualities by making suitable mixtures. Hematite pig was tenacious and tough, but did not work well alone; Cleveland pig was very useful, but weak. He recommended these facts to the consideration of those who were carrying out these investigations.

Mr. ROWLEY asked if the presence of more than 10 per cent. of silicon adversely affected the crushing and tensile strength of iron? He would also like to hear what chemical or mechanical reasons there were for the shape of the curve given?

Mr. HAINES asked whether the pig referred to was a normal production, or specially prepared? also whether it was cheap, and what effect it would have on the common white cinder pig of South Staffordshire?

Mr. TURNER, in reply, said that he fully recognised the importance of the point raised by Mr. Round and was only prevented from alluding to it by considerations of space. Where an account of the character of the iron used had been omitted, it would generally be found in the original papers to which references were given. He had not been able to carry his experiments beyond 10.3 per cent. of silicon, but this was ample for all practical purposes, and there was no doubt that the tensile and crushing strengths would continue to gradually decrease with more silicon, just as the density had been shown to do. The shape of the curve was probably due to the fact that it represented the resultant of two effects—namely: first, that of silicon on the iron itself; and secondly, that of silicon on the proportion of combined carbon. The latter, when graphically represented, gave a steep curve, with a maximum of 1–2 per cent. of silicon, while the former gave a curve which was probably more nearly straight. The two effects combined produced the curve in question (*J. Chem. Soc.*, 1885, 908). The Govan and Mostyn silicon pig, of which specimens were exhibited, were specially pre-

pered for use by the steel-maker. They often contained as much as 10 per cent. of silicon, and were proportionately dear. The Middlesbro' siliceous pig, for the specimen of which they were indebted to Mr. Charles Wood, was an ordinary product of that district, and cheaper. Some manufacturers in the Birmingham district were now prepared to sell siliceous iron by analysis at a cheap rate for use in the foundry for softening purposes. He had not yet tried silicon pig as a softener for common white cinder pig, but doubtless a soft iron could readily be produced in that way, though such material would be quite unsuitable for the production of cast-iron of high tensile strength.

J. NEILSON CUTHBERTSON IN THE CHAIR.

ARSENIC IN SPANISH PYRITES, AND ITS ELIMINATION IN THE LOCAL TREATMENT FOR PRODUCTION OF COPPER PRECIPITATE.

BY H. B. FULTON, F.C.S.

In this paper, reference is restricted to the local treatment of pyrites at the mines, where, owing to the small copper content of the ore, the scale upon which operations are conducted is necessarily one of great magnitude, and where the evolution of sulphurous gas during calcination is such as would not be tolerated in any densely-populated neighbourhood, or in any agricultural district.

The more rational treatment, by what is known as the Henderson process—where the sulphur, iron, and copper, as well as the noble metals found in the pyrites, are separately recovered—though universally adopted for the treatment of Spanish pyrites in this country, is clearly inapplicable under the conditions existing at the mines.

The commercial success of the Henderson process depends, in no small degree, upon the utilisation of the sulphur of the pyrites, and on the recovery of the residue of purple iron after all the other metals have been removed from it; and while in this country the ores so treated have never a copper content of less

than 3 per cent., a large proportion of those treated locally does not average more than 2 per cent.

Further, without considering the greater cost of fuel at the mines, the enormous amount of sulphur in the mineral treated locally would, if recovered, more than supply the requirements of the world, and could not be disposed of: and in a country teeming with rich iron ore the purple iron residue would be comparatively valueless, and would in few cases bear the costs of removal and exportation.

The importance of this local industry may be realised when it is remembered that, in the Iberian peninsula alone, a quantity estimated at upwards of 20,000 tons of metallic copper is annually produced by the methods hereinafter mentioned from pyrites containing on an average less than 3 per cent. of copper.

Although there is considerable variety in the copper and arsenic contents of ores of this kind from different mines, or from the same mine, as selected for export or for local treatment, the following analysis of San Domingos export mineral, by Mr. F. Claudet, may be taken as an average of what has generally to be dealt with:—

Siliceous residue	0.63%
Sulphur.....	49.00
Iron	43.55
Copper	3.20
Arsenic.....	0.47
Zinc	0.35
Lead	0.93
Lime	0.10
Water	0.70
Oxygen and traces of various metals ...	1.07
	<hr/> 100.00

Here, then, in the crude mineral, the proportion of arsenic to copper is as one to seven, and it is evident that if the extraction of arsenic and of copper goes on proportionately and simultaneously, and that if, during some of the intermediate stages of the process, the arsenic be not more or less perfectly removed, a supposed resulting copper precipitate of 70 per cent. would be contaminated with the excessive amount of 10 per cent. of arsenic.

The condition in which the arsenic exists in the bulk of the mineral cannot be easily determined, either by microscopical examination or by analysis; and, indeed, in various specimens, it may be found in different forms. The prevailing form is probably that of mispickel ($\text{FeAs}_2 + \text{FeS}_2$). The greater part of the iron and of the sulphur occurs as iron pyrites (FeS_2), and the copper most probably as cupric sulphide (CuS), small quantities of copper pyrites and of copper-glance being more rarely met with.

I purpose giving here a brief outline of the various methods of local treatment, and will take in turn—Treatment of Ore by Calcination; Treatment of Crude Ore by Oxidising Solutions; Treatment of Crude Ore by Slow-weathering; and Treatment by a Combination of these three methods.

I.—LOCAL TREATMENT BY CALCINATION.

In most parts of Spain, where mineral of this class is found, calcination of the ore in open heaps is the usual and time-honoured method of dealing with it. Owing to the hardness and massiveness of the mineral—which occurs in enormous lodes, free from any visible matrix—dynamite is almost exclusively employed in blasting it, and, in consequence of the shattering power of this explosive, a large proportion of the ore is at once obtained in fragments of a convenient size for calcination. Hand-breaking of some of the larger pieces is resorted to, and the ultimate

result is, that while the great bulk of the ore is reduced to about road-metal size, something like 25 to 30 per cent. of it remains either as lumps (measuring 12 or 14 inches through) or as smalls from nut-size downwards. In this state, the whole is removed in waggons to the calcination-ground, and is there tipped over the bank for selection and distribution. From this bank the mineral is carried by boys and girls, or on donkey-back, to the site on which the heap for calcination is being prepared. No screening is necessary, since, in filling the wooden trays upon which the mineral is carried, or the esparto panniers by which the donkeys remove it, sufficient selection may be made of broken ore, lumps, or smalls as may at the time be required.

In the construction of a heap for calcination, a series of chimneys—the number being dependent on the size and disposition of the heap—are built up to a height of 12 or 15 feet, using for this purpose the larger unbroken lumps of mineral.

These chimneys communicate with one another and with the exterior, at intervals all round the base of the heap by means of a network of flues similarly constructed of lumps. The broken mineral is laid upon this base till the chimneys—which thus form the apex of an extended pyramid—are covered, leaving their shafts open as vents. The sides of the pyramid rise at an angle of about 50° from the horizontal, this inclination being sufficient to prevent mineral running down, even when exposed to heavy rain. To complete it, the heap has to be externally covered with small ore, to check the rapidity of the calcination, and prevent the fusion of the mineral in the heart of the pile.

When thus prepared, the heap is lighted by thrusting burning logs of wood up the mouths or openings of the flues. This, at considerable inconvenience to the workmen engaged in it, is carefully attended to for some days, until it is evident that the heap has been thoroughly ignited all round. For mineral, so rich in sulphur, no foundation of firewood is necessary.

A large number of heaps, adjacent to one another, are generally lighted at the same time, and the dense sulphurous fumes which, for many weeks or months, are emitted from them, preclude further careful examination of each one in detail.

As will be readily understood, perfect calcination is scarcely attainable in this way; but it must be remembered that, in this treatment, calcination to such a degree as is effected in the burning of pyrites for vitriol making is not desired. The ultimate extraction of the insoluble copper remaining in the washed residue thrown on the waste heaps, and existing either as undecomposed mineral, or as "kernels," is largely dependent on the slow oxidation of the imperfectly calcined mineral.

In addition to this semi-calcined ore, a proportion, varying from 2 per cent. to 8 per cent. of the total mineral of the heaps, has generally to be removed after the operation in a practically crude condition. This mineral is collected and may be reconstructed into heaps for calcination as before.

The proportion of uncalcined mineral thus separated depends considerably on the size of the heaps, and where these are small, with 200 tons to 500 tons, the ratio of superficies to weight is so great as to yield the maximum of unburnt ore; while, when the configuration of the ground admits of it, heaps containing 2000 tons to 3000 tons will allow of calcination with the minimum amount of crude ore.

While the apparent object of this calcination is the removal of the greater part of the sulphur of the pyrites as sulphur dioxide, and the conversion of the iron into peroxide, the real aim is to obtain as much as possible of the copper in the state of soluble

sulphate accompanied by a small quantity of soluble iron persulphate. During the progress of the calcination a considerable part of the arsenic is oxidised to arsenious oxide, much of it being in this state sublimed and dissipated in the air. A further portion is condensed on the exterior of the heaps, partly as oxide, and partly as sulphide, which appears in the characteristic shades of realgar and orpiment. Of these forms the only truly objectionable one in which, to the copper producer, the arsenic can here appear, is that of trioxide. As sulphide it remains practically permanently insoluble, and is not washed out with the copper either in the process of lixiviation in tanks, or yet from the waste heaps to which the washed calcined ore is ultimately consigned. As trioxide, however, it yields at once to the lixiviation in the tanks, and becomes dissolved along with the copper.

Under ordinary circumstances where the calcination process is legitimately carried out, the presence at this stage, of arsenious acid in the liquors causes no serious difficulty.

These effluent liquors from the lixiviation tanks contain, besides cupric and ferrous sulphates and free acid, a copious supply of ferric sulphates which give them a brown or yellowish green colour, according to their degree of concentration. Whether it be from the presence in excess of ferric oxide in the calcined ore, or from the already formed normal or basic ferric sulphates, the arsenious acid is readily converted into ferric arsenite, which remains soluble in the free acid:—

In the subsequent continuous precipitation of these liquors by means of pig or scrap-iron the ferric arsenite is precipitated only in the last tanks of a series, when, the greater part of the copper having been deposited, the free acid attacks and becomes neutralised by iron, and is no longer able to maintain it in solution. Hydrogen is freely evolved while the iron is being thus attacked, and the ferric arsenite becomes more or less completely reduced to ferrous arsenite.

The arsenic thus appears in the last tanks as a fine greenish white precipitate rendering the liquors—which in the first tanks had been clear and free from suspended matter—at first milky, and ultimately white and opaque. In this way it becomes mixed only with the final portion of copper precipitated, and may, in a great measure, be separated from it by a crude washing or jigging process owing to its lesser specific gravity.

Almost the last traces of ferrous or ferric arsenite may be removed from copper precipitate by washing it with a dilute solution of any mineral acid; but, unless for the richest precipitate, this treatment is not very often adopted. As a rule the precipitate, after draining for a day or two, is, in one operation, dried and calcined in reverberatory furnaces, with the view alike of removing any adhering graphite as well as the remaining arsenic. This latter result is, by such treatment, only very imperfectly accomplished, the greater part of the arsenic so removed being apparently carried over by the draught during the stirring of the charge, and is found deposited with the finer particles of copper in the adjoining dust chambers or flues.

II.—LOCAL TREATMENT OF CRUDE ORE BY OXIDISING SOLUTIONS.

From the foregoing summary of the calcination process it will be seen that for the extraction of the copper in a soluble form, the treatment pursued is essentially one of oxidation. The cupric sulphide

submits to oxidation more readily than the iron pyrites, which practically fulfils only the office of fuel in the operation. Taking advantage of this fact, and with the view of diminishing the nuisance caused by the evolution and escape into the atmosphere of such enormous volumes of sulphur dioxide as are necessarily given off when the calcination process is had recourse to, works have, in some places, been established for the direct treatment of large quantities of crude ore by means of oxidising solutions which remove only the copper from the ore, leaving all the other constituents undisturbed.

Ferric sulphate, which can generally be obtained in abundance in dry weather as an efflorescence on old heaps of calcined ore, is most conveniently employed, and in some instances common salt is added so as to form ferric chloride or a mixture of ferric chloride and ferric sulphate.

The ore must be coarsely ground, since in the lump state it is impermeable to the solutions.

Under such treatment the cupric sulphide alone is oxidised with reduction of the ferric solution and liberation of sulphur, thus:—

and the effluent solutions for precipitation contain only cupric and ferrous salts, with perhaps a little unreduced ferric salt and soda salts, when chloride of sodium has been employed.

In this treatment, which is generally applied to fresh crude mineral, laid out in permanent heaps, there is no trouble with arsenic. It remains undissolved with the iron-pyrites, and the copper precipitate produced is free from any obnoxious impurity.

III.—LOCAL TREATMENT OF CRUDE ORE BY SLOW-WEATHERING.

Another mode of treatment which produces copper precipitate similarly pure, and which in Portugal—where calcination in the open air is entirely forbidden by law—is generally adopted, consists in exposing the crude lump mineral to atmospheric oxidation, in heaps, well ventilated by flues and shafts so as to induce *eremacausis* or slow combustion. Oxidation of the cupric sulphide principally takes place, the temperature never being allowed to rise sufficiently to drive off sulphur dioxide.

In the underground workings of these mines, where the mineral is exposed to the influence of air and moisture, the temperature generally rises, and it may be remarked that, notwithstanding the presence in excess of iron disulphide, the stalactites which gradually form, and, after a while, depend from the roof, are composed of cupric sulphate, with an almost inappreciable quantity of ferrous sulphate. The action which thus goes on in the interior of the mine, where the exposed surfaces are necessarily limited, is the same in kind as that which to a much greater degree takes place in the extensive heaps of crude lump ore, when the weathering process is adopted.

The soluble copper is periodically washed out of the heap, by flushing it with water, after which the whole heap, or a part of it, is allowed to rest for a while, so that, under the influence of air and moisture, further lumps of mineral may disintegrate and yield soluble copper before another flushing.

Solutions thus obtained contain only cupric and ferrous sulphate, and no contamination by arsenic takes place.

IV.—LOCAL TREATMENT OF MINERAL BY A COMBINATION OF THE PRECEDING METHODS.

In the hope of realising the advantages of each of the foregoing modes of treatment, a compromise,

embracing the essential features of all three, has been attempted, and it is under this treatment that the greatest trouble from contamination of the copper precipitate by arsenic arises, the arsenic appearing in its most malignant form.

When this treatment is adopted, the crude mineral is laid out in heaps, well ventilated by longitudinal and transverse flues, and with numerous vertical shafts in communication with them, precisely as for treatment by the weathering process. Common salt may or may not be mixed with the mineral. The weathering process is relied upon for the gradual disintegration of the lumps of mineral, and the cost of crushing it is thereby spared. In the weathering process, however, and especially after the flushing with excess of cold water, the mineral not unfrequently shows little disposition to begin reheating, often for months, and to meet this contingency, small clusters of crude ore are ignited round the upper part of some of the vertical shafts. These ignited clusters are isolated as carefully as possible from the great bulk of the crude ore in the heap, by surrounding them with a thick layer of previously calcined ore, and they are then covered up by crude mineral. Besides warming the adjacent mineral, they are supposed to assist the draught or influx of air by the flues below, and thus promote the weathering process.

Again, taking advantage of the facility with which cupric sulphide may be converted into cupric sulphate by weak oxidising solutions—ferric sulphate alone, or with an addition of common salt, is either mixed with the crude mineral of the heap, or is spread over its surface, or it is dissolved, or is produced by oxidation of the ferrous liquors employed in the lixiviation.

Plausible as it may at first appear to combine the application of these several processes, results do not justify it, and, when the requirements of each method come to be examined, it will be seen that a complete realisation of the weathering process is incompatible with the introduction in any way whatever of calcination.

No matter what care be taken to provide against the spread of calcination in a heap containing any large quantity of crude ore—an isolated part of which has been ignited—it is almost impossible to prevent it. The calcination may be somewhat retarded, but in most cases it cannot be altogether extinguished. To retard it, or to attempt its suppression, recourse must be had to the use of water, and to the blocking up of all air channels, and, while under these circumstances it is hopeless to expect any beneficial result by weathering, two distinct disadvantages at once present themselves:—

1. By closing up the air passages while the heap is in any part abnormally heated, arsenious acid is produced. By the heat and slight draught, it is sublimed and carried away to cooler parts of the heap, where it condenses, the closing of the ventilating shafts forbidding its escape.

2. By the application of water to the burning pyrites, sulphuretted hydrogen is locally produced, and this, acting upon previously formed sulphate of copper, reduces it again to an insoluble state.

Even if calcined and washed ore be used in great quantities to isolate the ignited clusters of mineral, these difficulties are not surmounted, for, as we have seen, not only is the original calcination of this co-called "calcined ore" very incomplete, but there is invariably mixed with it considerable quantities of sulphide of arsenic, which, owing to the heat, suffer decomposition, and further aggregate the evil.

In the flushing of a heap of mineral thus abnormally heated, either for the purpose of subduing

the calcination or for extracting the soluble copper therefrom, the effluent liquors for precipitation are found to contain cupric and ferrous salts, and arsenious acid. The crude mineral from which the arsenic has been volatilised remains as sulphide of iron, and cannot—as when it has been freely calcined—yield ferric oxide, or soluble ferric sulphates, with which the arsenic might combine.

When liquors such as those just indicated are precipitated by pig or scrap-iron, no sooner does copper begin to deposit on the iron, than it is accompanied or followed by a deposition of metallic arsenic, most probably in the same way as in the well-known "Reinsch" test for arsenic. Here, contamination by arsenic, and that in its most malignant form, occurs immediately, so that—unlike the result in the precipitation of liquors from calcined ore—the heavy granular copper of the first tanks, as well as the fine pulvulent precipitate from the last tanks of a series, is found equally alloyed with elementary arsenic.

Systematic washing and jigging of copper precipitate containing arsenic in this form, though it increases somewhat the copper content, by removing mechanically mixed impurities, such as graphite and clay, proportionately increases also the arsenic. Washing with dilute sulphuric or hydrochloric acids, or with caustic alkali, does not sensibly improve the precipitate. Calcination, with free admission of air, is similarly ineffective, and even if the temperature be raised till fusion takes place, the molten product will be found to contain copper and arsenic in the original proportions.

But while, as I will afterwards show, the removal of elementary arsenic from copper, difficult as it is, may be accomplished, the most obvious course is, if possible, to prevent its appearance in this obnoxious form. There can be no doubt whatever that what may be called "subdued calcination," or excessive heating with insufficient ventilation, is the direct and immediate cause of it.

If, therefore, treatment by calcination be preferred, the process should be carried out in its entirety: but, if weathering and treatment by oxidising agents be preferred, a calcining temperature in any one portion of the heap—no matter how inconsiderable or how carefully isolated it may be—must be scrupulously avoided.

When, however, by the continual addition of mineral thereto, a heap assumes very large proportions, complete control over it cannot always be maintained.

Owing, it may be, to the irregular configuration of the ground upon which it stands, free ventilation throughout all its extent will sometimes be attended with much difficulty.

Excessive heating will at times takes place, apparently spontaneously, in perhaps the deepest and most inaccessible parts of the heap, and this leads to accidental calcination.

When such unfortunately occurs, immediate steps must be taken to arrest it, by cutting off the air supply and flushing the part with water.

Meanwhile the evils attendant on "subdued calcination" may be looked for in the effluent liquors, and these should be provided for by any one of the following expedients, as local circumstances may suggest:—

1st. Considerable deposits of hydrated ferric oxide may in the summer months be found in the dry beds of streams, as a result of the oxidation of waste ferrous liquors from the mine or precipitating tanks. If this material can be easily had, a filtering bed of it may be prepared, and the liquors may be passed through this before entering the precipitating tanks.

2nd. When want of sufficient level, or other local

consideration, will not allow this, soluble ferric sulphate may be added directly to the copper liquors.

3rd. When, at the same works, calcination is conducted, the liquors obtained by lixiviating the calcined ore, containing as they do a superabundance of ferric sulphates, may, when gravitation admits of it, be mixed with the arsenious liquors from the heap.

In each of these cases the aim is to convert the arsenious acid into ferric arsenite, in which form, as we have seen, it is comparatively innocuous, and may be largely and easily removed. Several years ago Mr. Down, of the Tharsis Company, proposed to filter the liquors from calcined ore through limestone or broken sea-shells to neutralise the free acid, and thus precipitate and separate the ferric arsenate before the liquors entered the cementation tanks; but since in this form the arsenic causes so little trouble, and that only in the ultimate portion of the copper precipitate, his method has not been largely adopted.

When, by misadventure, arsenious acid enters the cementation tanks with the copper liquors, it is too late to apply any of the foregoing remedies, and attention must then be directed to the easiest method of removing it from the resulting copper precipitate.

As I have said, the treatment that usually suffices for the elimination of arsenic occurring as ferric arsenite in copper precipitate, is in this case of no avail. Calcination with common salt, in the hope of subliming the arsenic as chloride, is quite futile, and, under ordinary circumstances, copper precipitate thus contaminated can only be worked up by adding to it poor sulphuretted ore for the purpose of producing "ore metal" regulus of about 35 per cent. copper.

Copper made from such regulus by the usual sequence of operations known as the Welsh method, scarcely comes up to "G.O.B." quality—that is, when the operations are conducted throughout in reverberatory furnaces. When blast furnaces are employed for the production of the "ore metal" the arsenic is sensibly diminished, but not to such an extent as to yield "best selected" copper after the usual operations for that purpose. The use of such fluxes as lime, salt, carbonate, or nitrate of soda, in the smelting, unless employed in very great excess, has but little influence.

Any process which will completely eliminate the arsenic, in whatever form it may occur, without throwing back a rich copper precipitate of perhaps 70 per cent. to 80 per cent. to regulus of 35 per cent.—which regulus in turn requires to be submitted to at least four succeeding operations before tough copper can be had—will therefore, if not too costly, be well worthy of attention. There are two processes which, to a certain degree, fulfil these conditions, the one being a wet, the other a dry method.

The wet method depends on the solubility of ter-sulphide of arsenic in solutions of alkaline polysulphide; while the dry treatment is essentially a pneumatic process similar to the Bessemer process for removing carbon and silicon from pig-iron.

In applying the wet process to copper precipitate in which arsenic occurs to any serious extent in its most virulent form, it is necessary to reduce the whole of the metallic copper to the state of cupric sulphide, otherwise the elimination of the arsenic will not be complete. For this purpose, in submitting the precipitate to the usual calcination which it receives for the purpose of drying it, and for burning off graphite, to fit it for export, it is most convenient to add to the charge a mixture of sulphate of soda and small coal in sufficient quantity to convert the greater part of the copper into sulphide. When the reduction of the sulphate of soda is sufficiently complete, the charge is immediately raked out into a

tank with a false bottom, containing a solution of polysulphide of sodium, and is allowed to remain there for two or three hours. Meanwhile the solution is made to circulate from beneath the false bottom to the surface by means of a steam blower, and at the end of the operation the liquid is in this way removed to another similar tank to be ready for a fresh charge from the furnace. A washing with water which has been previously used for the same purpose—which wash water serves in time for the preparation of a new polysulphide bath—and a final washing with clear water which may be at once run away, reduces the arsenic in most cases to mere traces. If the arsenic be present in small quantities only, the calcination with coal and sulphate may sometimes be dispensed with, but in this case the bath solution must contain a large excess of sulphur in solution. The copper precipitate is now in the state of sulphide, and what was originally an impure metallic precipitate of say 75 per cent., is after the treatment reduced to a comparatively pure sulphide precipitate of perhaps 50 per cent. Owing to its spongy nature, the sulphide precipitate may be very easily dried and calcined by waste heat from any convenient flue, the calcination beginning almost spontaneously when most of the water has been driven off, and the calcined residue consists of cupric oxide, with about 60 per cent. of copper.

The economy of this process depends on the local facilities for obtaining crude sulphur and sulphate of soda; and in some instances—where, for example, gypsum abounds in the neighbourhood—sulphate and polysulphides of calcium may be advantageously substituted for the sodium salts.

The dry method requires that the precipitate be thrown back, by addition of sulphuretted mineral, so as to form regulus of 40 to 45 per cent. copper, or even more, provided that the rejected slags formed in the production of this regulus do not contain more than 3 to 5 per cent. of copper; but the sulphur so added is utilised as fuel, and after the treatment only one operation, that of refining, is required.

The pneumatic treatment of copper ores and regulus for the production of metallic copper, was proposed more than 30 years ago, anterior in point of time to the advent of the Bessemer process for iron, and at intervals since then it has been resuscitated by various experimenters. The chief difficulties encountered have been in finding a suitable lining material for the vessel in which the operation is conducted, and in providing against the oxidation by the blast of the reduced metallic copper as it forms. The formation of a slag of silicate of copper, by combination of copper so oxidised with the siliceous lining of the vessel, has suggested to some the arrestment of the process at the stage of "blue metal," or "white metal," and the consequent evasion of this difficulty. Two French metallurgists, MM. Manhès and David, have, however, succeeded in overcoming the difficulty without thus interrupting the process; and by employing their converting vessel, 98 per cent. copper, practically free from all objectionable impurities, and containing only small quantities of iron and sulphur, can in a few hours be obtained from copper precipitate containing as much as five per cent. of arsenic in its most objectionable form.

The converting vessel employed by these gentlemen is of the form of a horizontal cylinder, which can be made to rotate on its axis by means of a rack and pinion. The air blast enters the vessel in the direction of a tangent to the interior superficies, and by rotating the vessel the blast may be made to penetrate the molten regulus, at any angle, or to any desired depth. It may thus be injected through a

superficial layer of molten sulphide, without touching any accumulation of metallic copper underneath it.

The lining difficulty is met by making the lining as siliceous as possible, regarding it as the most convenient means of supplying silica to the oxidised iron, and making provision for its frequent renewal.

Under this treatment arsenic, antimony, and other such impurities, are, for the most part, oxidised and volatilised.

I do not know that this process is in use at any of the works where the impure precipitate is produced, but such precipitate is satisfactorily treated by it at Continental works to which the precipitate is sent. The process is at work in France, Germany, and the United States, and I believe the only works at which it has been adopted in this country are those of Messrs. Vivian & Sons, Hafod, Swansea. As an instance of how prejudices may be overcome, this latter fact forms a strange commentary on the opinion expressed by Sir Henry, then Mr. Hussey-Vivian, when in 1879 the Hollway process was under discussion before the Society of Arts, to the effect that "the Bessemer process was quite inapplicable to copper smelting."

I cannot conclude without adverting to the method of refining employed by Elliott's Metal Company, at Selly Oak, near Birmingham, in this country, and at several Continental and American works, where anodes of coarse copper are dissolved and deposited electrolytically in the purest possible state. Arsenical copper precipitate might be melted and cast into suitable anodes for this process, but as the resulting copper is unnecessarily fine for all but electrical purposes, the cost of the treatment, where neither silver nor gold would be recoverable as by-products, would scarcely permit of its general adoption.

The occurrence of arsenic in copper liquors obtained by the Henderson process in this country, and its removal from these, has been frequently discussed, but I am of opinion that in these discussions the all-important question as to the condition in which the arsenic exists in the respective liquors experimented upon has been entirely overlooked.

According to Lunge ("Sulphuric Acid and Alkali," vol. i. p. 621), Bischof found that when spongy iron was used for the cementation, arsenic was precipitated only after the copper had been precipitated; while Gibb, on the other hand, affirms that he never found any trace of arsenic in solution after the copper had been precipitated, whichever form of iron or solution of copper might be employed.

These statements, contradictory as they appear, are perfectly reconcilable one with the other, on the assumption that in the first case the arsenic was present as ferric arsenite, maintained in solution by free acid, and that in the second case it appeared in the liquors as arsenious acid.

DISCUSSION.

DR. WALLACE said that the author had not referred to the separation of arsenic as carried on in Glasgow and elsewhere in this country. His impression was that at the works in Glasgow the arsenic was precipitated by "bog liquor," or the drainage of the waste heaps of St. Rollox, which contained a large proportion of sulphide and polysulphides of calcium. This not being available in Spain, he would like to know what means they adopted there. He thought that the Spanish method of calcination prevented recovery of the gold and silver present in the ore; and it was only in this country, where the pyrites was first burned for its sulphur, and then calcined with common salt, that the precious metals were recovered. Perhaps the author would enlighten them on this point.

Mr. PATTISON asked if any objection was raised in the localities where these processes were carried on to the noxious fumes evolved?

The CHAIRMAN apologised for the lack of discussion, as the subject was so unfamiliar to the majority present. At the same time they all felt great interest in the question.

Mr. FULTON, in reply, said: Dr. Wallace has remarked that no reference has been made in this paper to methods of removing arsenic from copper liquors, as employed in works in this country, and he spoke of some method of precipitating the arsenic by means of liquors draining from heaps of alkali waste. I would remind him that at the outset I professed to deal only with the local treatment at the mines, which of itself is a sufficiently comprehensive subject. I do not see in what way the alkali waste solution could be employed for the precipitation and separation of arsenic from copper solutions, since, by employing it, both copper and arsenic would be precipitated together. In treatment by the Henderson process, I believe that arsenic principally occurs in the tower liquors, along with the hydrochloric acid; and the final washings of the mineral with these liquors are generally kept apart from the purer solutions obtained from the earlier lixiviations. Several years ago, Messrs. Gibb & Gelstharp, of the Bede Metal Works, Jarrow-on-Tyne, obtained a patent for the precipitation of arsenical copper from these tower liquors, prior to their use in the final lixiviations. They probably found that these metals could be precipitated by iron, before the free acid became saturated, and the acid liquors thus purified were suitable for the removal of the last traces of copper from the mineral, without contaminating it with arsenic. As for the recovery of gold and silver from the mineral submitted to local treatment by calcination, the solutions formed are, for the most part, sulphate solutions, and the noble metals are, under these circumstances, left in the washed, calcined ore. Attempts have been made to remove these, after the copper has been washed out, by treating the residues with brine. A further quantity of copper is thus obtained, and the whole may be precipitated by iron, as argentiferous copper, containing a little gold. As a matter of fact, however, treatment in this way has not hitherto been remunerative. In reply to Mr. Pattison's inquiry as to the damage occasioned by the sulphur smoke, and the attitude of the public towards this, I may say that before extensive operations, involving calcination, can be commenced, it is necessary to acquire large tracts of country around the site; but this does not prevent much damage being falsely ascribed to the influence of the smoke, in lands which have not been so acquired, and extravagant claims for compensation are being continually made.

ADDENDUM ON THE USE OF ANTIMONY MORDANTS IN HOSIERY DYEING.

BY HENRY FORTH.

THE use of tannate of antimony is, when compared with the tannates of tin, of recent introduction as a mordant. Its use, when prepared from solutions of tartar emetic and tannin, for fixing aniline colours, appears to have been discovered in 1861, by Dale, though it was but little used till long after that. Upon hosiery it does not seem to have been used till about five or six years ago, for my friend Mr. J. R. Ashwell tells me the first time he met with tannate of antimony upon dyed hosiery was in the year 1879. Since this date, antimony, either as tartar emetic, and more recently as the double oxalate of antimony and potash, or as the fluoride, has been increasingly and largely used for the production of tannate of antimony as a mordant upon hosiery.

The great recommendations for the use of tannate of antimony are—(1) It is a cheaper mordant than tannate of tin; (2) it produces faster or more insoluble compounds with "aniline" colours than tannate of tin; (3) goods so mordanted are very soft. Various statements, most of them very intangible, have been made respecting the poisonous properties of tannate of antimony as a mordant—e.g., R. Kaysner, *J. Soc. Chem. Ind.* August, 1883, says: "When tartar emetic and tannin are used as mordants, a very small quantity of antimony is always found in the finished cloth, if the work has been carefully executed. But when the operation has not been properly conducted, very large quantities of antimony compounds may remain. As an example, a piece of brown cloth was found to contain per sq. dem. 0.085grm. of antimony. This cloth worn next the skin produced troublesome sores, which however disappeared quickly on the removal of the objectionable cloth. It appears that the "cloth" containing 0.085grm. Sb per sq. dem., was cloth used for trouser pockets, and not hosiery worn next the skin.

Experiments have been made to obtain a very large amount of antimony fixed upon hosiery as the tannate. I employed what for hosiery is a very excessive quantity of tannin—viz., ten per cent. of tannic acid needles—and then, after steeping all night, a bath of tartar emetic at 20grms. per litre. Hosiery thus mordanted was then dyed with a common magenta containing a trace of arsenic, and all operations of rinsing with water and soaping (which are customary) were omitted; the hosiery being simply dried out of the dye liquor. This method ensured as much antimony being left upon the hosiery as was possible. On analysis it was found to contain 1.1682 per cent. of Sb, and one sq. dem. only contained 0.02145grm. Sb, or practically one-fourth of the Sb which was upon the sq. dem. of Kaysner's cloth. If, however, the weight of the hosiery fabric per sq. dem. was doubled, a fabric would be obtained of such weight that rarely, if ever, finds its way into the market as hose.

To carry this further, this dyed fabric containing 0.02145grm. Sb per sq. dem. I wore upon my feet for twenty-two consecutive days, and found no irritation proceed therefrom.

This case is throughout excessive as regards the quantity of antimony upon the hose, and every care was taken to so manipulate the dyeing and mordanting that the antimony compounds might

remain upon the hose, if not in a soluble form, at least loosely, adhering mechanically.

The use of antimony—through, I suppose, its novelty—has met with decided opposition in some quarters. Certain dyers are told that tartar emetic being poisonous and skin irritating, therefore they must undertake *not* to use it in dyeing their goods. These manufacturers either forget or do not know that whilst tartar emetic is easily soluble, the tannate of antimony which is present upon their goods is insoluble. Many hosiery dyers are thus prevented from using a mordant which they know to be much better than tin for fast and bright cheap colours.

A most successful dyer tells me that he always soaps his cotton goods *after* mordanting with tannate of antimony, and *before* dyeing. Thereby he removes any loosely-adhering particles completely, and renders the mordant quite insoluble. The fastness and brightness of the resulting colours more than repays for the extra expense.

So much better does he find an antimony mordant than a tin one, that, excepting where restrictions are forced, he has entirely adopted it, and has had no complaints of the dyed goods acting in a poisonous or irritating manner upon the skin.

Other dyers give me similar information.

This mordant, therefore, I submit, after the ordinary severe rinsing and soaping combined with friction always given in hosiery dyeing, has no poisonous or irritating action on the skin.

Tannate of antimony is used as a mordant in precisely the same way as the tannates of tin are. The method employed is similar, a solution of an antimony salt being substituted for a solution of a tin salt, and the goods saturated with tannin solution, are steeped in the antimonial solution, etc., as we have heard described as customary when the salts are employed.

DISCUSSION.

The CHAIRMAN alluded to the double aspect—both chemical and medical—of the papers by Mr. J. H. Ashwell and Mr. Henry Forth, and invited discussion both from members and visitors.

Dr. HANDFORD agreed with a great deal that the papers had stated with regard to the non-irritating character of nearly all colours upon dyed hosiery. He could not recollect a single instance where he had been satisfied that the dyeing matter had been a definite cause of irritation. But there were such cases on record; though in five or six years' experience at a large hospital he could not recollect a single one. It was well known that the entrance of small quantities of antimony or lead into the system over a lengthened period had a bad effect, but did not necessarily produce any local irritation. In his opinion, undue importance had been given to the insolubility of these bodies in cold water. During wear they were moistened with perspiration and subjected to friction, and it was therefore necessary to ascertain whether they were insoluble in a slightly acid solution—such as lactic acid. But even if they were insoluble under these conditions, traces of them might still find their way into the pores by means of friction, and so gradually pass into the lymphatics. In the *Lancet* of February 27, a letter appeared describing a case of severe irritation of the skin arising from wearing a pair of scarlet socks. The material was not mentioned, but was probably silk or cotton. The socks were analysed, and two decigrammes of arsenic were obtained. Now it was more especially arsenic which would produce skin irritation, and many cases of eruption had occurred in the town from handling paints containing it. Chromium had much the same effect. He might add that

aniline dyes were much used in colouring microscopic preparations, but were so extremely soluble in water that they were easily washed off.

Mr. WHITELEY thought that the question which ought to be decided was whether, in the likely event of antimony or arsenic coming in contact with the skin, they would produce irritation. He thought not. Here was an isolated complaint made against one pair of socks out of a large number prepared at the same time and in the same way. How was it that there were not cases wherever the socks had been worn? It was more probable that the constitution of the wearer was really in fault. Tartar emetic was a skin irritant, but were all other antimony compounds, such as the tannate, irritants as well, any more than tannate of tin or iron, against which no complaint was laid?

Mr. COLEMAN suggested that alkali might dissolve antimony and arsenic; and perspiration which contained alkali might cause absorption under friction.

Dr. APLEY STEPHENSON confirmed the remarks of Dr. Handford. He had never met with any cases attributable to irritants in hosiery. On the other hand, he facetiously remarked that distinct benefit accrued from the slight colouration caused by the dyes coming off the hosiery, for it induced more frequent washing, and hence greater cleanliness. The effect of tartar emetic was general rather than local; and as to dyes as a whole, he had not found them specially unwholesome to those engaged either in their manufacture or their application. Skin diseases arose more from lack of personal cleanliness or ordinary precautions than from any other cause.

Mr. GOODALL, speaking for the hosiery trade, welcomed the discussion, and said that they were desirous of challenging chemical tests of every kind. Hosiers ought to be prepared to state that their dyes and ingredients were neither irritants nor poisonous, but just now they had to face a wave of suspicion. One most difficult case that had lately arisen was that of a gentleman who had worn a sock made of cotton and silk, the silk part of which was dyed with picric acid. Would picric acid produce skin irritation? In New York there had been much discussion about a certain "bright cardinal" imported from Germany, and said to contain arsenic, and the local medical officer of health had taken up the question.

Mr. PENTECOST asked whether there were any cases of silk goods having proved irritating to the skin; and whether, when irritation had been alleged, the goods were all wool, all cotton, or a mixture. If they were cotton then tartar emetic might be accused; if silk, arsenic might have been the cause.

Dr. HANDFORD, in answer to the question that skin irritation attributed to dyed hosiery might in reality be due to the general health of the wearer, said that where they found that the wearer had no previous irritation, and that his complaint was not only local to the parts in contact with the hosiery, but also disappeared when the garment was left off, one could hardly fail to attribute the irritation to the wearing of these coloured goods. As to the power of the skin to absorb insoluble bodies, there was the well-known instance of salivation caused by anointing the skin with mercurial ointment.

Mr. FORTH, in reply, stated that his remarks upon antimony were founded upon personal observation, by wearing socks for a length of time charged with as much antimony as they would hold.

Mr. J. R. ASHWELL, in reply, said that he fully recognised the difficulty as to perspiration, and was engaged in making some experiments which would throw light upon the matter. The New York case had been referred to, but the examination of a medical officer, as detailed in the papers on the sub-

ject, had elicited that he knew nothing whatever of the proper tests for antimony or arsenic. When asked how he could detect these bodies, he replied, in effect, "Very simply; take the red fabric and treat it with dilute acid, and if these bodies be present it immediately turns blue." At some future date he hoped to reopen the question, and to speak about some mordants the action of which upon the skin, if not injurious, was at least to be avoided.

Meeting held April 9, 1886.

ON SOME POINTS IN THE ANALYSIS OF OILS.

BY LEONARD ARCHBUTT, F.C.S.

DURING the course of the last four or five years a good deal of my time has been engaged in the examination of oils, especially olive and rape oils. A considerable amount of information has thus been gained, and experiments have had to be made, some of the results of which are embodied in the following paper:—

Maumené's Temperature Reaction.—Some years ago, M. Maumené proposed a very simple and expeditious method of testing oils, based on the rise of temperature which takes place when the oil is mixed with concentrated sulphuric acid. His plan of operating is to weigh 50grms. of the oil into a beaker, and place in it a thermometer; the temperature of the oil having been recorded, it is stirred with the thermometer while 10cc. of strong sulphuric acid are added from a pipette, and when the mercury ceases to rise, the temperature is again recorded. The difference between the two numbers thus obtained is the "rise of temperature" for the particular oil; and seeing that this ranges from about 40° C. for olive oil up to about 135° C. for linseed oil, it is evident that we possess in this very simple process a most valuable method of testing oils, provided of course that the results obtained are constant for each kind of oil. The figures published by Maumené were subsequently confirmed by Fehling, Faisst and Knauss, and by Allen, and the figures obtained by all these observers are to be found in a paper by Mr. Allen, published in the *Analyst* for 1881, p. 102, where the method is fully discussed.

In the *Comptes Rendus* for 1881, Maumené published some further notes on the test, wherein he stated that sulphuric acid which had been recently heated, "without having lost the least trace of water," liberated far more heat with linseed oil than the original acid. Allen, however, on repeating these experiments, failed to verify this statement, and my own observations confirm those of Allen. In explanation of Maumené's results, Allen suggested that the acid used must have been a weak one to commence with, and that it really did lose water on heating; but the increase of strength must have been very considerable to account for the very great differences in Maumené's figures.

It was just about this time that I began to use the test very frequently in examining samples of rape and olive oil, and I soon found that without great care very discordant results might easily be obtained, and that even with the greatest care, and the adoption of every precaution to ensure uniformity in the mode of operating, the figures yielded by the same sample of oil are liable to obscure variation.

Thus, at the outset, I made the two following experiments:—

(1.) SHOWING THE RESULT OF USING ACID NOT CAREFULLY PRESERVED.

"Concentrated" Sulphuric Acid. Rise of Temperature.

a. From Laboratory Reagent Bottle	32½° C.	} With the same sample of oil.
b. From a "Winchester"	76°	
c. From same "Winchester," recently heated	76°	

(2.) SHOWING THE INFLUENCE OF STIRRING.

Rise of Temperature.

a. Oil and acid stirred until all the acid had been added; then, the thermometer held stationary in the middle of the oil	75° C.	} With the same sample of oil.
b. Stirring kept up until the temperature ceased to rise	73½°	

The plan of working which I then adopted, and still employ, is as follows:—I use *sulphuric acid* of definite strength preserved in a capped ether bottle; a 10cc. pipette, accurately graduated and kept specially for this test; beakers, No 3, 7oz. capacity, of tall form, which fit into a "nest" of cardboard, having hollow sides stuffed with cotton wool; a centigrade thermometer, 50grms. of the oil to be tested are weighed into one of the beakers, to within 10 or 20 milligrammes. The bottle of acid and the beaker of oil are placed in a vessel of water until both have acquired the temperature of the water, the thermometer having been placed in the oil. The beaker is then removed from the water, wiped outside, and placed in the nest. The temperature having been verified and recorded, 10cc. of acid are rapidly withdrawn from the bottle, which is immediately closed again, the acid is allowed to flow into the oil while it is being stirred with the thermometer, and the stirring is continued until no further rise of temperature is observed. The stirring must be so managed as to effect as perfect an admixture of the oil and acid as possible, thereby ensuring an even development of heat throughout the mixture. It is highly advisable to keep at hand a stock of oil of known purity, and to test some of this side by side with every batch of oils examined.

Some observers lay stress on the importance of having the oil and acid at some *constant initial temperature*. I believe this to be unnecessary. Thus, the examination of a large number of samples of olive oil have given the following results:—

Initial Temperature.	Limits for Genuine Olive Oil.	
19°—20° C.	39½°—44½° C.	} Rise of Temperature.
10—12	38½—45½	
7—8	40—42½	

The vessel of water used to equalise the temperature of the acid and the oil may therefore be conveniently maintained at the temperature of the laboratory for the time being.

So far, I have said nothing as to the strength of the acid employed. Though it is perfectly well known that the heat developed depends to a large extent on the strength of the acid used, no experiments have hitherto been published showing what this variation actually is. The direction is generally given to use acid of some fixed specific gravity, but it has been shown by Lunge and Naef that the sp. gr. of sulphuric acid above a certain strength undergoes very little variation, and moreover above 98 per cent. it decreases. Some experiments of my own which were made before the publication of Lunge and Naef's figures, confirm their results. Nine specimens of acid were prepared, calculated to differ from each other by 1 per cent of real H₂SO₄, and each of these was very carefully analysed by titration with a standard solution of sodium carbonate,

methyl orange being used as indicator. About 3grms. of the acid were taken for each experiment. The standard alkali used was set by means of a specially prepared normal hydrochloric acid, the sp. gr. of which was ascertained, and which was analysed by precipitating weighed quantities with silver nitrate. The volumes of acid and alkali employed throughout were weighed, so as to avoid errors in measuring, the alkali being added in very slight excess, and the solution then adjusted to neutral point by running in deci-normal hydrochloric acid.

The following experiments, made with these acids on three typical samples of oil, show the influence of the strength of the acid on the heat developed:—

Percentage by weight of real H_2SO_4 .	RISE OF TEMPERATURE OBSERVED (° C.).		
	Genuine Olive Oil	Genuine Rape Oil	Impure Olive Oil.
97.38	43½, 42½	63, 62	48½, 48½
96.71	42	61	47, 47½
95.72	39	58	43½, 44½
94.72	36½	54	40½, 40½
93.75	34½	50½	38½, 39
92.73	31	47	35½, 35½
91.85	28, 29½	40½, 43	32½, 32½

With 94.72 per cent. acid the rise of temperature was slow. With 93.72 per cent. acid it was very slow, and with weaker acid it was very much slower. The results show that there is no advantage in using the weaker acids on the ground of greater concordance in the results, so that I prefer to use an acid of 97 per cent. strength. The sp. gr. of this acid, and of those employed in the above experiments, was taken by Sprengel tube, with every precaution, at 60° F., as compared with freshly boiled distilled water at 60° F. The results are as follows:—

Percentage by weight of real H_2SO_4 .	Specific Gravity at 60° F. (Water at 60° F.=1.0000).	Difference.
97.38	1.8411	—
97.02	1.8440	.0001
96.71	1.8438	.0002
95.72	1.8427	.0011
94.72	1.8406	.0021
93.75	1.8378	.0028
92.73	1.8341	.0034
91.85	1.8309	.0035
90.73	1.8255	.0051
(89.73)	1.8201	.0051

Soon after I had made these experiments, I obtained an interesting confirmation of the results. A friend of mine wrote me to the effect that he was getting very much less rise of temperature with olive oil than the figures published by Maumené. I suggested to him that his acid was weak, and asked him to send me some of it, and also some of the oil he was testing. I then tested his oils with my acid and with his acid, and I took the specific gravity of his acid. The results are given in Table A.

The acid which my friend had used had been supplied to him as concentrated sulphuric acid, and this led me to test several Winchesters of acid from my own stock. The results showed that the "pure con-

centrated sulphuric acid" (free from lead), as ordinarily supplied in Winchesters by the dealers, is liable to considerable variation in strength. Thus, I found the acid in eight unopened Winchesters varied as follows:—

H_2SO_4 per cent.	
1.....	97
2.....	97
3.....	95.3
4.....	92.7
5.....	97.4
6.....	97.4
7.....	95.9
8.....	96.8

} Analysed directly.

} Calculated from specific gravity.

Adopting all the precautions which I have described, Maumené's test leaves much to be desired. The indications yielded by it, taken in conjunction with other tests, are of very great value; nevertheless, they sometimes vary in a most unaccountable way. The results to be found in Allen's "Commercial Organic Analysis" serve sufficiently to show what each kind of oil may be expected to give; but every observer should construct a table for himself, and whenever a sample of oil is tested, a comparative experiment with one of the same kind, and of known purity, ought to be simultaneously made.

The following additional experiments were made in endeavouring to find the proper rate at which to add the acid. A genuine rape oil was used:—

	Rise of Temperature (° C.)
A. By the method already described, the acid being allowed to flow from the pipette as fast as it would deliver.....	61, 61.
B. Same as "A," but the acid was allowed only to drop slowly from the pipette.....	61, 61, 61, 61, 63, 63, 62.
C. Same as "A," the acid being allowed to drop rather fast.....	63, 60½.

From these experiments, it appears best to allow the acid to drop slowly into the oil; but I think it is very probable that more concordant results would be obtained if some better method of mixing the oil and acid were to be adopted than is possible by simple stirring with the thermometer. No satisfactory plan of effecting this has at present occurred to my mind.

The Elaidin Test.—The fact that olive and other non-drying oils possess the property of becoming converted into solid isomeric modifications under the influence of nitrous acid was first applied to the detection of adulteration in olive oil by Pontet, in 1819.

Pontet's reagent was prepared by dissolving, at the ordinary temperature, 6 parts by weight of mercury in 7½ parts by weight of nitric acid of 38° Beaumé (sp. gr. 1.35). The solution so formed was shaken with the oil to be tested, in the proportion of 1 part by weight of the reagent to 12 parts by weight of the oil, and the agitation repeated every ten minutes during two hours. The bottle containing the now possibly solid mass was placed in a cool cellar for twenty-four hours, at the end of which time the consistence of the product was noted. If the oil were genuine, a hard mass was the result; if mixed with oils of a drying character (especially poppy oil), the contents of the bottle were fluid, or imperfectly solid. By this means, 10 per cent. of poppy oil could be detected, but with a smaller proportion the results were uncertain.

I am not aware that a systematic study of this reaction of Pontet's, showing how far it is really applicable to the detection of adulteration, and the best mode of applying the test, has ever been made. Subsequent observers appear to have considered Pontet's reagent too troublesome to prepare, or uncertain in its indications, and have proposed others; but little real advance in the application of the test appears to have been made since the time of Pontet.

Boudet, in 1832, found that the active principle of Poutet's reagent was free nitrous acid, and he proposed to employ the latter mixed with three times its weight of nitric acid, of 1.31 sp. gr., as a substitute. Boudet found that $\frac{1}{10}$ th part of nitrous acid is sufficient to cause the solidification of olive oil. Less than this was without effect.

Fauré made some experiments with Boudet's reagent on mixtures of olive oil with poppy and walnut

At 8° C.—

Fermented oil + 5 Sesame.—Formed a solid but soft mass.
 „ + 5 Cotton.—Formed a mass of consistence of tallow.
 „ + 5 Arachis.—Gave a solid mass, softer than fermented oil alone.

Roth's experiments are the only ones with which I am acquainted in which the temperature is recorded, other observers having contented themselves with

TABLE A.

	I OBTAINED WITH		B.'s Figures.
	My Acid,	B.'s Acid,	
	Sp. Gr. 1.6440	Sp. Gr. 1.6352.	
1. Olive Oil	39° C.	29° C.	29½° C.
2. Sublime Olive Oil.....	40½	30½	31
3. Finest Sublime Olive Oil	40½	30½	31½

oils. 100grms. of oil were mixed with 3grms. of the reagent, and the time required for solidification was observed. The temperature, a most important point, does not appear to have been recorded.

Percentage of Adulterant.	Number of Minutes required for Solidification.	
	Poppy Oil.	Walnut Oil
0	55	55
5	90	85
10	115	108
20	215	117
30	680	310
50	1597	435

Barbot, in 1841, proposed the use of nitric acid saturated with nitric oxide, but the experiments which he recorded show that his reagent is decidedly less useful than Poutet's.

Kopp adopted the very simple plan of adding to 9 volumes of the oil 1 volume of nitric acid, of 1.3 to 1.4 sp. gr., and dropping into the nitric acid (which forms a layer at the bottom of the vessel) some copper turnings. When the evolution of gas had proceeded a short time, the whole was stirred up and set aside. The indications obtained in this rough manner must be very uncertain and unreliable.

Lastly, Jules Roth used sulphuric acid, containing 56 per cent. of H_2SO_4 , saturated with nitric and nitrous acids. The reagent was prepared by acting on iron, in large lumps, with nitric acid, the nitrous gas evolved being passed at a moderate rate into sulphuric acid of 46° Beaumé, which at the end of six to eight days (!) became saturated with the gas, and assumed a deep bluish-green colour. 9grms. of oil were mixed with 7grms. of the reagent by stirring with a glass rod, and the mixture then left to itself. Some of Roth's results are given in Table B on next page.

Mixtures :—

At 5° C.—

Fermented oil + 10 Sesame.—Assumed consistence of honey.
 „ + 10 Cotton.—Remained semi-fluid, but more solid than the sesame mixture.
 „ + 10 Arachis.—Became more solid than the cotton mixture.

making the test “in a cool place.” He appears to have adopted a very tedious method of preparing his reagent, and the results of his experiments on mixtures do not at all agree with my experience.

I have not actually tried Roth's plan, but I have made a somewhat similar reagent by passing dry SO_2 (from one of Boake's siphons) into cold nitric acid of 1.42 sp. gr. In about ten minutes a liquid was produced which solidified olive oil in from twenty to thirty minutes at 10° C., a white product being formed, similar to that described by Roth. But the same reagent solidified cotton oil in forty minutes, and a mixture of olive with 10 per cent. of cotton oil in twenty-five minutes, with formation of a white mass resembling that produced by olive oil alone; so that, as a test for cotton oil in olive oil, the reagent proved to be useless. The product yielded by pure cotton oil was red, and that given by rape oil deep red; but 10 per cent. of either of these oils in olive oil did not sensibly colour the elaidin.

Some further remarks on this reagent may be of interest. At a temperature of 10° C. nitric acid of 1.42 sp. gr. rapidly absorbs dry SO_2 gas, assuming at first a red, and ultimately a brown-green colour. On continuing to pass the gas, a very deep green liquid separates out, which rises to the surface and continues to increase in bulk; and then a white crystalline body forms in the liquid below, which ultimately chokes the tube. The deep green liquid is free from every trace of sulphuric acid, and consists wholly of nitrous acid, with some nitric acid. The white crystalline body is, I suppose, nitro-sulphonic acid. By stopping the passage of the gas as soon as the deep green liquid begins to form, a solution is obtained containing sulphuric, nitric, and nitrous acids, with which the following experiments were made :—

Quantities, of 100cc. each, of the same sample of olive oil were taken, and severally mixed with the following proportions of the reagent. The mixtures were placed in water at 10° C., and shaken at intervals of ten minutes until solidification took place, the test of solidification being that the mass did not move on moderately vigorous shaking.

No. of cc. reagent used.	Minutes required for solidification.
1cc.	120
1½	55
2	35
2½	35
3	35
3½	30
4	35
10	40

Boudet showed that less than '05 per cent. of nitrous acid failed to cause the formation of elaidin. The above experiments show that the increase of the proportion beyond a certain amount no longer hastens the change. In fact, when too much of the reagent is used, a portion simply falls to the bottom of the vessel after shaking, and is removed from the sphere of action: besides which, heat is developed during the shaking, and the experiment may become dangerous. Moreover, too large a proportion of nitrous acid is disadvantageous, because, as I have already mentioned, the adulterating oils themselves become solidified, and the value of the test is spoiled.

1.42 sp. gr., a reagent can be obtained which gives perfectly constant results, and which will keep for at any rate several days. I will describe exactly the way in which I proceed.

I have made out of a piece of barometer tubing a small measure which holds exactly 6grms. of mercury. Three "measures" of mercury are placed in a dry stoppered 50cc. cylinder, and 15.6cc. of nitric acid of 1.42 sp. gr. are added from a burette. Action at once commences, but there is no escape of gas, the nitrous acid being entirely absorbed, with production of a deep green colouration, which slowly rises and spreads throughout the nitric acid. After a short

TABLE B.

	5° C.	8° C.	Summer Temperature.	24° C.
Virgin olive oil.....	Solid in 20–30 mins.	—	Solid in 60–90 mins.	Solid in 420 minutes.
Fermented oil— <i>i.e.</i> , expressed from olives which have fermented	Solidifies more slowly than virgin oil—often only at the end of some hours in summer. The product is softer, and not white, like that yielded by virgin oil, but greenish-yellow.			
Arachis oil	Solid in 75 minutes.	—	Remaining fluid for some days.	—
Oleic acid.....	Behaves like arachis oil.			
Colza oil	Deep red mass, of consistence of pomade, after some time.	—	Does not solidify.	—
Sesame oil	Does not solidify, but assumes the consistence of honey in winter.			
Cotton oil.....	—	After some time, assumes consistence of tallow.	—	—

TABLE C.

MINUTES REQUIRED FOR SOLIDIFICATION.

TEMP (° C.)	0°	5°	10°	15°	20°	25°	30°
Series 1..	50	60	60	80	120	—	—
.. 2..	60	60	60	75	150	—	—
.. 3..	—	—	60	—	—	—	—
.. 4..	—	—	60	—	—	200	—
.. 5..	—	—	60	—	—	—	(Not solid in eight hours; but at end of twenty-four hours was a solid yellow, tolerably firm mass, with a little yellow oil on the surface.
.. 6..	—	—	—	—	—	230	
.. 7..	—	—	—	—	—	210	—

I now return to the consideration of Poutet's reagent. As originally described, nitric acid of 1.35 sp. gr. was directed to be used, and the proportion of mercury employed was so adjusted as to practically saturate the acid in the cold. The solution thus prepared has a blue-green colour, and very rapidly undergoes change. Hence, it had to be always freshly prepared, which was certainly an inconvenience. I have only made two experiments on olive oil, following Poutet's instructions exactly, and in one case the sample solidified in 175 minutes, while in the other experiment only 100 minutes were required. The temperature was in each case 10° C., and the same oil was used; but the reagent was freshly prepared for each experiment.

I have found, however, that by employing acid of

time, the cylinder is placed in water at 10° C., the stopper being tightly screwed in to prevent the escape of any red fumes which may be evolved. In from five to ten minutes the mercury has entirely disappeared, and a deep green liquid remains, with some white solid at the bottom. The stopper is cautiously removed, and the white deposit, if considerable, is dissolved up by careful stirring and, if necessary, very gentle warming. .96grms. of the oil to be tested are next weighed into a wide-mouthed stoppered bottle, and 3.25cc. (or 8grms.) of the deep green reagent are added from a burette. The whole is then shaken up, placed in water at the required temperature, and again shaken at intervals of ten minutes until solidification takes place, or until further shaking is considered unnecessary.

I have thus described the method in detail, because I think an empirical test of this nature ought to be so described; but very likely it is not necessary to adhere rigidly to all the proportions given. I may, however, here remark, that when working at low temperatures, I have found shaking at more frequent intervals than ten minutes give less concordant results.

The series of experiments given in Table C were made exactly as above described, in order to ascertain—(1) whether the results were concordant, and (2) the influence of temperature. The same sample of olive oil of superior quality was used throughout, and each series of experiments was made on a different day, with a fresh reagent.

After the solidified mass had remained at the temperature of the experiment for about twenty-four hours from the time of starting, the hardness of the elaidin was tried by forcing down upon it a stout glass rod, $\frac{3}{8}$ inch diam. In this way it was noted that, with the particular oil here used, the elaidin formed at—

0° C. was pale yellow and impenetrable;
10° C. " " " " " "
20° C. " " " " " " barely penetrable;
25° C. " lemon " " " only just "
30° C. " " " " " " easily " but fairly firm.

The colour of the product deepens as the temperature is raised, and the hardness diminishes.

These experiments show the importance of working at some uniform temperature, and they also establish the concordance of the results, more especially at low temperatures. The solidification at a lower tempera-

est were performed on a large or a small quantity of oil, and in order to settle this I made three mixtures, viz. :—

- 1.—96grms. of oil + 8grms. of reagent.
- 2.—48 " " + 4 " " "
- 3.—12 " " + 1 " " "

The first two experiments were made in stoppered bottles of different sizes, the last in a corked specimen tube. The temperature was 10° C., and each mixture solidified in 60 minutes.

The results being so far satisfactory, I wished to ascertain whether the reagent required to be freshly prepared. My impression was that so long as it maintained its *deep green* colour it would be fit for use. To prove this, I made up enough to fill a 50cc. cylinder. Two olive oils were then tested with the freshly made reagent, and the cylinder was stoppered and placed aside in a cool and dark corner of the laboratory for future experiments. This reagent has given the following results :—

Reagent.	Minutes required for Solidification.	
Temperature 10° C.	Olive Oil A.	Olive Oil B.
Freshly prepared	50	60
1 day old	—	70
7 days old	—	65
10 days old	60	—
14 days old	50	65
21 days old	60	—
39 days old	60	—

Thus, so long as the reagent is carefully preserved and retains its deep green colour, it is fit for use.

In Table D I give the results of experiments made at 10° C., on different varieties of oil, and in the manner already described.

TABLE D.

NAME OF OIL.	Minutes required for Solidification at 10° C.	After 24 hours at 10° C. from time of starting.	
		Colour.	Consistence.
Olive Oil (superior)	60	canary yellow	Impenetrable with stout glass rod
Oleic Acid (commercial)	50	{ first blood-red, ultimately lemon-yellow }	Easily penetrable
" Best Nut Oil "	60–90	pale lemon	Soft
Neatsfoot Oil	180	lemon	Barely penetrable
Refined Rape Oil	more than six hours	deep orange	Apparently solid *
Bottle-nose Whale Oil	160	deep lemon	Soft
Sperm Oil (old sample)	(not solid, but very thick in 6 hours)	orange	Buttery
" Ground Nut Oil "	—	orange	Mainly fluid
Cotton Oil	—	orange	Thin turbid fluid
Refined Niger Oil	—	orange	Thin fluid
Cod-liver Oil	—	blood-red	Fluid, with good deal of sediment
Castor Oil (cold drawn)	—	lemon	Much same as original oil
Sesame Oil	—	orange	Very thick fluid
Strained Menhaden Oil	—	dark red	Turbid fluid

* Rape oil gave an apparently solid mass at the end of 24 hours at 10° C., but on standing the bottle in water at 15° C. the whole became fluid. Moreover the stability of the mass at 10° C., if tried with a glass rod, was destroyed, and it became converted into a thick cream.

ture takes place suddenly, whereas at the higher temperatures it is more gradual; and this explains why the results at higher temperatures are less concordant, it being more difficult to estimate the time accurately. It became next of interest to ascertain whether the concordance would hold whether the

It now remains to consider the best mode of applying the test, so as to detect fraudulent admixtures, and though I have made a considerable number of experiments to investigate this point, they are scarcely at present in a sufficiently complete state to record in detail.

The results so far obtained, however, point to the following conclusions:—

- (1) That the test must be made at a temperature not lower than 25° C., and that the temperature must be uniform throughout the experiment.
- (2) That the length of time required for solidification is of far greater importance than the ultimate consistence of the elaidin formed.

Experiments made on genuine olive oils at 25° C. have given the following results:—

	Number of Minutes required for Solidification.		
	Expt. 1.	Expt. 2.	Expt. 3.
Genuine Olive Oil (of superior quality, for eating) ..	200	230	210
Genuine Olive Oil (another sample) ..	230	260	250
Commercial Oil for lubrication; believed to be genuine			
Olive Oil (3) ..	260	—	—
" (4) ..	300	—	—
" (5) ..	300	—	—
" (6) ..	310	—	—
" (7) ..	330	—	—
" (8) ..	365	—	—
" (9) ..	370	—	—
" (10) ..	370	—	—
" (11) ..	390	—	—

The results given in Table E show the influence of certain admixtures:—

TABLE E.

OIL.	Minutes required for Solidification at 25° C.	After 24 hours at 25° C.	
		Colour.	Consistence.
Olive Oil ..	230	} lemon yellow	Hard, but penetrable
" + 10 per cent. Best Nut ..	300		} Softer than pure olive
" + 20 " " ..	310

" + 20 " " ..	from 9 to 11½ hours		
" + 10 " Cotton ..	from 9 to 11½ hours	} lemon yellow	} Very soft butter
" + 20 " " ..	more than 11½ hours		

The oils used in these experiments are those most difficult of detection by the test. The "best nut oil" itself behaves very much like olive oil, so that its influence in modifying the results could scarcely have been expected to be very considerable.

Rape oil has a decided influence in retarding solidification, and also darkens the colour of the product. The effect of cotton oil is very marked.

With regard to other oils, sesame would probably (judging by experiments made at a lower temperature) be more readily detected than cotton oil, and the more strongly-drying oils would exert a still

greater effect. Among the latter is poppy oil, which appears to have a most remarkable influence in preventing the formation of elaidin. Some experiments which I made some time ago with a particular sample of poppy oil, showed that 10 per cent. entirely prevented solidification at 15° C., and with 5 per cent., though solidification took place, some fluid

100cc. 10cc. quantities of this solution were transferred to five stoppered bottles, and to the contents of each bottle there was added an increasing proportion of iodine solution. The bottles were then placed in a dark cupboard, and the contents titrated at the end of 3¼ hours. (See Table F.)

The results of these experiments show that, in

order to obtain the maximum absorption, it is necessary to add about double the quantity of iodine actually absorbed, and to allow the solution to stand at least from three to six, but not more than twenty-four, hours before titrating.

I have confirmed several of Hübl's figures for different varieties of oil, and have slightly extended them. The same has already been done by R. W. Moore (*Chem. News*, li. 172).

In Table G all these results are recorded side by side, and they show a very satisfactory agreement. The process is comparatively simple in execution, and may be looked upon as a valuable addition to the existing methods of assaying certain kinds of oil.

during the past three years. They nearly all represent large bulks of oil, were received at different seasons of the year, and under circumstances best calculated to ensure their genuineness.

The oils, 52 in number, are placed in the order of their *specific gravities*, which range from '9132, the lowest result which I have yet obtained, up to '9159.

7 samples have a sp. gr. below '9140
27 " " " " above '9139, but below '9150
18 " " " " " '9149, " " '9160
I have no results of oils of exactly '9160 sp. gr.

The second column in the table gives the *rise of temperature observed on mixing the oils with sulphuric acid*, and I have only included those figures which

* The “Best Nut” Oil was a non-drying oil of sp. gr. '9163, giving a solid elaidin in seventy-five minutes at 10° C. by the method I have described. The “Ground Nut” Oil showed a decided tendency to dry, had a sp. gr. of '9192, and did not yield a solid elaidin. Both samples yielded a considerable proportion of arachidic acid by Renard's process.

† In an advanced stage of decomposition.

Rape Oil.—The most useful determinations to aid us in giving an opinion upon rape oil are—

Specific gravity.
Rise of temperature with sulphuric acid.
Percentage of alkali required for saponification.
Viscosity.
Melting-point of fatty acids.

In each of these some variation must be allowed.

In the *Chemical News* for 1874, Coleman stated that the sp. gr. of genuine refined rape oil never exceeds '9160. I am not aware that this statement has ever been called in question; and Mr. Allen, in his “Commercial Organic Analysis,” has adopted the figure. I have found it to be a practicable working limit in the examination of a large number of commercial samples; and whenever a sample has come to me from a source which I consider specially reliable, I have always found the sp. gr. fall below '9160.

I have, therefore, used this figure as my principal guide in selecting the typical samples given in Table H from among those which have passed through my hands

have been obtained with 97 per cent acid. These results may be arranged as follows:—

Sp. gr. of Oils.	Rise of Temperature observed. (° C.)
'9132—'9139.....	55°—60°:—Average, 58°
'9140—'9149.....	56—62:—“ 58½
'9150—'9159.....	55—64:—“ 59½

The third column contains the *percentage of potash required for saponification* of the oils. These results may be collected thus:—

Sp. gr. of Oils.	Percentage of KOH required.
'9132—'9139.....	17.00—17.25:—Average, 17.17
'9140—'9149.....	17.04—17.47:—“ 17.29
'9150—'9159.....	17.19—17.64:—“ 17.31

Or the figures may be arranged in this way:—

Percentage of KOH required.
17.0 to 17.1 by 4 samples.
17.1 “ 17.2 “ 12 “
17.2 “ 17.3 “ 9 “
17.3 “ 17.4 “ 14 “
17.4 “ 17.5 “ 11 “
17.5 “ 17.6 “ 1 “
17.6 “ 17.7 “ 1 “

TABLE H.

9159	—	17.19	626	5.5	20	—
9159	57	—	—	—	—	—

The great majority of rape oils, therefore, require less than 17.5 per cent. of potash for their complete saponification.

In examining rape oil, I have frequently derived considerable assistance from a determination of *viscosity*. Reference to the table will show that in no case has the oil taken less than 600 seconds to flow out of my tube; and it will be noticed that a number even so small as this is only met with among the heavier oils on the list, and those which either develop an abnormal amount of heat with sulphuric acid, or require more potash than usual for saponification. In each case where the time required was less than 625—630 seconds, there is something abnormal about the sample. Two instances will be observed in which more than 700 seconds were required. Cotton oil has considerably less viscosity than rape oil, linseed oil less still. Menhaden and other common fish oils resemble linseed in this respect.

The *Free Fatty Acid* of rape oil is seldom large. When the oil is to be used for burning, it is of the greatest importance that the proportion should be as small as possible.

The *Melting point of the Fatty Acids* of rape oil is a useful confirmatory test. The figures given in the table were obtained by the ordinary capillary tube method; but I think a far more satisfactory plan is that described by Bach, and which consists in introducing some of the acids into a narrow test tube of thin glass, and allowing them to solidify. A thermometer is then moved about in the acids, which are very gradually heated by means of a water-bath, and the temperature is observed at which the liquid becomes perfectly clear. The melted acids are next allowed to cool again, and the temperature noted at which a cloud begins to form. The principal use of the test in the case of rape oil is to detect the presence of linseed oil, whose fatty acids remain liquid at a considerably lower temperature than those of rape oil.

The "*Unsaponifiable Matter*" is the extract obtained on shaking the solution of the saponified oil with ether. It would, of course, contain any mineral oil which might be present. The determinations recorded in the table show that oils requiring as little as 17.0 per cent. of potash for saponification were free from mineral admixture.

The *readiness with which the Oil dries on exposure to air* is a further means of verifying the results of the other tests. The best way to proceed is to weigh 1 grm. of the sample on a watch glass, and an equal weight of an oil of known purity on another similar glass, and place the two glasses side by side in a water oven for 24 or more hours. Pure rape oil shows little tendency to dry at the ordinary temperature, but it becomes oxidised much more readily at 212° F. Some rape oil which I smeared on a piece of glass in October, 1883, and which has been freely exposed to the air in a cupboard ever since, is not yet dried, though it has become considerably oxidised.

Olive Oil.—The most generally useful determinations in the case of olive oil are—

- (Specific gravity.
- Percentage of free oleic acid.
- Rise of temperature with sulphuric acid.
- Percentage of potash required for saponification.
- Iodine absorption.
- Elaidin test.

I have already (*Analyst*, ix. 170), shown how very variable the percentage of free fatty acids in olive oil is, and that it may range from less than 1 per cent. in the finest varieties, up to as much as 25 per cent. It is clear, therefore, that the result of the sp. gr. test must be interpreted in accordance with the percentage of free oleic acid in the sample.

In the examination of about 200 samples of olive oil (not all genuine) mostly intended for lubrication, I have, in only two instances, met with more than 24 per cent. of *free fatty acid*, and these samples have had the lowest specific gravity.

	Free Oleic Acid.	Sp. Gr. at 60° F.
No. 1.....	25.1	9138
No. 2.....	21.5	9136

Among the remainder, the *free acid* ranged as follows:—

Percentage of Free Oleic Acid.	Number of Samples.
20 to 24	1
15 .. 10	10
10 .. 15	31
5 .. 10	66
Less than 5	19

According to my experience, the *specific gravity* of genuine olive oil containing less than about 5 per cent. of free fatty acid does not exceed 917 at 60° F.

The liability of olive oil to contain so much free fatty acid seriously reduces its value as a lubricant; but when the oil is to be used for burning, it may prove a still greater source of trouble. I discovered this fact some time ago when investigating the causes of a difficulty in burning olive oil in railway carriage roof lamps.

The following experiments were made with one of these lamps:—

1. A sample of *fine olive oil* with only 1.5 per cent. of free oleic acid continued to burn brilliantly until the supply of oil was exhausted (about 15 hours).

2. A sample of *refined rape oil* containing 2.3 per cent. of free oleic acid also continued to burn in the same lamp until the supply of oil was exhausted.

3. A sample of *oleic acid* in the same lamp commenced to burn with great brilliancy, but in a short time the flame began to fail, and in less than one hour was completely extinguished, that portion of the wick above the holder being completely converted into a brittle charred mass.

4. To the same sample of *rape oil* used in experiment 3, 5 per cent. *oleic acid* was added. The mixed oil continued to burn satisfactorily for only 4 to 4½ hours.

5. Experiment 4 repeated, gave the same result.

The following further experiments were made with ordinary olive oils:—

	Percentage of Free Oleic Acid.	Lamp began to fail in
A.	7.0	4½ hours.
B.	7.0	4½ "
C.	12.6	3½ "
D.	18.0	2½ "

These last results were not all obtained with the same lamp, and they are not strictly comparative. But they serve to illustrate the facts, which are worthy of further investigation.

With regard to the *rise of temperature with sulphuric acid*, the figures given in my remarks on Manmèn's test were not all obtained with acid of 97 per cent. strength. My experience with acid of this strength up to the present, shows that genuine olive oil gives a rise of temperature of from 41½ to 45½° C.

The *saponification value* of olive oil is useful, both as a test for rape oil, and as a means of detecting mineral oil. But I have never yet found mineral oil used as an adulterant of olive oil.

The *Elaidin test* has already been considered. What is now wanted is a number of experiments at 25° C. (and perhaps 30° C.), made in the manner I have described, on genuine olive oils from various sources.

In conclusion, I may add the following remarks:—

Earth-nut Oil of the best quality is a non-drying oil, and its presence in olive oil is not likely to seriously reduce its value as a lubricant. The only means of detecting it, with which I am acquainted, is Renard's process*, based upon the detection of its arachidic acid. The successful carrying out of this process is a most tedious operation; far too much so for it to be useful in cases where time is limited. The results of my experiments show that earth-nut oil delays the solidification of the elaidin at 25° C.; and it may be found possible to get a suspicion of its presence in that way, so that Renard's process can be used subsequently if required.

Rape Oil darkens the colour of the elaidin, besides delaying its solidification. This oil also reduces the percentage of potash required for saponification, and may be detected by means of its sulphur. Mäilho's test, which consists in boiling the oil with a 10 per cent. solution of pure potash in a silver dish, is one method of doing this; but its indications are uncertain. In one experiment I succeeded in detecting 5 per cent. of rape oil; but in two others, made with the same oil, 5, and even 10 per cent. were undetected.

Cotton Oil has a very marked influence in delaying the solidification of the elaidin at 25° C. It also raises the sp. gr. of the oil, and increases the rise of temperature with sulphuric acid.

Sesame Oil can be detected, even in traces, by shaking the oil with hydrochloric acid and sugar. 10cc. of the sample should be mixed with 5cc. of hydrochloric acid (sp. gr. 1.16), containing 1grm. of sugar in solution. The mixture is shaken for at least ten minutes, and then set aside. I have repeatedly proved that one drop of sesame oil in 10cc. of olive oil is sufficient to impart a distinct rose colouration to the acid which separates on standing.

Poppy Oil I have already referred to, and other possible adulterants call for no special remark.

Action of Light on Olive Oil.—In the *Journal of the Chemical Society* for 1871, page 1192, there is an abstract of a paper by L. Moschini (*Gazzetta Chim. Italiana*, i. 580), in which the author states that olive oil, by exposure to sunlight, is bleached, loses the property of giving a greenish colouration with acids and with caustic soda; loses also the property of forming elaidin (I suppose this is what is meant, though the abstract is scarcely intelligible), and acquires a rancid taste and odour.

Some time ago I had a sample of olive oil—a very fine sample, and of the usual yellow colour—part of which was kept in a wine bottle on a dark shelf, and part stood in a white glass bottle freely exposed to the diffused daylight (and possibly occasional sunlight) of the laboratory. This portion was found after a time to have acquired a pale green colour, while the other portion was unaltered. On further examination the following results were obtained:—

Original Oil.	Same Oil preserved in the dark.	Same Oil after exposure to light.
Free Oleic Acid	4.0%	1.0%
Rise of temperature with Sulphuric Acid	40.5° C.	52.5° C.

There was not enough oil to make any more experiments; but I hope to investigate the subject more fully, as it is one of great interest and importance.

* Some results recently obtained with this process appear to show that it requires further investigation.

DR. RAMSAY IN THE CHAIR.

ON THE JAPANESE METHOD OF MAKING WHITE LEAD.

BY R. W. ATKINSON, B.Sc.

WHILST living in Japan I had the opportunity of seeing this process in operation, and so far as I am aware no one else has made any mention of it; on which account, and also because it presents some novelties, I trust I may be permitted to give a short description.

White lead is there very largely used as a cosmetic, almost every woman in Japan when fully equipped being painted on the face and neck with it to a greater or less extent. It is also very largely used by actors, especially by those who personate female characters (women not being permitted to act on the stage), and this extensive use of the material as a cosmetic offers a field for medical research on the subject of lead-poisoning which is perhaps unique.

Numerous cases are given by Dr. Taylor, in his treatise on Poisons, of lead-poisoning resulting from the use of white lead as a cosmetic, though it is proper to state that the inference drawn from these cases is disputed by M. Tanquerel, who maintains that so long as the powder does not come in contact with any abraded surface, absorption into the system does not take place. And so far as I could learn from the evidence of M. Nagayo, then Chief of the Department of Public Health in Japan, as well as from conversations with actors and medical men, none of the usual symptoms of lead poisoning have been there noticed arising from the use of white lead, although cases of plumbism occur amongst the workmen engaged in its manufacture.

The absence of injurious action may, however, be caused by the presence in the powder used for the toilet of a large proportion of starch, which would reduce the number of points of contact between the powder and the skin.

The following is a description of the method of making the white lead as I saw it carried out in the works of Mr. Murakawa, of Kiyoto, who gave me all the information I asked for with the greatest readiness.

The appearance of the plant was certainly different from anything found in this part of the world. Around the sides of the room a platform one foot high ran, and upon this, at intervals of about

three feet, rose wooden cylinders about twelve feet high and two feet in diameter. These are built up as follows:—A good solid floor is first selected, and upon this is built a platform of brick about one foot above the ground, supported at intervals of about three feet upon brick walls, which, with the top, form a recess. In the centre of the roof of each recess a small round aperture is left to receive a coarse earthen dish which is filled with weak vinegar. The space round this dish is carefully filled up with clay, so that to all appearance there is no communication between the recess and the space above the earthen dish. Over this dish a half-barrel, about two and a half feet high, is placed, provided with an opening at the side to allow access to the dish, and usually carefully closed. About the middle of the half-barrel a bamboo grating is made, upon which the rolls of metallic lead rest. Upon the upper part of this half-barrel rests one of the tubs used for holding *sake* (Japanese rice beer) with the bottom removed and upon the top of this one another is placed, and so on to the number of four. The lower part of the barrel is a little wider than the upper part, so that the upper barrel covers the lower one to a small extent, and the space between the two is filled with clay. Before the apparatus is built up the plates of metallic lead have to be prepared. The lead used at these works was brought from Marseilles. It is first melted at a low temperature and poured upon a shallow iron dish shaped like a shovel. The contact with cold metal causes the lower part to become very quickly solid, while the upper part is still liquid. The latter is then poured away, and a thin sheet of lead is produced, one surface of which is rough and therefore presents more points of contact for the action of the vapour of acetic acid. These sheets are then rolled up and packed vertically upon the bamboo grating before-mentioned. The first hollow barrel is now placed on the top of the half-barrel and likewise filled with rolls of lead in the same way, and so on; each barrel as it is put in position is packed with lead, whilst the uppermost one is covered with a wooden cover, and the edges tightly closed by means of paper and glue. In the works visited there were 21 of these cylinders, all of which were charged at the same time. Weak vinegar is now placed in the earthen dish and a charcoal brazier introduced into the recess, so that it heats the bottom of the dish and evaporates the vinegar. The position of the charcoal fire-box in the recess is to be carefully regulated in order to avoid an excessive heat which would cause the vinegar to be wasted. Fresh vinegar is added from time to time as it is required, about $\frac{1}{2}$ -litre per day for each cylinder being the average amount. The temperature at the bottom of the cylinder was found to vary in different cases from 127° F. to 148° F. As all the furnaces were closed at the top, and removing the covers would have caused loss of vinegar, it was impossible to measure more than one, which we found to be 114° F., the temperature at the bottom of the same furnace being 132° F., a difference of 18° F.

At the end of twenty days the covers at the top are removed, and if the surface of the lead is found to be coated with a white powder the process is stopped, although the whole of the lead has not yet been converted into the carbonate. The apparatus is allowed to cool, and each roll of lead as it is removed is beaten to break off the scale of white lead with which it is covered. The scale is then placed under water in wooden tubs and constantly agitated by means of wooden poles in such a way as to reduce it to the finest possible particles; the milky liquid being then passed through fine sieves and collected in a settling vat. In the centre of this vat, which is

about three feet high by three feet in diameter, there is a cylinder of bamboo gauze, covered with fine cloth in order to prevent the passage of any solid particles into the interior, and the water which finds its way through the cloth is drawn off by means of a syphon. In this way the water is rapidly removed and a thick paste is obtained, which is further dried in shallow, unglazed earthenware dishes, about two and a half inches deep and seven inches square, piled upon one another to a considerable height. Sometimes these are placed on the tops of the cylinders in which conversion is taking place, so that they are gently heated, and by this means the cakes of white lead are more quickly dried. Before they are quite dry, the cakes are cut into square pieces for the convenience of purchasers, and covered with paper. This forms the first quality of white lead. A second quality is obtained by grinding the residue left in the vats and on the sieves in stone mills, submitting this material to levigation and drying as above described.

The weight of lead put into the twenty-one cylinders amounted to 35,000lb. The vinegar used contained 0.942 per cent. of acetic acid, and during the twenty days for all the cylinders 315 litres were used, which would, therefore, contain 11.25lb. of pure acetic acid.

No very certain information was obtained concerning the amount of white lead produced in one operation, the workmen saying that 2700lb. were obtained, and also that it filled a barrel, which was afterwards ascertained to have a capacity of $28\frac{1}{2}$ cubic feet, and when full would, therefore, hold nearly 12,000lb. of white lead. It is probable that the real number lies between the two above given; but assuming the lower one to be correct, it proves that Dr. Ure's theory is not correct even in this case, where it is not evident from what other source the carbonic acid can come. This theory supposes that a hex-basic acetate of lead is formed, $Pb(C_2H_3O_2)_2 \cdot 5PbO$, which by oxidation breaks up into the carbonate and water, thus:—

On this theory 120 parts of $H_2C_2O_2$ ought to yield 1550 of white lead, and 11.25lb. would, therefore, produce not more than 145.3lb. of white lead, whereas the lowest estimate is nearly 3000lb. The composition of the white lead produced corresponds with that prepared by the Dutch and German methods.

Oxide of lead	86.42 per cent.
Carbonic acid	11.60 " "
Water	2.00 " "
	<hr/> 100.02 <hr/>

Those familiar with the two foreign processes just mentioned will see from this brief description in what points the Japanese method differs from them. Whereas in the European methods the source of the carbonic acid is well-known, in the process carried out in Japan every care appears to be taken to exclude the gases which rise from the charcoal fire; but in the absence of any other source, I see no way to account for the successful conduct of the process except by supposing that the products of the combustion of the charcoal leak in through accidental crevices, although only in one case was I able to detect any.

The white lead is sold of several qualities, the best and second best being unmixed with any other substance, and costing 7d. and 7d. per pound respectively. The two lower priced kinds are mixed with starch in the proportion of 7lb. white lead to 10lb. of starch.

Obituary.

JAMES MUSPRATT.

ON Tuesday, 4th May, James Muspratt, the founder of the South Lancashire Alkali Industry, which has its principal seat in the neighbourhoods of Widnes, St. Helens, and Newton, with which may be included Runcorn and a portion of Flintshire, died at Seaforth Hall, near Liverpool, at the ripe old age of 93 years. He preserved his strong and characteristic faculties to the end. Not only was he a veteran manufacturer and founder of an industry, which in the districts referred to has for many years given employment to and found sustenance for hundreds of families, but he was a veteran, and a hero too, in the more literal sense, in connection with the service he saw and strove to render, and the moral courage he displayed in connection with the Peninsular War at the commencement of this century. But, in being denied the dangers and glory of a soldier's career, he was preserved for more peaceful contests on higher ground than the battlefield.

James Muspratt was born in Dublin, on the 12th of August, 1793, and received a good commercial education, which his natural quickness and aptitude of acquirement, as well as love of learning, enabled him to make the most of. At fourteen he was apprenticed to a wholesale druggist and apothecary named Mitcheltree, with whom he acquired some practical knowledge of chemistry, which served him well in later life when thrown on his own resources. At that time there were no facilities for learning science such as exist at the present day, but the intimate knowledge of drugs and chemicals, acquired in the laboratories of apothecaries, gave a practical training of no small value. From such laboratories sprang many of the most eminent chemists of the last generation, such as Liebig, Pettenkofer, and Nicholas Leblanc.

A quarrel with his master terminated the apprenticeship in 1810, and he returned home; but as his father died in or about that year, and his mother in 1811, he was left to make his own way in the world. For his mother he had a deep veneration, and she no doubt had great influence in the development of his character. His father's small property was involved in a chancery suit, and, weary of waiting for its termination, and having exhausted what little ready money he possessed, he embarked for Spain in 1812 to join the army and seek his fortune as a soldier.

In Spain, though unable to obtain the commission in the cavalry he coveted, on account of lack of influential support, and still hoping to attain the object of his wishes, he followed the track of the army far into the country, enduring the hardships and perils of a soldier's life. Subsequently he was stricken with fever in Madrid, but this his robust constitution enabled him to conquer, and narrowly escaping falling a prisoner into the hands of the French, he reached Lisbon, where he obtained a minor post on board a fast sailing warship, in which he afterwards saw some service off Brest. A less congenial post in another vessel, rendered at length insupportable by the stringent discipline imposed, compelled

him to desert his ship at the risk of his life. This successfully effected, he returned to Dublin, where he spent some short time in literary pursuits, pending the decision of the Court of Chancery with respect to a small property his father had left him. The chancery suit terminated, he found, as is not uncommonly the case with such suits, very little of the property left for division amongst the family, and Mr. Muspratt was impelled to turn again to the source first pointed out to him by his father when he apprenticed him, and now he seemed to recover his right position on the right path. He commenced the manufacture of acetic acid, hydrochloric acid, spirits of turpentine, and other chemicals, and after a few years entered into partnership with Mr. Abbot, who possessed some capital, and commenced the manufacture of prussiate of potash on a considerable scale. During this period the subject of the manufacture of artificial soda never ceased to occupy his thoughts. From one or two treatises on chemistry, such as Nicholson's Dictionary, he obtained a glimpse of the theory of the manufacture as proposed by Leblanc, and from calculations of the equivalents of the materials used and the products obtained, he saw a prospect of large profits.

But the initial stage of the manufacture—the erection of sulphuric acid chambers—required capital which he could not command. After a time he became convinced that to successfully compete with kelp he would have to remove to England, where the raw materials of the manufacture were so much cheaper. He waited some years, until he thought he had acquired sufficient capital to risk the transfer of his business to England. His partner, Mr. Abbot, would not join him in the venture, so he came over by himself to Liverpool in 1822, and in a few weeks arranged for the lease of land on the canal bank, in Vauxhall Road, and erected the works which are still in existence. The place he took was an abandoned glassworks, and the country round was quite unbuild on. Not having sufficient capital to erect suitable plant for making sulphuric acid, he continued the manufacture of prussiate of potash, and with the profits realised commenced the erection of sulphuric acid chambers. Already in Dublin he had erected sulphuric acid chambers, and by numerous improvements he eventually succeeded in reducing the cost of making the acid, part of which he sold, using the remainder for the production of hydrochloric and nitric acids, and sal ammoniac, which he obtained by treating the ammoniacal liquors from the gasworks. In 1823 Mr. Muspratt commenced the manufacture of soda by Leblanc's method. He effected considerable improvements in the manufacture of the crude soda (black ash), in which form it was first used by the soap manufacturers. Notwithstanding the difficulties he encountered in inducing the soap makers to use it, the advantages of using the stronger and cheaper soda after a time became apparent, and he was forced rapidly to increase the manufacture in order to meet the demand. The black ash was sold on the basis of 20 per cent. of alkali, but usually tested 24 per cent., and the price in or about 1824 was 12s. per cwt., equivalent to £24 per ton for 48 per cent., but by the year 1830 the price was reduced to £8

per ton in bulk for black ash of 24 per cent., and the demand continued to increase so much that he erected works in 1829 at St. Helens, in partnership with Mr. Gamble, and in 1830 commenced the large works at Newton.

For upwards of 30 years, notwithstanding the litigation in which he was engaged, Mr. Muspratt endeavoured to cheapen the cost of manufacture by lessening the price of the raw materials—coal, salt, and sulphur,—which, under the stimulus of increased demand, rapidly advanced.

In conjunction with Mr. Tennant, of Glasgow, he purchased sulphur mines in Sicily, and salt-works at Winsford.

But the litigation referred to already, was not the only difficulty Mr. Muspratt had to contend with. One of the raw materials used, sulphur, was then a monopoly of the Neapolitan Government, and in 1834–5, Mr. Muspratt, in partnership with Mr. Tennant, of Glasgow, bought some mines in Sicily, in order, by introducing improved methods of raising the mineral, to cheapen the cost of the article to the consumer. The King of Naples, with that short-sightedness common to governors, imposed a duty of £4 per ton on all sulphur exported to England, thus giving a monopoly to a French firm, Messrs. Tair & Co., of Marseilles, and, as this was a manifest infraction of the treaties, the English protested, and this protest, supported by the presence of the British Fleet, induced the king to extend the duty to all sulphur exported, which he had a perfect right to do. But neither king nor people can infringe the laws of political economy with impunity.

The effect of the legislation was that Messrs. Muspratt and Tennant, whose mines had unfortunately been inundated during the progress of the negotiations, gave up the enterprise, and looked at home for a substitute, which they found in iron pyrites, large mines of this mineral having been found in county Wicklow, Ireland. Many inconveniences and difficulties were encountered in its use, but in a short time these were overcome, and the use of native sulphur in the manufacture of alkali has long been abandoned. For a time, when the export duty was remitted and sulphur fell to its normal price, the competition between the two minerals was keen, but on the introduction of pyrites, which also contained copper, from Spain and Portugal, in the year 1857, the economical advantages were so greatly in its favour that after a time its use became universal, and about 670,000 tons are imported annually.

Mr. Muspratt, at a time when many English manufacturers depended entirely on "rule of thumb," had recourse to the best scientific knowledge of the day to improve his processes.

He engaged Mr. James Young (of paraffin celebrity), who at the time was assistant to Professor Graham, at University College, London, to superintend the laboratory at Newton and carry out experiments for improving the manufacture. One great object was to dispense with the intervention of sulphur and sulphuric acid in the decomposition of salt; and about the year 1840 Messrs. Dyar & Hemmings' ammonia-soda process was worked on a considerable scale for some years, but was ultimately abandoned, as, owing to the imperfection of the apparatus and consequent loss of ammonia, the alkali produced cost more than by the old process.

He also endeavoured, in the year 1839, to recover the sulphur from alkali-waste, under Mr. Gossage's patent, and under that gentleman's personal supervision, but the results were unsatisfactory.

It may be interesting to note the great effect produced on the prices of alkali, sulphuric acid, and sulphate of soda by the development and improvement of chemical manufacturing operations.

In 1823, when he commenced the manufacture, soda-ash was sold at the equivalent of £24 per ton of 48 per cent.; but considering the inaccuracy of the test and the improvement of the quality of refined ash, the value was nearer £30 per ton. In 1852 the price was £10 per ton, and to-day, owing to the ammonia soda competition, £4 per ton.

Sulphuric acid, when Mr. Muspratt commenced its manufacture, was 3d. per lb.; it now sells at less than 3d. per lb. Soda crystals, in 1817, were £60 per ton; they fell gradually to about £40 per ton, and are now selling at about as many shillings. Sulphate of soda (guaranteed to contain not more than 10 per cent. of salt, equivalent to about 88 per cent.) which cost, so late as 1835, £7 per ton, is now sold (guaranteed 95 per cent. and upwards) at 2s. per ton.

When we consider how indispensable each of these articles is to the manufacturing industry of the nation, some conception may be had of the boon conferred by the development of the manufacture of alkali, which was the life-work of Mr. Muspratt.

Mr. Muspratt was well acquainted with most of the eminent chemists of a former generation, and more particularly with Graham, the late Master of the Mint, and Dr. Thompson. Sir Lyon Playfair, Dr. James Young, Professor Knapp, and many others well known in the chemical world worked and gained much experience in the laboratory of his works. In 1837, when the British Association first came to Liverpool, he met for the first time Professor Liebig, and then commenced the close friendship between them which only terminated with the death of the Baron in 1873. Whenever Baron Liebig came to England he sought out Mr. Muspratt, and was his companion in several journeys through Ireland and Italy. It was natural that when the great German chemist wished to put his theories of agriculture into practice he should turn to Mr. Muspratt, who undertook the manufacture of Liebig's patent manures. An error in the theory of the way in which manures are assimilated by the soil led to the attempt to render some of the substances used less soluble; this was fatal to the commercial success of the speculation. The manufacture was abandoned, but the making of superphosphate and other artificial manure has resulted from the experiments of Liebig, carried on in conjunction with Mr. Muspratt.

From the years 1842 to 1854 Mr. Muspratt lived on the Continent, in Giessen, Munich, and Italy; since then in comparative retirement at his residence at Seaforth, now that of his son, E. K. Muspratt, Esq., the President of the Society of Chemical Industry.

He continued to the last to take a lively interest in business and politics, and his love of reading afforded him ceaseless enjoyment when failing health kept him constantly confined to his room.

During the many reactions from Liberal opinions, Mr. Manspratt remained always true to the Liberal cause. When many of his former friends at the time of the great American war were warm supporters of the South, he remained true to the principles of liberty, which were represented, notwithstanding many superficial blemishes, by the North. At the time of the great Free Trade struggle, he was prevented by his business engagements from taking a prominent part in the movement, but he was one of the first subscribers to the League, and remained through life a staunch Free Trader.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in Registering Thermometers or Thermographs. W. Müller, London. From Carl Derckmann, Dortmund. Eng. Pat. 7147, June 11, 1885. 11d.

This invention relates to apparatus for continuously and automatically recording successive temperatures of a room or body during a certain period of time, similar to the means by which steam pressures are recorded in registering indicators. For actuating the recording pencil, the inventor employs the longitudinal expansion of a metal rod, its range of motion being multiplied by a lever or levers. The pencil marks a piece of travelling paper ruled in two directions for divisions of time and temperature, and an electric bell or other signal may be put in action by the lever to call attention to the attainment of any pre-arranged heat.—B.

An Improved Thermostatic Heat Recorder and Electric Signal. J. Gilmore, Lower Norwood, and W. R. Clark, London. Eng. Pat. 7153, June 11, 1885. 8d.

This relates to apparatus for indicating by electric signal the highest or lowest permissible temperature of any place. The inventors use a flat strip composed of two strips of metal of unequal expansion, the strip being fixed at one end, and allowed free lateral movement at the other. The free end carries a pin which comes in contact with one of two pivoted insulated metal bars according as the higher or lower limit of temperature is reached, and thereby completes an electric circuit which causes a signal to be given either by a bell or any other means. The pivoted bars are adjustable around their pivot, and are set by a dial plate to the limiting temperatures. The moving pin can also be attached to a pointer indicating on the same dial the actual temperatures existing in the place at any moment.—B.

Improvements in Evaporating Apparatus. H. H. Lake, London. From J. F. Oakes, New York. Eng. Pat. 7964, June 30, 1885. 8d.

This is an apparatus for evaporating and concentrating liquids, such as dyes, by leading them through a chamber fitted with heating pipes, and through which at the same time a current of hot air or gases is allowed to pass. The accompanying figure will explain the system.

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Lack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.	1d.
Above 8d., and not exceeding 1s. 6d.	1d.
" 1s. 6d., " " 2s. 10d.	11d.
" 2s. 10d., " " 3s. 10d.	2d.

The inner space of the chamber carries a series of shelves down which the liquid to be concentrated is allowed to trickle, encountering in its course a serpentine range of heated pipes over which it spreads in its descent. The sides of the chamber form reservoirs for

heated air, which issues under slight pressure from the openings shown through the sides under the shelves, whilst the vapour-laden air escapes through the short tubes above these shelves, either into the atmosphere or into outer receivers.—B.

New or Improved Apparatus for and Process for Producing, Applying, and Keeping up Extreme Temperatures. E. Solvay, Brussels. Eng. Pat. 13,466, November 6, 1885. 8d.

THE inventor proposes to produce high temperatures by subjecting gases to successive compressions, the heat resulting from each compression being utilised in the compressor itself for raising the next charge to a higher temperature—the compressed air issuing finally at the desired degree of heat, for instance, such as may be required for the fusion of metals and minerals. Similarly the inventor produces intense cold by repeated exhaustion of gases, the cold resulting from each exhaustion being used to cool the next incoming charge until very great reduction of temperature is reached, such, for instance, as may be required for the liquefaction of gases.

The principal part of the apparatus consists of a pump with a very much prolonged plunger and cylinder, the prolongations leaving a small annular space between them. This space serves as passage from and to the inlet and outlet valves, and constitutes with its large surface an accumulator for the heat, or cold, as the case may be. The cylinder is surrounded by non-conducting materials, and for further particulars the specification should be consulted. The patent also embraces a reservoir for preserving liquefied gases under ordinary atmospheric pressure.—B.

II.—FUEL, GAS, AND LIGHT.

Improved Method of Expanding Gases and Vapourising Fluids by Direct Intermixture and Molecular Contact with Heated Gases. C. J. Ball, London. Eng. Pat. 4023, December 29, 1885. 8d.

THE main feature of this invention is that the liquid to be vapourised is brought into a fine spray or other state of minute division, and, in this condition, comes directly into contact with the flame and highly heated gases produced by the combustion of any suitable gas with the

required quantity of air. A pressure of 100 lb. per square inch is recommended in the gas-burner, and 90 lb. per square inch in the vessel where the spray comes into contact with the flame.—A. R. D.

Apparatus for Compressing Coal and introducing the same into Coke Ovens. H. J. Haddan, London. From Julius Quaglio, Berlin. Eng. Pat. 10,438, January 4, 1886. 11d.

The compressor consists of a portable apparatus for producing a compressed block of coal of the shape of the coking chamber. The side walls of the compressor are taken off when the block is formed, and the compressed mass is run into the chamber by a suitable contrivance, being held in position meanwhile upon the bottom of the compressor by the two ends thereof. The bottom is then drawn out, and the doors of the oven made tight.

Full details and drawings are given in the specification.—A. R. D.

Improvements in the Manufacture of Artificial Fuel and in Machinery employed therein. S. Butler, Cardiff. Eng. Pat. 4798, January 16, 1886. 11d.

This invention consists in the combination of the two processes known to manufacturers as steam and dry heat. The material passes through a steam pug, where steam is injected into it, and from here is carried by various mechanical contrivances, enumerated in the specification, over heated iron surfaces, or into contact with a hot-air blast, for the purpose of removing the moisture absorbed in the pugging process.—A. R. D.

Improvements in Gas Producers. A. Wilson, Stafford. Eng. Pat. 5880, February 15, 1886. 11d.

Air, or a mixture of air and steam, is injected through the fuel in a combustion chamber, which it enters by a vertical pipe placed inside the chamber, so that it first comes into contact with the lower portions of the fuel, and passes upward through the mass. The injector is so situated with regard to the charging hopper and poking holes that any gas escaping here is drawn into the vertical pipe and passes back to the interior of the combustion chamber.—A. R. D.

Improvements in the Purification of Air or Gases from Solid or Gaseous Impurities contained therein, and Apparatus therefor. A. Gentard, Mockau, near Leipsic. Eng. Pat. 6931, March 4, 1886. 8d.

The gases to be purified are caused to pass between wet plates of suitable material set at suitable distances from one another. The plates are either fixed or movable, as may be judged best for effecting the moistening of their surfaces in particular instances.—A. R. D.

Improvements in Machinery or Apparatus for Manufacturing Blocks of Artificial Fuel. J. Y. Johnson, London. From La Société Anonyme des Forges et Chantiers de la Méditerranée of Paris. Eng. Pat. 6884, March 5, 1886. 8d.

By a mechanical contrivance described in the specification and applicable to any ordinary moulding machine for this purpose, the blocks are made with perforations so that they can be broken up without crumbling, and at the same time allow of the economy which obtains in the manufacture of the larger sizes.—A. R. D.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Recovery of Hydrocarbons from Aromatic Sulphonic Acids by means of Superheated Steam. W. Kelbe. Ber. 19, 92–94.

ARMSTRONG'S process of treatment with steam at 100° (J. Chem. Soc. 1884, 148) being said by the author to

give unsatisfactory results with, for instance, bromotoluenesulphonic acid, the author modified the process, employing instead, steam superheated by passing through a copper tube heated to bright redness in a combustion furnace. Decomposition then proceeds both quickly and regularly, water and hydrocarbon distilling over in about equal proportions. The flask containing the dry sulphonic acid, or one of its salts, with sufficient sulphuric acid (3 acid to 1 water) to decompose it and form a thin emulsion, is heated during the operation in an oil-bath from 180–220° C. As under these modified conditions the dry sulphonic acid alone is readily attacked, when using a moist acid, it is unnecessary to use an excess of strong sulphuric acid beyond that needed to bind the water. The yield of hydrocarbon was very good; as an example, from potassium bromopseudocumenesulphonate, 95% of the theoretical quantity was obtained. Bromo-derivatives obtained in this way appear to behave differently towards oxidising agents to those obtained in the usual method, being much more stable. Orthobromotoluene and bromoxylene were not at all oxidised by long continued boiling with a mixture of 1 vol. nitric acid (sp. gr. 1.205) and 3 vols. water. The author is now further investigating this behaviour.

—T. L. B.

Base Isomeric with Benzidine formed by passing the Vapour of Aniline through a Red-hot Tube. A. Bernthsen. Ber. 19, 420–425.

THE behaviour of aniline vapour when passed through a red-hot tube was investigated by Hofmann (Proc. Roy. Soc. 12, 383), and Graebe (Jahresber, 1862, 335), who isolated benzene, hydrocyanic acid, ammonia, benzonitrile and carbazole, and observed the formation of a high boiling base, but did not investigate its properties. Having repeated this reaction the author found that this oily base consists of *Isobenzidine* $C_{12}H_{12}N_2$, which crystallises in snow-white iridescent plates melting at 125°. This base closely resembles benzidine in some of its properties, but differs from it in the following reactions: Its aqueous solutions are not affected by potassium ferricyanide in the cold. With chlorine water the base gives a grey, and subsequently greyish-brown colouration, and, on standing, separates a brown precipitate. Benzidine with the first drop of chlorine water would have given a splendid blue colour, becoming on further additions bluish green, and then red. The solution of *Isobenzidine* in carbon bisulphide gives only a slight red colouration with bromine water. Concentrated nitric acid turns the base a greenish-black colour without sensibly dissolving it. Benzidine is dissolved with a yellow colour, accompanied by the separation of a white substance. The hydrochloride $C_{12}H_{12}N_2 \cdot 2HCl$ forms greyish white laminae.

Besides *isobenzidine*, quinoline, a colourless oily base and other compounds were separated from the basic oil obtained in the above reaction.—D. B.

The Presence of Methyl Alcohol in the Products of Distillation of Plants with Water. Maquenne. Compt. Rend. 101, 1067.

THE author finds that fresh plants distilled with water yield small quantities of methyl alcohol. In certain cases the quantity obtained amounts to 0.3% of the weight of the plant. About 15 to 20 kilos. of the plants are distilled with 40 to 50 litres of water. The methyl alcohol either exists ready formed in the plant, or it is produced as a decomposition product during the process of distillation.—E. G. C.

Improvements in Hydraulic Mains for Gasworks. C. D. Abel London. From F. A. M. Alavoine, Beauvais. Eng. Pat. 6257, May 21, 1885. 8d.

THIS invention consists in fixing to the dip-pipe of the ascension-pipe in gasworks horizontal sieve-like plates situated beneath the water-level in the hydraulic main, and so arranged as to subdivide the gas issuing from the dip-pipe, and to cause it to travel a long distance in con-

tact with the water. By another arrangement, the tar is made to run off simultaneously with the gas-liquor. A constant depth of the liquor is thus maintained, and the necessity for frequent cleansing is also avoided. The object of this invention is to retain in the hydraulic main a large portion of the condensible products of the gas, which is of great importance for the application of gas-works to workshops, where the great cost of condensers forms an obstacle to their adoption. With this apparatus 90 per cent. of the tar produced is said to be retained in the hydraulic main, whilst the formation of pitch is completely avoided, owing to the constant flow of the tar. An increase of from 4 to 5 per cent. is obtained in the illuminating power of the gas.—D. B.

Improved Manufacture of Turpentine from the Resins of Conifers. C. D. Abel, London. From E. Schaal, Stuttgart. Eng. Pat. 15,471, December 16, 1885. 4d.

The resins of conifers, such as fir resin, colophonium, Burgundy pitch, etc., are distilled in a partial vacuum. The distillates, passing over at a temperature of from 250–280° C., are mostly oleaginous mixtures of turpentine oil and resin oil, which are utilised in manufactures. The distillates subsequently given off at temperatures up to about 300° C., and even higher, yield a turpentine closely resembling Venice turpentine, and exceeding the same in clearness and purity. The degree of heat to be applied will depend more or less upon the size, shape and arrangement of the distilling vessels, and on the degree of vacuum employed. Similar results will be obtained if, instead of being treated in a partial vacuum, the resins are distilled in the presence of neutral gases, or of superheated steam.—E. G. C.

Improvements in the Distillation and Decomposition of Coal, Shale, and other Matters to obtain Illuminating Gas and other Products. H. Kenyon, Manchester. Eng. Pat. 1016, January 23, 1886. 6d.

THE inventor claims the following novelties:—(1) A process of making illuminating gas, consisting in the introduction of paraffin or hydrocarbon oils and superheated steam into the distilling ovens at certain stages of the process. (2) A process of making illuminating gas, wherein the distilling ovens are worked in pairs, the gases from the last-charged oven in a pair being passed into the other oven, paraffin or hydrocarbon oils being injected into the last-charged oven, and superheated steam into the other oven. (3) In order to increase the yield of ammonia in the manufacture of water- or heating-gas by the discharge of superheated steam through incandescent coke, an additional supply of superheated steam is introduced into the upper part of the oven above the coke. (4) The production of cyanides by quenching or treating the coke with alkaline solutions, and rendering the coke thus treated incandescent in a suitable chamber or furnace, and by passing superheated steam and heated air through the coke, the cyanides being recovered from the ashes by lixiviation; or, as an alternative, before withdrawing the residue from the chamber, superheated steam may be passed alone through the coke, in which case the cyanides are decomposed, ammonia being liberated. The alkali may then be recovered from the residue by lixiviation and used again.—D. B.

Improved Means for Distilling Turpentine, and for the Purification of the Crude Products of Distillation thereof. E. W. McClave, New York. Eng. Pat. 1511, February 2, 1886. 8d.

THIS invention relates essentially to the treatment of the crude products obtained from pine-wood when subjected to heat in a retort. The retort is set in a furnace in which the heat-products are distributed in order to prevent concentrated impingement on any portion of the retort subject to the ascending currents. From the condenser, to which the vapours from the retort proceed, the crude products are first caused to pass through a trap, with special contrivance for facilitating the removal of

poisonous and inflammable gases. The vapours, after condensation, are collected in settling tanks, wherein the liquid products separate in an oily and a subjacent acid portion. The oily portion is redistilled by means of steam in a suitable still, the pure turpentine thus obtained passing through a condenser to the proper receptacle. This product is obtained from the crude spirit extracted from the wood before it begins to char in the retort. The crude oils unfit for purification resulting from continuing the operation are separated by withdrawal from the tank after the first products have passed into the steaming still, the passage from the tank to the still having been closed. Besides these products, a pitchy base remains in the retort useful for paints, varnishes, and other purposes.—D. B.

IV.—COLOURING MATTERS AND DYES.

Bases of Methyl-violet and of Magenta. H. Wiechelhaus. Ber. 19, 107–110.

THE methyl-violet obtained from pure dimethylaniline consists of a mixture of two bases, very troublesome to separate perfectly, as the author has shown in a previous paper (Ber. 16, 2006, and this Journal, 1884, 26). The amorphous base forms salts, which dry down into yellow or copper-coloured glittering masses, and dye an intense violet with a reddish-brown tone. Owing to the rapidity with which the leuco base reoxidises, it could not be prepared in a sufficiently pure state for examination: recourse was therefore had to the products obtained by decomposing a salt of the ordinary base with hydrochloric acid. On cohabiting the hydrochloride for about 200 hours with an excess of acid, it is decomposed slowly, but completely, into dimethylaniline and trimethyldiamidobenzophenone—

This substance is a base crystallising from alcohol in groups of small acicular crystals, melting at 156°. It forms a crystalline platinochloride, and on reduction yields a hydriole. From this, it follows that the amorphous base of methyl-violet is pentamethyltriamidotriphenylcarbinol. The well-formed crystals of the crystalline base melt at 195°; they are easily soluble in ether, acetone, and petroleum spirit; less soluble in alcohol, easily soluble in CS₂, chloroform, and benzene. The salts crystallise well, and dye a blue violet. Decomposition with hydrochloric acid resulted in the formation of dimethylaniline and tetramethyldiamidobenzophenone, melting at 178°, already described by Michler and Dupertius (Ber. 9, 1900). The crystalline base is therefore *heexamethyltriamidotriphenylcarbinol*. Pararosanine and rosaniline, on decomposition in a similar manner with hydrochloric acid, both yielded the same amidoketone, CO(C₆H₄NH₂)₂, the former giving at the same time aniline, and the latter orthotolidine. The ketone is sparingly soluble in the usual solvents, crystallises from alcohol in needles, melting at 237°. The sulphate and hydrochloride crystallise well in flat needles.—T. L. B.

Azo-derivatives of Metaxylenol. E. Grevingk. Ber. 19, 148.

ON mixing an alcoholic solution of metaxylenol with diazobenzenechloride, *phenylazo-metaxylenol*—

is formed. From petroleum spirit it crystallises in fine hair-like needles of a brownish-red colour with violet reflex. It melts at 175°, is insoluble in water, easily soluble in alcohol, ether, petroleum spirit, chloroform, and benzene. Diazobenzenesulphonie acid also combines with metaxylenol in a similar way, forming a sulphonie acid, dyeing wool and silk a brownish yellow. The sodium salt is a yellowish-brown flocculent precipitate. The barium salt—

is very sparingly soluble in water. On reduction, sulphanilic acid and orthamidoxylene is obtained.—T. L. B.

Ethylparaphenylenediamine. W. Schweitzer. Ber. 19, 149–150.

PARANITROETHYLANILINE can be most conveniently prepared by heating a mixture of 14grms. paranitraniline with 11grms. ethyl bromide and 6grms. of potash dissolved in alcohol, for 3 to 4 hours in a sealed tube at 100–110°. This compound yields, on reduction with tin and hydrochloric acid, ethylparaphenylenediamine, $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{NH}_2\cdot\text{C}_2\text{H}_5$. The pure base, obtained by decomposing the hydrochloride with potash, and distilling the oil obtained in a stream of hydrogen, is a yellow, odourless oil, becoming soon brown and thick, soluble in benzene, alcohol, and ether, less soluble in water and dilute potash. It boils at 261–262° under 746mm. pressure. When oxidised with phenol, α - or β -naphthol, resorcinol, etc., colouring matters of the indophenol class, are formed.—T. L. B.

Safranines. W. Schweitzer. Ber. 19, 150–153.

WITT, NÖLTING and COLLIN have shown that ethylparaphenylenediamine is capable of forming safranine. Two isomeric monethylsafranines can be obtained, which the author has investigated.

α -Ethylsafranin, $\text{C}_{18}\text{H}_{15}(\text{C}_2\text{H}_5)\text{N}_3$, is obtained by dissolving 10.4grm. ethylparaphenylenediamine and 12.7grm. of aniline, both in the form of their hydrochlorides, in 700cc. of water, with the addition of acetic acid, heating to boiling, and slowly adding 400cc. of a solution of potassium bichromate (40grms. per litre). Milk of lime is then added, the red solution filtered, evaporated to dryness, and the colouring matter extracted with absolute alcohol. The hydrochloride is a very hygroscopic bluish-green crystalline powder with metallic lustre, easily soluble in water and alcohol, but insoluble in ether. The aqueous and alcoholic solutions possess a fine olive-green fluorescence. The platinochloride forms sparingly-soluble small dark-coloured needles. By the action of silver oxide on the hydrochloride, the free base is obtained as a non-crystalline mass, with cantharidine-green reflex. The leuco base is formed by reduction with tin and hydrochloric acid; but is immediately oxidised on contact with air. The nitrate is an amorphous mass, and the sulphate forms a dark-green crystalline powder.

β -Ethylsafranin is formed by oxidising a mixture of 10.8grms. paraphenylenediamine, 7.7grms. aniline, and 12.3grms. ethylaniline dissolved in 500cc. of water, with 340cc. of solution of potassium bichromate (60grms. to the litre). The hydrochloride is an amorphous, cantharidine-green mass, very similar to the α -compound, but even more hygroscopic. The platinochloride is a dark-violet lustrous powder. The nitrate was obtained as a dark-green crystalline mass. α -ethylsafranin has greater tinctorial power than the β -compound, and dyes with a bluish shade, whilst the latter dyes brighter and yellower; the difference is best visible on silk.

—T. L. B.

Metanitrodimethylaniline, Metanitrodiethylaniline, and their Reduction Products. A. Groll. Ber. 19, 198–201.

ACCORDING to Nölting and Collin, when dimethylaniline is nitrated, only paranitrodimethylaniline is formed; on repetition of their experiments, however, the chief product was found to be metanitrodimethylaniline, whilst the yield of para-compound never exceeded 25 to 30 per cent. on the dimethylaniline used.

200grms. dimethylaniline are dissolved in 4000grms. of strong sulphuric acid in a vessel surrounded with a freezing mixture, and into this is slowly dropped a cold mixture of 193grms. nitric acid of 38° B. and 600grms. sulphuric acid, taking care that the temperature does not rise above 5°. After standing four to six hours the mixture is poured into about 10 litres of ice water, filtered from the precipitated para-compound, to the filtrate soda is added, until a red precipitate commences to be formed; the solution is then again filtered, and the filtrate neutralised with soda. The red substance is extracted from the sulphate crystals with hot alcohol, from which it crystallises in large compact red prisms.

Metanitrodimethylaniline, thus obtained, melts at 60–61°, and distils with partial decomposition at 280–285° C.; it forms a salt with hydrochloric acid, but its basic powers are less than those of the ethyl-compound. The yield obtained was from 80 to 85 per cent. on the dimethylaniline used.

Metanitrodiethylaniline is obtained on nitrating diethylaniline in a similar manner; it is a deep yellow oil, boiling at 288–290°, and easily soluble in hydrochloric acid.

Metanitrodithylaniline is an oil distilling at 268–270° under 740mm. pressure; it forms well-crystallised salts, reacts with nitrites in a similar manner to metaphenylenediamine, and yields, with diazobenzene, dimethylchrysoidine.

Metanitrodiethylaniline is a pale yellow oil, boiling at 276–278°, and in all respects similar to the dimethyl-compound.—T. L. B.

Coccerin from Living Cochineal. C. Liebermann. Ber. 19, 328.

HAVING obtained a plant of *Opuntia coccinifera* covered with the living cochineal insect, the author is able to note the presence of the above waxy substance described by him (this Journal, 1885, 585) on the living insect itself. It exudes from the wax-glands of the coccus in fine white hairs, much resembling white mould. The cocoons of the insect are also largely composed of this substance; several examined contained about 75 per cent. coccerin.—T. L. B.

Synthesis of Xanthopurpurin and Purpurin. E. Noah. Ber. 19, 332–334.

THE above two substances are obtained by heating the following mixture for seven hours in an oil-bath at 105–110°:—1 part of symmetrical dihydroxybenzoic acid, 5 parts of benzoic acid, and 25 parts of sulphuric acid. The melt is poured into water and at once extracted with ether, which removes the unattacked benzoic acids and the xanthopurpurin. The ether is distilled off, the benzoic acid removed by steam, and from the residue the xanthopurpurin is extracted with benzene, the yield being about 6 to 7 per cent. The liquor from which ether extracted the xanthopurpurin contains anthrachrysene, of which about 40 per cent was obtained.

Xanthopurpurin sublimes easily in yellowish-red needles, easily soluble in benzene, forms a soluble barium salt, but does not dye mordanted fabrics. When fused with potash it readily forms pure purpurin, which precipitates on acidifying the melt.—T. L. B.

Azo-opianic Acid and a New Indigo-derivative. C. Liebermann. Ber. 19, 351–354.

ON reducing nitro-opianic acid, Prinz (*Journ. Prakt. Chem.* 24, 362) obtained an acid which he termed azo-opianic acid, and to which he assigned the formula— $(\text{CO}_2\text{H})(\text{COH})(\text{OCH}_3)_2\text{HC}_6\text{H}_3\text{N}=\text{N}=\text{C}_6\text{H}_3(\text{OCH}_3)_2(\text{COH})(\text{CO}_2\text{H})$ —although he noted that its reactions and the absence of colour hardly pointed to an azo-compound. Assuming the opianic acid to have one of the two following formulae—

—the entering nitro-group can occupy the ortho-position relatively to the aldehyde-group, and the nitro opianic acid would thus represent a further substituted ortho-nitrobenzaldehyde. According to Friedländer and Henriques (Ber. 15, 2105 and 2572), ortho-nitrobenzaldehyde yields on reduction anthranil; therefore, ortho-nitro-opianic acid should give dimethoxyanthranilcarboxylic acid—

—with which substance the properties of azo-opiatic acid would better agree. That the nitro-group does really occupy the ortho-position is proved by the production of an indigo-derivative when the nitro-opiatic acid is condensed with acetone. (Comp. Baejer and Drewsen, *Ber.* 15, 2860.)

Nitro-opiatic acid, when heated to 40–50° with acetone and dilute soda or baryta-water, yields tetramethoxyindigodicarboxylic acid, $C_{16}H_4(OCH_3)_4(COOH)_2 \cdot N_2O_2$, which is a blue-green mass, insoluble in alcohol, benzene, chloroform, acetone, slightly soluble in acetic acid, better in aniline and phenol. It is sparingly soluble in boiling water, easily soluble on the addition of a little ammonia; the solution gives the indigo-carmin spectrum. With zinc-dust and alkali, it is reduced to a yellow liquid which is oxidised on exposure to the air, depositing blue flakes of the zinc salt (?); it dyes a fine blue. It does not form a sulphonic acid; the solution in sulphuric acid gives a strongly-marked absorption-band from D to F; water precipitates the colour unchanged.

—T. L. B.

Compounds of Perchlormethylmercaptan and Aniline, etc. B. Rathke. *Ber.* 19, 395–396.

IN a paper on perchlormethylmercaptan (*Ann. Chem. Pharm.* 167, 241), the author has shown that it reacts—in the first place, with aniline, thus:— $CCl_3SCl + NH_2 \cdot C_6H_5 = CCl_3 \cdot S \cdot NH \cdot C_6H_5 + HCl$. When alcoholic potash or ammonia is added to the concentrated ethereal solution of this substance, a new compound precipitates in the form of needles, which recrystallises from ether in fine prisms; to this substance the formula $CHCl_2 \cdot S \cdot OC_6H_5$ was given. Further investigation has shown that it contains nitrogen, and the analytical data given correspond to the formula $C_6H_5 \cdot N \cdot S \cdot CCl_2$. It melts at 140°, and then quickly blackens, after having already assumed a red colour at 136°. If heated quickly in a test-tube it evolves red fumes, appearing to contain azobenzene; the evolution is accompanied with slight explosion. Its constitution may be expressed thus:—

or more probably— $C_6H_5 \cdot N \begin{array}{c} \diagup CCl_2 \cdot S \\ | \\ S \cdot CCl_2 \end{array} \cdot N \cdot C_6H_5$

A similar substance is formed with paratoluidine, which crystallises from ether in white needles, melting at 138°; it is far less stable than the compound obtained from aniline; if boiled in alcohol it decomposes into a tarry mass and a red colouring matter. Orthotoluidine gives similar bodies also; in this case the compound $CCl_3 \cdot S \cdot NH \cdot C_6H_4$ is fluid, but the other body, $CCl_2 \cdot S \cdot N \cdot C_6H_4$, is crystalline, begins to melt and decompose at 134°, giving off gas.—T. L. B.

Formation of Methyl-violet with Perchlormethylmercaptan. B. Rathke. *Ber.* 19, 397–400.

THE Farbenfabrik vorm. F. Bayer & Co. obtained a patent for the production of methyl-violet from dimethylaniline and perchlormethylmercaptan. The author having been engaged previously with the study of this reaction, gives explanations of the process. One molecule of perchlormethylmercaptan reacts with three molecules dimethylaniline, preferably in the presence of aluminium chloride. On boiling out the crude melt, with water, much green tarry matter remains, which, however, is soluble in hydrochloric acid. The first crystallisation of violet from the aqueous solution yielded fine golden needles, but the quantity was small, the major part necessitating an evaporation, or salting-out, whilst a fair amount could only be obtained in the form of its very insoluble zinc double salt. Two by-products exist in these mother-liquors and in the tarry substances, consisting of dimethylaniline sulphide, $S \cdot [C_6H_4 \cdot N(CH_3)_2]_2$ (comp. Tursini, *Ber.* 17, 586), and a leuco-violet. The former is sparingly soluble in petroleum spirit, is precipitated by sodium acetate from solutions of its salts, and is oxidised readily to a blue colour; nitrites form with it a

nitroso-compound, but do not give rise to the formation of methylene-blue. The formation of leuco-violet is explained as follows:—The perchlormethylmercaptan is decomposed into carbontetrachloride and sulphur; the former reacting with dimethylaniline forms methyl-violet— $CCl_4 + 3C_6H_4 \cdot N(CH_3)_2 = (C_6H_4 \cdot N(CH_3)_2)_3 \cdot Cl + 3HCl$, whilst the latter yields dimethylaniline sulphide— $S + 2C_6H_5 \cdot N(CH_3)_2 = S[C_6H_4 \cdot N(CH_3)_2]_2 + 2H$; the hydrogen reduces the violet to leuco-violet.—T. L. B.

Diparaxylyl Ketone. K. Elbs and G. Olberg. *Ber.* 19, 408–410.

DIPARAXYLEYL KETONE $CO(C_6H_4 \cdot (CH_3)_2)_2$ is obtained from paraxylylene and carbonyl chloride in presence of aluminium chloride. The ketone is a pale yellow viscid liquid boiling at 325–327°, and soluble in alcohol, ether, and benzene. On reduction with zinc dust and alcoholic potash, *diparaxylylcarbinol* $CH(C_6H_4 \cdot (CH_3)_2)_2 \cdot OH$ is obtained, which is insoluble in water and crystallises from hot alcohol in colourless needles melting at 132°. This carbinol yields on condensation 2 : 1' : 4 trimethyl-anthracene, melting at 227°.—D. B.

The Eurhodines, a New Class of Colouring Matters. Otto N. Witt. *Ber.* 19, 441–448.

IN a previous paper (this Journal, 1885, 397) the author has described the prototype of these new bodies, which he obtained by the action of orthamidazo-toluene on a-naphthylamine hydrochloride. Instead of using naphthylamine in the melt as solvent, it is better to use phenol, from which excess of toluene precipitates the eurhodine. He now gives to this substance the formula of $C_{17}H_{13}N_3$ instead of $C_{24}H_{15}N_4$, and expresses its constitution thus:—

The free base sublimes easily, forming voluminous woolly crystalline aggregates, of a splendid orange colour. The hydrochloride forms glittering garnet-red needles, containing 1 mol. H_2O , which, however, cannot be removed without simultaneous loss of hydrochloric acid; the sulphate and oxalate have very much the same appearance, but the nitrate is almost insoluble even in boiling water.

On heating eurhodine with moderately dilute sulphuric or hydrochloric acid in sealed tubes for 3 hours at 180°, it is decomposed into ammonia and eurhodol. This base is a lustrous yellow powder, consisting of minute dichroic crystals, almost insoluble in all solvents except in aniline and phenol. It sublimes easily and possesses phenolic properties. The analysis points to the replacement of the amido- by the hydroxyl-group. Eurhodol dyes animal tissues orange. A substance, which is probably identical with the naphthyltoluquinoxaline obtained from orthotoluylenediamine and β -naphthoquinone by Hinsberg (this Journal, 1885, 511), is obtained by heating a solution of eurhodine hydrochloride in absolute alcohol, with amyl nitrite. It is a pale yellow substance, melting at 156°.

In order to settle the constitution of the eurhodines, in their relationship to the quinoxalines, the author endeavoured to obtain an amidoquinoxaline of known constitution. Phenanthrenequinone and the 1 : 2 : 4 triamidobenzene obtained by reducing chrysoidine, were allowed to react; the resulting amidoquinoxaline—

shows all the properties of eurhodine. It was not found necessary to isolate the triamidobenzene; good results were obtained in the following way. A solution of 2 grms. chrysoidine in 50cc. glacial acetic acid is prepared and reduced with zinc dust; this solution is then, after slight cooling, poured into a solution of 1 grm. phenanthrenequinone in 50cc. of glacial acetic acid; on the addition of

plenty of water the new compound precipitates in a slimy form, but becomes crystalline on boiling. The yield was 1.5 gm. Recrystallised from phenol and alcohol, it forms a glittering brown powder: it dissolves in strong sulphuric acid with a crimson colour, becoming, on dilution, first yellow-green and then red; it sublimes in woolly crystalline aggregates, and the ethereal solution shows the characteristic green fluorescence.

β -Naphthoquinone, benzil, isatin, diketones of the fatty series, polyketones, such as leukonic acid, form, with 1:2:4 triamidobenzene, eurhodines of varying shades.

Dr. Witt considers the double $-C=N-$ chain of the quinoxalines as the "chromophor," which needs the introduction of salt-forming groups to become active. (See *Ber.* 9, 522; see also *J. Chem. Soc. (Trans.)* 1886, 391-405.)—T. L. B.

On the Aromatic Ketones. Karl Elbs. *Journ. für Prakt. Chem.* 33, 180-188.

IN the prosecution of a research on triphenylmethane and some of its derivatives, the author has investigated the various known methods of preparation of these bodies, that, ordinarily employed—the action of chloroform or chloropicrin on aromatic hydrocarbons in presence of aluminium chloride—only yielding homologues in which the three hydrogen atoms are replaced by the same group. Of these methods the three following appeared the most practicable:—(1.) The action of benzyl chloride on aromatic hydrocarbons in presence of zinc dust or aluminium chloride (Böttger, *Ber.* 12, 976)—

(2.) The condensation of secondary aromatic alcohols with aromatic hydrocarbons by means of phosphorus pentoxide (Bayer and Hemilian, *Ber.* 7, 1204)—

(3.) The decomposition of the β -pinacolines by alkalis (Thörner and Zincke, *Ber.* 10, 1475; 11, 65)—

The yield by the first method was very poor, and the third was rejected on account of the difficulty of preparing pure pinacones; the second method gave satisfactory results.

The homologues of benzophenone, from which the secondary aromatic alcohols were prepared, was obtained by the method of Friedel and Crafts, and as a number of new ketones were prepared, their properties were examined, and also their capability of forming homologues of anthracene by condensation, with elimination of water.

Preparation of Homologues of Benzophenone.—To a mixture of equivalent quantities of hydrocarbon and acid chloride enough carbon bisulphide was added to give a clear solution. An equal volume of carbon bisulphide was placed in a large flask with reversed condenser, together with a sufficient quantity of aluminium chloride. The solution was then added in small quantities at a time through the open end of the condenser, and the mixture was warmed until hydrochloric acid was no longer evolved. After cooling, water was added in small quantities in a similar manner, until the reaction was completed, and the solution was then distilled with steam. The acid from the decomposed chloride is carried over, but some occasionally remains together with the homologues of benzophenone, which are only in traces volatilised with the steam, and are left as a heavy oil or a buttery mass. The solution of aluminium chloride was poured off, and the benzophenone heated (by the introduction of steam), first with very dilute hydrochloric acid, and then with very weak caustic soda. The benzophenone was then separated, dried at 110°, and fractionated. The yield was from 50 to 80 per cent. of the theoretical. The carbon bisulphide acts as a diluent, keeps the temperature at about 50°, and prevents the formation of resinous matters. The weight of aluminium may sometimes amount to half that of the acid chloride. The reaction is complete in from half-a-day to two days. Very good results were obtained with benzene and its homologues, less satisfactory with complex aromatic

hydrocarbons. The method cannot be employed for halogen or nitro derivatives of hydrocarbons in which the hydrogen of the benzene ring is replaced; but the presence of negative atoms or groups in the molecule of the acid chloride is not prejudicial.

Reduction of the Ketones to Secondary Alcohols.—This was accomplished by dissolving one part of the ketone in 10 to 20 parts of alcohol, adding 5 to 10 parts of zinc dust, and a little concentrated caustic potash, and allowing the mixture to stand in a warm place for several days, a little caustic potash being added from time to time. The clear solution was poured off and treated with much water, and the alcohol distilled or crystallised. In the case of soluble alcohols, the potash and zinc were precipitated by carbon dioxide, and the alcohol filtered. The yield amounted to 60 to 80 per cent. of the calculated.

Synthesis of Anthracenes from Aromatic Ketones with Elimination of Water.—It had been observed by Behr and Dorp (*Ber.* 7, 17) that when orthotolylphenylketone is heated, anthracene and water are formed—

The author finds that homologues of anthracene may sometimes be formed from other ketones by a similar condensation, but he is unable at present to state whether the reaction can be considered a general one for homologues of benzophenone which contain a methyl and the carbonyl group in the ortho position. In those cases in which the formation of an anthracene did not occur, it was not brought about by the addition of reagents which usually cause condensation.

The ketones were heated to the boiling point in long-necked flasks for three to six days, and the products extracted with boiling alcohol, from which the anthracenes separated as brown crystalline powders or in crusts, and could then be purified by recrystallisation from benzene or carbon bisulphide. The residues, after evaporation of the alcohol, were again heated, and yielded further quantities of the anthracene.—S. Y.

New Process of Chlorination. A. Colson and H. Gautier. *Compt. Rend.* 101, 1064.

THE writers of this paper heat various homologues of benzene (such as orthoxylylene, paraxylylene, toluene, etc.) with phosphorus pentachloride, PCl_5 , in sealed tubes. Seven grms. of toluene heated with 30 grms. of PCl_5 yield benzyl-di-chloride, $C_6H_5.CHCl_2$. 15.5 grms. of paraxylylene be heated with 40 grms. PCl_5 , for about two hours at 195°, a substance is obtained having the formula $C_6H_4(CHCl_2)_2$, and soluble in ether, alcohol, benzene, and chloroform.—E. G. C.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Improvements in Machinery for Treating Waterproofed Fabrics. Isidor Frankenburg. Eng. Pat. 6008, May 16, 1885. Sd.

THIS invention relates to improvements in machinery employed in the so-called "curing" of waterproofed fabrics, the object being to protect the workmen from noxious fumes and dust. This is attained by enclosing part of the machinery in a specially constructed chamber. The specification is accompanied by drawings.—E. J. B.

Improvements in the Treatment of Fibrous Substances for the Manufacture of Paper Pulp and Textile Fabrics. Robert Charles Menzies, Charles Frederick Cross, and Edward John Bevan. Eng. Pat. 6840, June 5, 1885. 4d.

THIS process consists in exposing straw or other fibrous materials which have been previously saturated with a solution containing caustic soda and sodium sulphite, and from which the excess of liquor has been drained or otherwise removed, to the action of steam. By this means a considerable economy of chemicals is effected.—E. J. B.

Improvements in Treating Webs, Wool, Rags, Waste, and the like, to be Carbonated in the so-called Wet Way, and in Dyeing the same. Moritz Iwand, and Felix Kühne. Eng. Pat. 14,393, November 24, 1885. 6d.

THE object of this invention is to do away with the expensive and troublesome centrifugal machines used for drying wool which has been previously saturated with acid preparatory to the carbonisation process. The material after having been saturated with acid is, in the form of a web, wound round a hollow perforated copper cylinder into one end of which steam is introduced. If in a loose condition the material is packed between two cylinders placed concentrically, and steam introduced into the inner one.—E. J. B.

Improvements relating to the Treatment of Silk-cocoons, Raw Silk, or the like. William Robert Lake. Eng. Pat. 1896, February 9, 1886. 6d.

THIS invention relates to a method for removing the gummy or waxy material cementing together the fibres of the cocoons, which is said to occupy much less time than the methods of fermentation and treatment with soap solutions hitherto employed. It consists in treating the cocoons with a dilute hydrochloric acid solution containing about three quarters of an ounce to the gallon, at a temperature varying from 150° to 160° F. The action should be so regulated that a certain amount of cementing material remains, as this, if entirely removed, would weaken the fibres. The process can also be applied to raw silk or silk waste.—E. J. B.

Improvements in the Method of and Composition for Treating Textile Fabrics, Cordage, Ropes, Nets, and Similar Materials. Herbert John Haddan. From the United States Waterproofing Fibre Company. Eng. Pat. 2616, February 23, 1886. 4d.

THE inventor treats the material to be rendered waterproof with a mixture obtained by melting together equal parts of rosin and paraffin wax, which may, if necessary, be thinned by the addition of fifty parts of benzene. For treating such materials as fish-nets, etc., the residue from the distillation of mineral oils may be added to the above mixture. Instead of benzene, paraffin oil or turpentine may be used as the thinning material.—E. J. B.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

Industrial Society of Mulhouse. Meeting of May 10, 1886.

S. WEBER gave a further account of his investigations concerning the red colour imputed to cotton textures which have been exposed to the vapour of commercial aniline. He has found that the unbleached pieces which are coloured best are those which are coloured pink the most distinctly. These are generally fabrics made of Egyptian and Indian cottons. The red colour of the bleached goods is most marked when they have been subjected to a long treatment with chlorine. In a texture which had been bleached in the usual way, but not with chlorine, no colour could be developed. Passage through an alkali bath, after chlorinating, prevents the piece being dyed at all. The fabrics, which have been subjected to the action of chlorine and are coloured red by aniline vapours, attract basic colouring matters more readily than ordinary cotton does; whereas, no affinity was observed for acid colouring matters, or those derived from phenol. In this respect a great analogy seems to exist between Witz's hydro-oxy-cellulose and with the chlorinated bodies which Cross and Bevan have studied in connection with their investigation on the bleaching of jute. Horace Koechlin communicated to G. Galland an article on colouring matters derived from benzidine, concerning their application as mordants for basic colouring matters.—A. R.

Improvements in Apparatus for use in Fixing the Colours upon Printed Cotton Fabrics, and for Washing the same. W. R. Lake. From F. Storeh, Smichow, near Prague, Austria. Eng. Pat. 6888, June 5, 1885. 8d.

THIS invention relates to apparatus for treating printed cotton fabrics, in which apparatus the fabric is drawn through a cold fixing-liquid in a tank, then through a chamber in which by means of steam the fixing liquid is caused to act; then through one or more washing vats, rollers being arranged to squeeze the liquid out of the fabric after it leaves one and before entering another vat.—H. A. R.

Improvements in the Means or Apparatus employed in Purifying, Bleaching, Dyeing, and otherwise operating upon Yarns or Threads. J. C. Mcburn, London. Eng. Pat. 7187, June 12, 1885. 8d.

THE original should be consulted for drawings, and descriptions of an arrangement of hollow perforated or fluted cop tubes whereby the dyeing liquid, etc., is enabled thoroughly to permeate the whole mass or body of the yarn, even that which is applied against the sides of the tube.—H. A. R.

VII.—ACIDS, ALKALIS, AND SALTS.

Remarks on Mr. Mond's Communication respecting the Origin of the Ammonia Soda Process. M. Scheurer-Kestner. Bull. Soc. Chim. 45, 302.

THE conclusions of Mr. Mond require amending. A careful study of the question proves that the ammonia soda process has been gradually perfected, and that if Mr. Solvay was the first to inaugurate large and prosperous works, the labours of his predecessors were not in vain. This is borne out by the following list of patents for which the author is indebted to the courtesy of Mr. E. Solvay:—

1838.—Patent: Gray Dyar and Hemming introduced in France by Mr. Delaunay.

1840, April 1.—Mr. Canning recommends the employment of a current of carbonic acid. Applied for in France, May 18, 1840, by Mr. Delaunay.

1852, Feb. 14.—M. Grinus, of Marseilles, recommends to cool the liquors during the reaction, and employs for this purpose a freezing machine, and collects for further use the carbonic acid resulting from the calcination of the bicarbonate of soda.

1854, May 2.—Mr. Gossage urges the use of pure carbonic acid free from nitrogen or air and indicates an apparatus for its preparation.

1854, May 26.—Mr. Turek details form of apparatus.

1855, Jan. 29.—Ditto.

1855, Dec. 13.—Ditto.

1854, Jan. 21.—Mr. Schloesing gives a description of an entirely new form of apparatus, and he very clearly states the problem that one must look to improvements in the apparatus employed, and a consequent saving of ammonia.

1854, July 8.—Mr. Johnson, representing Mr. Deacon, recommends the use of carbonic acid under pressure.

1855, Feb. 28.—Mr. E. Loradoux.

1858, March 12.—MM. Schloesing and Rolland render the process automatic, and thus continuous. Their predecessors only had in view plant in which each operation took place separately without connection with those which precede or follow. They recommended and put into actual work at Puteaux, cylinders fitted with agitators for absorbing the carbonic acid. They considered the absorption was facilitated by this means. Like Mr. Gossage, they noted a considerable difference when using pure instead of dilute carbonic acid. They cooled their apparatus as M. Grinus had recommended in 1852. Their arrangements were entirely of a mechanical character. A centrifugal apparatus was employed for separating the bicarbonate with special means of avoiding the loss of ammonia, and drying arrangements enabled them to collect all the carbonic acid in a gas-holder. A limekiln produced this gas, and economical evaporators were devised by using the waste steam, etc.

1861, April 15.—Mr. Ernest Solvay.

1863, Sept. 10.—Ditto.

Besides the two principal patents, Mr. Solvay has taken out others, having reference to modifications of apparatus and other improvements. It seems that the chief improvements of Mr. Solvay on the old processes consist in the employment of novel apparatus and methods for absorbing the carbonic acid. After an exhaustive study of the laws determining the absorption of the carbonic acid by brine, he substitutes for the cylinders with agitators of MM. Schloesing and Rolland, absorbing columns of a more practical and advantageous kind. He utilises the heat disengaged in slaking the lime, and introduces a regulator separating the steam from the ammonia, and preliminary purification of the brine, the regulating the action of the carbonic acid on the brine; and he uses filter-presses, and decomposes the bicarbonate of soda by means of steam.

The list of patents taken out before Mr. Solvay entered the field, compared with his own, prove that the chemical reaction was first indicated by Messrs. Dyar and Hemming, in the year 1838. All attempts—the most noteworthy among them being MM. Schloesing and Rolland's—to render the process lucrative had been abandoned until Mr. E. Solvay established and started his works at Coniliet, in Belgium. It is beyond doubt that, if MM. Schloesing and Rolland's predecessors paved the way for a great industry, Mr. E. Solvay was the first to work the ammonia soda process so as to derive benefit from it, and to establish it on such a footing as to seriously threaten the older Leblanc process.

But, for circumstances to which I shall have to refer later, it is highly probable that MM. Schloesing and Rolland, notwithstanding their less economical process, might have established and successfully carried on this industry as early as 1858.

In his 1863 patent Mr. E. Solvay lays especial stress on the column for absorbing the carbonic acid; he declares that by his arrangement complete decomposition of the salt used takes place.

It is therefore evident that the most important points for the practical working of the ammonia soda process, as introduced by Mr. Solvay, has been the introduction of a judicious and ingenious absorbing apparatus, the regulation of the action of the carbonic acid on the brine (mixture of salt water and ammonia), and the direction given to the liquids and to the carbonic acid gas which traverses the absorbing column. These conditions have all been fulfilled by Mr. E. Solvay in a most happy manner, resulting in a more complete decomposition of the sodium chloride.

Like MM. Schloesing and Rolland, who, in this, had preceded him, Mr. Solvay has established an automatic and continuous process; but he has accomplished this by a simpler and yet more effective means.

When the carbonic acid meets the brine it is highly charged with free ammonia, and the bubbling of the gas carries away a large quantity of it. Mr. Solvay conceived the notion of reversing the two currents. He causes them to travel in the same direction, so that the liquid most highly charged with free ammonia, when meeting the carbonic acid, should be below a layer, already partially saturated, in which the ammonia carried away by the gas can dissolve.

An ingenious arrangement for the circulation of the liquid overcomes what otherwise represents the greatest difficulty of the process, so far as the absorption is concerned.

The brine first passes to the middle of the column, then to the top, and finally to the bottom of the column, whilst the carbonic acid traverses from the bottom to the top.

It is difficult to distinguish from the patents of Mr. Solvay which improvements furnish the best results, or are actual advances, as Mr. Solvay has managed to this day to carry on this great industry as a secret. Various other works having meanwhile been erected, it is, however, known that the absorbing column devised by Mr. Solvay fulfils the conditions recognised as being most suitable.

As Mr. Solvay states in his patent, it is not sufficient

merely to use pressure and cold in the absorbing apparatus, however advantageous they may be, but it is highly important to sub-divide the action of the carbonic acid so as to obtain an absorption as complete as possible without causing a disengagement of free ammonia outside the apparatus.

Be this as it may, and in spite of the immense advantage resulting from the employment of Mr. E. Solvay's apparatus, it is not less a fact that the process started at Puteaux by MM. Schloesing and Rolland could have been successfully carried out on a large scale at the very time of closing their experimental works.

The considerations which induced them not to proceed were not of a technical character. Want of capital, the duty on salt, which pressed more heavily on their industry than that of the Leblanc makers, discouraged them, although the difference did not exceed 5 to 6 francs per 100kilos. soda ash. The capitalists withdrew from the enterprise perhaps on account of this very difference of duty, however unimportant it must appear at a time when the price of soda was 60 francs per 100kilos.

Mr. Mond speaks of a cost price of 65 to 75 francs. MM. Schloesing and Rolland have not, however, indicated this figure, but a much lower one, in their communication which appeared in 1868 in the *Annales de Chimie et de Physique*.⁶

It is probable that Mr. Mond reasoned that as soda was worth 65 to 75 francs, when MM. Schloesing and Rolland were engaged in their experiments, and did not carry these experiments any further, he must conclude that their cost exceeded the then selling price. This is not so.

The works at Puteaux were merely of an experimental character, too small to be worked profitably. They were to serve as a model for a larger plant, capable of producing at least 10 tons of soda per day.

Besides MM. Schloesing and Rolland have anticipated Mr. Mond's reasoning, and have furnished in their publication of 1868 all the necessary data for arriving at the cost price, cost of raw material, fuel, labour, and such as the general charges, which they put extremely high—as, for instance, interest on money is calculated at 6 per cent., and for incidental expenses a sum of 50,000 francs is provided.

The following figures are taken from the publication of 1868:—

For 100kilos. of 99 per cent. Soda.

Salt	180.0
Limestone	135.0
Coal for heating	50.3
Coal for steam	78.0
Ammonia	1.0
Coke	72.0
Labour	1.40
General charges	9.67

These figures lead us to a cost price which is out of all proportion to that of 65 francs. Assuming that the salt was boiled out of brine, the cost would not exceed 21 francs. Using natural brine as recommended by MM. Schloesing and Rolland, the cost falls below 20 francs. The paper of MM. Schloesing and Rolland gives a perfect analysis of all the reactions; they indicate all the quantities of liquids and gases which play a part in a soda works. These particulars have nowhere else been so completely stated. It is proved from the actual selling price that the cost of soda manufactured by Mr. Solvay is less, by more than one-half, than that furnished by the figures supplied over 18 years ago by MM. Schloesing and Rolland. It is evident from the above that since 1858 Messrs. Schloesing and Rolland could have competed with the old Leblanc process, and this notwithstanding the tax on salt, which, in comparison with the latter, handicapped their product by 6 francs per 100kilos. soda.

Why then did MM. Schloesing and Rolland not carry out their project on a large scale? They answer this question in their paper of 1868: "The fiscal duties

⁶ *Annales de Chimie et de Physique*, T. 64, page 1, 1868.

causing a difference in the taxes affecting us adversely to the extent of 10 francs* per 100kilos., reduced too much the margin of profits that should exist to cover the risks that have to be encountered in starting a new industry."

The company about to be formed for carrying out this process on a large scale hesitated to face so great a difference in the tax, but oversteated by MM. Schloesing and Rolland, who overlooked the fact that the Leblanc process demands much more than the theoretical quantity of salt. MM. Schloesing and Rolland abandoned, therefore, their scheme, not on account of defect in their process, but owing to their over-estimating their difficulties. Such at least is the author's conviction after carefully studying the question. He arrives at the following:—It is clear from the patents:—

(1.) The chemical process of manufacturing carbonate of soda from sea-salt by the agency of ammonia has been known since the year 1838, and even before that date according to some authorities. Messrs. Harrison, Gray Dyar and Hemming were the first to publish the reaction in their patent of 1838.

(2.) Several attempts were made in England between the years 1838 and 1855 to work the process on a large scale, but the works built for this purpose were closed one after another because the soda produced cost more than by the Leblanc process.

(3.) In 1855 MM. Schloesing and Rolland, like several Englishmen had done before them, erected plant at Puteaux. Their establishment was merely experimental, not a working plant. According to the account and data given by MM. Schloesing and Rolland, the soda produced by their process at Puteaux could compete as regards cost with that produced by the Leblanc process, but the enforcement of vexatious and unwise salt taxes discouraged promoters of the enterprise, who, had they been better informed, might have successfully competed with the Leblanc process.

Since the year 1861, Mr. E. Solvay succeeded, by dint of perseverance and ingenuity, in completely remodelling the mechanical portion of the process, and in consequence in considerably reducing the cost of production.

He founded at Couillet, in Belgium, the first extensive ammonia soda works. His process is original, and notwithstanding the labours of his predecessors we must consider him the true founder of a cheap soda process. He has rendered a great service to the world—not, however, without dealing a severe blow to the old soda industry. One may ask whether, without the labours of Mr. Solvay, the production of soda by the ammonia process would have remained a long time without practical application. I have little doubt on the point. The serious checks, attributable to diverse causes, which arrested and cut short experiments prior to those of Mr. Solvay, would certainly for a long time have deterred chemists and engineers from this field, to the great detriment of a number of industries depending on the soda manufacture.

On the Use of Pyrites in the Manufacture of Sulphuric Acid, and on Progress made in the Burning of this Ore. Scheurer-Kestner. Bull. Soc. Chem. 45, 227.

THE author gives a historical sketch on the use of pyrites in the manufacture of sulphuric acid. He claims that this mineral was first employed in France for the above purpose, and that the best methods for utilising the sulphur it contains are also due to French manufacturers, notably to M. Perret. A description follows of various furnaces used at different periods for burning pyrites. Perret has recently constructed a new furnace for crushed ore, which has the shape of a prism, and resembles Gerstenhöfer's, being however free from the defects of the latter. The working of this furnace has hitherto been most satisfactory; the pyrites are thoroughly utilised and much labour saved, the cost of the latter being reduced by one-half.—A. R.

* The calculation shows barely 6 francs.

Schloesing's Law relating to the Solution of Calcium Carbonate by Carbonic Acid. R. Engel. Compt. Rend. 101, 949.

THE author states, in opposition to Caro's assertions, that Schloesing's law as to the solubility of calcium carbonate in water saturated with carbonic acid holds good, not only for pressures less than one atmosphere, but for higher pressures. The law also applies to barium carbonate.—E. G. C.

Manufacture of Sulphocyanides. F. Nafzger. Chem. Zeit. 10, 370.

THESE salts are finding an increased application for various purposes in dyeing and printing, as well as for the manufacture of colours. The sulphocyanides are not generally obtained from gas liquor, unless the latter has a specific gravity corresponding to 10–15° B., and this being of rare occurrence, "Laming's ferric oxide mass" has been used of late years for their preparation, as it sometimes contains 10 to 12 per cent. of ammonium sulphocyanide. This salt is always mixed with ammonium salts, and the best method of separation—viz., that of partial crystallisation—is connected with considerable difficulty and loss. Numerous patents have been taken based on the preparation of sulphocyanides from the residue of the Laming's mixture, with subsequent removal of the sulphur of the compound and formation of ferrocyanides. But as regards relative values of these two salts, it would be more rational to endeavour to prepare sulphocyanides from ferrocyanides. The manufacture of sulphocyanides can only be carried on profitably in works where certain other products, such as ferrocyanides, Prussian blue, etc., are prepared, and where the process is under the supervision of experienced chemists. (Gasch, Chem. Zeit. 10, 274). In connection with this matter the author draws attention to the method known as the "liming-process," used in England in some gas works, whereby the nitrogen of the coal is more fully utilised.—A. R.

Improvements in effecting the Decarbonation of Earthy Carbonates, such as Carbonate of Barium, Carbonate of Strontium, and the like, and Apparatus therefor. W. L. Wise, London. From R. Radot, Paris. Eng. Pat. 5280, April 28, 1885. 8d.

IT is proposed to effect the reduction by the combined action of reducing carbonated gaseous agents and superheated steam. In practice this may be carried out in many ways—either by the employment of a carbonated gas, which heats and reduces the material at the same time; or by the employment of hydrogenated gas, which heats the material and produces by its combustion the superheated steam necessary for reduction; or by the employment of a hydrocarbonated gas; or by the employment of any suitable combustible gas mixed with steam; or, lastly, by the employment of a liquid or solid hydrocarbon or of water-gas. The decarbonation is best performed in a furnace of the crucible type, or in a reverberatory furnace analogous to those employed for melting glass. In either case the process is continuous; the material to be acted upon is fed from the top, and gradually slides downwards until it arrives on the hearth proper, where it is exposed to the heat and the reducing gases, which are passed into the furnace by one or more tuyères. The reduced mass is withdrawn at the bottom. Instead of feeding the furnace with the pure carbonate, it is often preferable to add to it a small quantity of pure carbon or pure carbonaceous material, as under its influence the decomposition takes place more rapidly and at a lower temperature than would otherwise be the case.—S. H.

Improvements in the Manufacture of Hyposulphates and Sulphates of Alkalis. H. B. Condy, London. Eng. Pat. 5388, May 1, 1885. 6d.

THE process depends on the conversion of chloride, nitrate, or acetate of sodium or potassium into hyposulphates (dithionates) of either of these alkalis by treating

them with manganese hyposulphate (dithionate) in aqueous solution. The latter is prepared by treating sulphurous acid in solution with manganese dioxide. On mixing the two solutions in equivalent proportions, nearly the whole of the alkali contained in the alkaline salts is obtained as hyposulphate, the latter being only slightly soluble in solutions of chloride, nitrate or acetate of manganese. For the subsequent conversion of sodium or potassium hyposulphate into very pure sulphate it is only necessary to dry the salt and heat it to redness.—S. II.

Improvements in the Utilisation of Certain Residuals obtained in the Manufacture of Copper and Alkali. C. Wigg, Liverpool. Eng. Pat. 5620, May 7, 1885. 6d.

THE object is to provide efficient means for utilising the spent liquor obtained in the extraction of copper by the wet process, and also the vat waste of the Leblanc process. Spent copper liquor which mainly consists of sodium sulphate and chloride, and iron in various forms, is treated with ammonium sulphide until all iron is precipitated. The precipitate is then filtered, dried, and burned in the usual pyrites kilns. The iron peroxide left may be prepared for use as a pigment, and the sulphur dioxide given off disposed of in any convenient manner. The filtrate, now consisting of sodium sulphate and chloride, and ammonium salts in solution, is passed into apparatus for the formation of sodium carbonate. The ammonium sulphide required in the process is produced by the decomposition of vat waste with an acid and passing the gas into ammoniacal liquor.—S. II.

Improvements in the Production of Nitrate of Ammonia and Bicarbonate of Soda. J. F. Chance, Birmingham. Eng. Pat. 5919, May 14, 1885. 6d.

THE invention consists of a mutual decomposition between sodium nitrate, ammonia and carbonic acid. Sodium nitrate is dissolved in water, which is made slightly alkaline by some of the washings produced in a later part of the process. The solution is filtered and treated with an equivalent of ammonia. Such mixture is then subjected to a current of carbonic acid under pressure when there ensues a decomposition producing sodium bicarbonate and ammonium nitrate.—S. II.

Improvements in the Purification of the Alkaline Lays known as Tank or Vat Liquors. J. F. Chance, Birmingham. Eng. Pat. 5920, May 14, 1885. 6d.

IT is proposed to remove the sulphides by treating the liquor with a mixture of oxides or carbonates of iron and lime or carbonate of lime, prepared by precipitating a solution of iron chloride with a considerable excess of lime, or with a mixture of lime and carbonate of lime. The mixture is introduced into a vessel where by violent agitation it is brought into intimate contact with the liquor, the sulphides of alkalis being thereby readily converted into the hydrate and carbonate, the sulphur forming insoluble iron sulphide, which is separated by filtration. The purified lays are then treated in the usual manner.—S. II.

Improvements in the Production of Alkaline Phosphates in the Manufacture of Iron or Steel from Phosphoric Pig Iron. T. Twynam, Middlesbro'. Eng. Pat. 6867, June 5, 1885. 6d.

THIS invention relates to the manufacture of alkaline phosphates during the conversion of phosphoric pig iron into iron or steel. It is proposed to add in the converter or Siemen's furnace either trisodium or tripotassium phosphate or an alkaline phosphate containing three equivalents of a base for every equivalent of phosphoric acid. This tribasic phosphate is best obtained by fusing the alkaline phosphoric slag with sodium carbonate. In the furnace or converter the trisodium phosphate is converted into the monosodium salt, which by a subsequent fusion with alkali is reconverted into the trisodium compound.—S. H.

Improved Apparatus for Facilitating the Dissolution of Oxide of Lead and other Substances used for making Lead Salts for the Manufacture of White Lead, etc. A. W. Anderson, London. Eng. Pat. 12,891, October 27, 1885. 5d.

THIS apparatus consists of a horizontal cylindrical drum, which may be either stationary or revolving, provided with an internal revolving shaft or axis, fitted with stirrers or paddles.—E. G. C.

Improvements in Apparatus for Cooling Gases and Vapours. W. F. Weldon, Cambridge. From A. R. Pechiney & Co., Salindres, France. Eng. Pat. 6066, May 18, 1885. 5d.

THIS invention concerns an improved apparatus for cooling gases and vapours which are capable of attacking metals—viz., free chlorine, hydrochloric acid, etc. It consists essentially of a stone tower of rectangular horizontal section, in the interior of which tower are arranged, either horizontally or in an inclined position,

glass tubes, through which cold water is kept flowing. In Figures 1, 2 and 5, the glass tubes are marked *c*. One extremity of each tube protrudes through the A side of the tower, and its other end protrudes through a corresponding hole in the B side of the tower. On the A side of the tower the end of each glass tube is connected by a piece of caoutchouc tubing *d* with pipes T. Water passes into the pipes T from the hollow column X, and then

from T into the glass tubes *c*. On the B side of the tower each glass tube is connected by caoutchouc tubing *d'* with an open gutter *m* into which the water from the glass tubes is discharged, passing away by the hollow column M. The inclined position of the glass tubes is necessary to ensure their being always filled with water. Figures 3, 4, and 5 represent the joint between the glass tubes and the stone sides of the tower. It consists of caoutchouc pieces *i*, which are tightly pressed against the stone by means of bolts and glands *n*. The gas, or mixture of gases and vapours, to be cooled by this appa-

ing the lead. The filling proper consists of pieces of quartz, which are made to press strongly against the lining of quartz powder, all the holes and cavities along the edge being filled up with spalls of quartz. In lieu of the usual fire-brick arch, there are two posts of quartz, which carry blocks of quartz, spanning the spaces between the walls, some spaces being left open for the passage of the gas and the acid. On the top of these cross-pieces, and at right angles thereto, are placed smaller pieces of quartz, and above this series the filling proper is built up.—S. H.

FIG. 3.

FIG. 4.

FIG. 5.

ratus enters near the top of the tower at P, and the cooled gases pass off near the bottom on the opposite side at P'; any liquid condensing runs out at S. If one of the glass tubes happens to break, it can be readily removed and a new one put in its place without stopping the working of the apparatus.—S. H.

An Improved Sulphuric Acid Tower. Nichols and Herreshoff, Brooklyn, U.S.A. Eng. Pat. 1861, February 9, 1886. *Sd.*

THE main difficulty connected with the use of a Glover tower is caused by the brick lining and the lower brick arch not being able to withstand the severe action of the hot acid gases and of the hot acid. The bricks are gradually eaten away, shortening the life of the tower and rendering the acid impure. The present invention seeks to obviate these difficulties in proposing to line the tower within its outer sheeting of lead with quartz, and constructing the lower part of the tower entirely of quartz. It being impossible to cut quartz into blocks in such a manner as to form a self-sustaining wall, the quartz is crushed to so fine a powder that it will pack closely enough to prevent the hot gases from reach-

Improvements in the Extraction of Nitrate of Soda and other Salts. M. R. Pryor and A. C. Jameson, London. Eng. Pat. 2233, February 16, 1886. *Sd.*

THE object of this invention is the economical extraction of soluble salts from their native earths by a continuous process. The apparatus consists of an Archimedian screw fixed inside an inclined tube. This tube is caused to rotate with the screw whilst a stream of cold water flows into it at the higher end. The lower end of the tube takes up at each revolution a portion of the native earth which is slowly worked up the tube and passed out at the higher end, leaving the soluble salt in the water. The latter enters in a continuous stream at the higher end and passes out at the lower end, where it overflows into a spacious tank in order to deposit any insoluble matter carried away by the current. If it be desired to treat the native earths with hot water, the apparatus can be readily modified accordingly.—S. H.

An Improved Measuring Apparatus for Liquid Carbonic Acid. E. Lühmann and C. G. Rommenholler, Niedermendig and Rotterdam. Eng. Pat. 2262, February 16, 1886. *Gd.*

THE apparatus is shown in the accompanying drawings (Figs. 1 and 2). It consists essentially of a sliding rod G,

which can be worked air-tight through several stuffing boxes. Through the centre of the sliding rod for a distance extending from *e* to *w*, and with openings at these points, is a passage *u*. According as the rod *G* is moved forwards or backwards, the central passage connects a measuring vessel *K* with lateral channels *a* and *b*, which serve respectively as inlet and outlet for liquid carbonic acid. The modification shown in Fig. 2 is a simple form of apparatus, the measuring vessel *K* being firmly fixed

Amalgam or Cement capable of being Moulded or Pressed while in a Plastic Condition. J. Cawley, London. Eng. Pat. 2806, March 3, 1885. 6d.

AN argillo-calcareous clay from the neighbourhood of Boulogne is mixed with either marls or clays, in order to secure a perfectly homogeneous mixture of calcium carbonate and clay, as well as with other well-known cements. The argillo-calcareous rock is first crushed

on the end of the sliding rod *G*, and the central passage *u* opening directly into *K*. By moving the rod *G*, the measuring vessel is alternately connected with the inlet and outlet passages *a* and *b*.—S. H.

and then burnt: and, after mixing, the stone is burnt, again crushed, and finally sifted.—E. G. C.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Improvements in the Manufacture of Cement. W. Joy, Northfleet. Eng. Pat. 9154, January 30, 1885. 6d.

WET slurry, or a mixture of wet slurry and fuel, is charged into the cement kiln while the kiln is in action, the wet slurry, or the mixture, being deposited in successive portions on the burning charge as the burning proceeds, and at the parts where for the time being the charge is burning most freely.—E. G. C.

Production of Surfaces resembling Marble, Malachite, or other Stone on Tubular or other Hollow Objects or Bodies of Glass. J. Budd. Eng. Pat. 642, January 16, 1885. 6d.

THE inventor prepares the inner surface of hollow tubes, cylinders, etc., of glass, in imitation of marble, malachite, or other stone; the said glass is then provided with an internal lining of wood or other suitable material, if desired, with headings of brass, etc. In the case of cylinders or tubes to form pillars or pedestals, a wooden or other core is used, and the space between this core and the inner surface of the glass is filled with sand or other suitable substance.—E. G. C.

Improvements in the Manufacture of Artificial Stone. J. H. Johnson, London. From Ignay Brandstätter, Vienna. Eng. Pat. 3897, March 26, 1885. 6d.

PURE quartz, and similar materials, are ground and sieved, and mixed with magnesia or (if a higher degree of hardness be desired) with minium or litharge. Chalk, marble, or limestone is also used for some purposes. Twelve to sixteen parts by weight of a concentrated solution of silicate of soda are then added. The mixture is next poured into moulds, and submitted to a high pressure in a hydraulic or other press. Finally, the moulded and compressed stones are dried, burnt in an oven or kiln, and carefully cooled.—E. G. C.

Luminous and Damp-proof Cements. E. Ormerod and W. C. Horne, Battersea Park and Charlton. Eng. Pat. 3916, March 27, 1885. 6d.

LUMINOUS sulphide of calcium, in powder, is mixed with Keen's, Parian, or other suitable cement in varying proportions. The luminous cement so made is moulded into the required form, dried, and either placed in a bath of paraffin-wax and benzoline, or brushed over with a solution of paraffin-wax or other suitable damp-proofing material.—E. G. C.

Improvements in the Manufacture of Cement. F. Ransome, Norwood. Eng. Pat. 5442, May 2, 1885. 8d.

THE cement material is reduced to the state of a fine powder before it is passed into the burning chamber.

The latter consists of a slowly-revolving receptacle heated by the combustion within it of gas obtained from coal, coke, petroleum, or other hydrocarbon, in a gas producer of any suitable construction.—E. G. C.

Improvements in the Manufacture of Cement and Lime. H. Matthey, New York. Eng. Pat. 14,064, November 17, 1885. 4d.

INSTEAD of first making up the different constituents of Portland cement into a pasty mass or "slip," and then making bricks, which require to be dried either naturally or artificially before calcination in the kilns, the inventor grinds together the proper proportions of the several ingredients, and then feeds the fine powder so produced into a heated receptacle, which is kept constantly moving so as to agitate and disseminate the particles. Plaster of Paris is prepared in a similar way, the gypsum being at once ground to a fine powder and then calcined as described. For the manufacture of ordinary lime, the rock is first crushed so as to pass through a No. 4 or No. 6 sieve, and then conveyed directly to the heated and moving receptacle.—E. G. C.

Improved Process of and Furnace for Burning Lime and similar Materials. P. M. Justice, London. Eng. Pat. 15,252, December 11, 1885. From Carl Dietzsch, Malstatt. 6d.

THE process consists in first heating the limestone, lime, or similar substances by means of the escaping heat from the furnace, then adding fuel to the heated mass as it sinks down into the burning chamber, and then cooling, or partially cooling, the mass before withdrawing it. The furnaces are constructed so as to possess a preliminary heating chamber above, connected by inclined shoots or channels with one, two, or more burning chambers beneath. The lower parts of the burning chamber or chambers are contracted into a funnel shape towards the bottom, and form the cooling portion or zone of the main chamber.—E. G. C.

X.—METALLURGY, Etc.

Production of Antimony in Blast Furnaces. C. A. M. Balling. Chem. Zeit. 9, 1825.

THIS process is worked at Banya, in Hungary, where the crude antimony obtained possesses a composition indicated by the following figures:—Sample No. 1. Sb = 91.02, Fe = 6.23, S = 2.85. No. 2. Sb = 73.80, Fe = 16.66, S = 8.42. No. 3. Sb = 65.04, Fe = 23.80, S = 10.46. These figures show the differences between the three kinds or qualities of crude antimony obtained. The two first kinds are refined in a reverberatory furnace, and the third quality is returned to the blast furnace. The proportions obtained of these three sorts of crude antimony are, respectively, 82.5, 9.0, and 8.5. The slag produced has the following composition:—1. SiO_2 = 46.9, CaO = 34.6, FeO = 15.1, Sb = 0.5. 2. SiO_2 = 45.5, CaO = 31.4, FeO = 19.9 and Sb = 0.9.—E. G. C.

Improvements in the Machinery and Appliances for Treating, Dressing, and Cleaning Tin and other Mineral Ores, and in Modes, Means, and Processes connected therewith, and for other useful purposes. G. M. Edwards, London. Eng. Pat. 6347, May 23, 1885. 11d.

SEVERAL arrangements are detailed for washing tin slimes. First, the slimes are to be passed over an inclined stepped plane, set in a wooden frame in the successive recesses formed by the steps of which the tinstone will be deposited, and will, moreover, be graduated into various sizes, each recess collecting a smaller mean size than the preceding one. By a simple arrangement of pivoted partitions (only brought into use when required) the various qualities may still be kept separate when it is necessary to clean up the frame. Next, the slimes may be passed through a funnel, delivering at a depth of

two-thirds of the total height, into a cylinder of clear water. The heavier particles will sink, those which are lighter being carried away by the water overflow. Or they may be introduced into a tall cylinder of water containing a central rod, carrying at its lower end a propeller screw. Over this rod slides a deep plunger, the diameter of which is two inches less than that of the cylinder, and which is actuated by a hand lever. When the slimes are thus introduced, the propeller blades are rapidly revolved until the whole of the ore is by agitation got into suspension; the whole is then allowed to stand quietly until it is judged that all the tin has settled, and the plunger is then lowered and displaces a part of the water with the gauge still in suspension. When, by repetition of the process, the slimes have lost about 40 per cent. of their original bulk, they are divided into two parts by means of a double cylinder, the upper half of which fits accurately upon the lower, but may be made to slide from it laterally along a grooved channel. The heavier portion in subsiding takes the lowest position, and thus the lighter portion above is removed with the upper half of the cylinder.—W. G. M.

Improvements in Concentrating or Washing Apparatus for the Treatment of Ores or other Materials. P. M. Justice, London. From The Frue Vanning Machine Co., Detroit, Michigan, U.S.A. Eng. Pat. 6758, June 3, 1885. 8d.

SUPPORTED by freely-swinging legs within a substantial framework, is a long rectangular frame of light construction, to which a rapid longitudinal oscillation is constantly imparted by a connecting rod communicating with an eccentric. Around this frame, which is placed not quite horizontally, is stretched an endless flanged belt, preferably of smooth surfaced rubber. This belt rests on a series of transverse rollers above the frame. Passing over a drum at the higher end, it is then belled beneath, so that it shall traverse a water tank, by means of a second drum; it is restored to the level by passing over a third, and finally re-attains the top over a fourth placed at the lower extremity of the frame. A slow travelling motion is imparted to the band by connecting one of the pulleys by suitable gearing with the shaft which drives the oscillator eccentric: the band thus travels (above the frame) up the incline, near to the top of which is an ore distributor delivering the pulp evenly over its surface, and higher than this is a row of clear water jets reaching across the frame. Thus by the action of the water, aided by the oscillation, the heavier matter sinks to the bottom and is carried onward by the band, and eventually washed off in the tank beneath, whilst the lighter gangue is swept forward and downward and deposited in a launder at the lower end. Where tailings from amalgamation of gold ores are to be concentrated, the mercury is caught in the distributor by riffles and an amalgamated copper-plate.—W. G. M.

Improvements in the Manufacture of Steel. John Gjers, Middlesborough. Eng. Pat. 6873, June 5, 1885. 6d.

THE principle of forcing of carbonic oxide, alone or with nitrogen, through steel in a converter, as described in Eng. Pat. 6484, 1884, is extended to steels made otherwise than by the pneumatic process. In the open hearth furnaces the gas is introduced into the metal bath by means of a hollow rabble; in the crucible or ladle by a steel or iron pipe passing to the bottom of the metal and protected (or not) by a refractory covering, the diameter of the pipes being in the former case 4-inch, in the latter 1 inch.—W. G. M.

Improvements in Preparing Ores, Oxides, or Compounds of Iron for Smelting or Reducing. John McCulloch, Airdrie, Lanark. Eng. Pat. 6894, June 8, 1885. 4d.

THE ore or oxide, well dried and pulverised, is mixed with coal or coke in the proportion of from one to three equivalents of ore to one of carbon, and with dry calcium carbonate or other flux, and sufficient pitch to ensure agglutination; the mixture is then moulded and pressed

into bricks, preferably by the apparatus described in Eng. Pat. 9591 of 1885, and is then ready for use in the blast furnace.—W. G. M.

Improvements in the Manufacture or Treatment of Iron and Steel. J. H. Johnson, Lincoln's-Inn-Fields. From La Société Anonyme "Le Ferro-Nickel," Paris. Eng. Pat. 7179, June 12, 1885. 6d.

To a charge of melted soft iron or steel is to be added a mixture of about 1 per cent. of manganese, 0.5 of potassium ferrocyanide, and 0.05 of aluminium, with the object of increasing the tenacity of the metal. If, at the same time, it be desired to render it less oxidisable, malleable nickel to the extent of from 3 to 25 per cent. (according to the degree of inoxidisability required) is also to be used. Carbon may be wholly, or in part, substituted for the ferrocyanide; but with less satisfactory results.—W. G. M.

Improvements in the Manufacture of Steel Converter Bottoms, Plugs, or Blocks. Geo. Jarvis, St. George's, Salop, and Alex. E. Tucker, Smethwick. Eng. Pat. 7571, June 22, 1885. 4d.

SLAG from the blast furnace or the converter, alone or fused with other refractory bodies, is run direct, or after remelting, into moulds of the required shape and containing tubes or pins to give the requisite perforations. These blocks may be afterwards annealed if necessary.—W. G. M.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

Ammoniated Soaps. C. R. Huxley. Eng. Pat. 3441, March 17, 1885. 4d.

A SOAP made from 8 parts of stearic acid, 4 cocoa-nut oil, 1 potash, 1 soda, 6 water, is cut into shavings and placed in a retort in which is a pressure of 15lb. per square inch of ammonia gas until thoroughly permeated with it.—W. L. C.

Improvements in the Distillation of Glycerine, and in Means or Apparatus employed therein. A. G. Brookes. Eng. Pat. 5382, May 1, 1885. 8d.

THE still and superheating coil are heated by the same furnace, and the former is connected with condensing coils which terminate in vacuum pans large enough to hold the whole charge. The series of condensing coils ends in a surface condenser connected with a vacuum pump, and kept cold by streams of water which do not mix with the condensed glycerine. A drawing is given.—W. L. C.

An Improved Soap-paste for Cleansing Woollen and other kindred Fabrics. M. S. Gosling. Eng. Pat. 5998, May 15, 1885. 4d.

ONE part of borax, and 32 parts of Castile soap are incorporated with water into a thick paste, and a fragrant essence is added.—W. L. C.

A Lubricating Powder for Machinery. A. M. Clark. From B. Lenglet, Amiens. Eng. Pat. 670, January 15, 1886. 4d.

POWDERED talc or kaolin is incorporated with paraffin, spermaceti, wax, etc., to produce a white lubricating compound, for machinery employed in making white fabrics, such as tulle, etc.—W. L. C.

Improvements in Lubricating Compounds. C. Fink. Eng. Pat. 1525, February 2, 1886. 4d.

WITH any animal, vegetable, or mineral oil, about an equal bulk of a mixture compounded as follows, is incorporated: 42 gallons lime water, 10lb. French chalk, 4oz. ammonium chloride, 4oz. ammonium carbonate, 2oz. potassium carbonate, 2oz. borax, 10lb. sulphur.—W. L. C.

XII.—PAINTS, VARNISHES, AND RESINS.

Improvements in the Manufacture of White Lead, and in Apparatus to be used therefor. E. V. Gardner, London. Eng. Pat. 3839, March 25, 1885. 8d.

THE inventor claims—*Firstly*, the arrangement of the melting pots and heating chamber, described at length in the specification; *secondly*, the use of the higher oxides of nitrogen other than nitric acid, mixed with acetic acid and water, or watery vapour; *thirdly*, a method of supplying the gases and vapours to the converting chamber, by means of a combined "injector-exhaust-evaporator;" *fourthly*, an arrangement of troughs containing water or diluted acid and an electro-negative to lead, and the connection thereof with the lead to be converted, within the converting chamber; and, *fifthly*, the construction of apparatus for drying white lead.—E. G. C.

Anti-fouling and Anti-corrosive Composition for Ships and Submerged Structures. P. Denniston, Glasgow. Eng. Pat. 4415, April 9, 1885. 6d.

THE inventor uses paraffin scale as the base of his anti-fouling composition, and he prefers to employ such a mixture as the following: Paraffin scale, 10 parts; white lead, zinc, or other paint, 7; bronze green, 6; light green, 1; rosin, 2; arsenic, or cyanide, or oxide of mercury, 2.—E. G. C.

Gutta-percha from Bassia (Butyrospermum) Parkii. G. Don, Ed. Heckel and Fr. Schlagdenhauffen. Compt. Rend. 101, 1069—1071.

ACCORDING to the experiments described in the paper, as regards density, solubility, and amount of ash, the above gutta-percha is almost identical with ordinary gutta-percha, but yields on extraction less substance than the latter does, to petroleum spirit, ether, turpentine and boiling acetic acid.—T. L. B.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

Improvements in Leather, and in the Manufacture or Treating of same. A. Johnson. Eng. Pat. 7818, June 27, 1885. 6d.

LEATHER, tanned by the ordinary process, is coated on the flesh side with a dressing composed of common rosin (3 parts) and tallow (1.25 parts). Japan wax and paraffin oil or Japan, carnauba, paraffin or bees-wax, alone, may be used instead. The hide is then placed in a suitable chamber, kept warm enough to liquefy the dressing. The operation is repeated till the hide has absorbed sufficient dressing. The cooled hide is then placed in a bath of water, maintained at 80° F., till saturated. It is then reset, and when dry is ready for use.—B. H.

The Industrial Utilisation of Leather Waste. J. W. Davies. Eng. Pat. 11,880, October 6, 1885. 6d.

THE leather waste is passed through a suitable disintegrator or devil, the degree of fineness to which it is reduced depending on the size or smoothness of surface to be given to the resulting product. The sieved leather flock is then mixed with a small percentage of glue, gutta-percha, or similar binding material, so as to form a stiff paste, with which other substances are incorporated, according to the class of goods to be made. The final form is given to the articles by pressing or rolling the paste in any well-known way. A number of recipes are given for making boot heels, door knobs, reels, flooring tiles, etc.—B. H.

XIV.—AGRICULTURE, MANURES, Etc.

On the Thomas Slag. Dr. Pieper. Chem. Zeit. 9, 1629.

AT a meeting of the German Society of Manure Manufacturers, held at Berlin, on November 7, 1885, Dr. Pieper gave the results of some experiments made by him with

the Thomas slag. He employed a slag (1) containing 17 per cent. P_2O_5 , and 49 per cent. CaO ; another (2) containing 18 per cent. P_2O_5 , and 47 per cent. CaO ; and a third (3) with 20 per cent. P_2O_5 , and 33 per cent. CaO . Coprolites, containing 18 per cent. P_2O_5 , and a phosphorite, with 25 per cent. P_2O_5 , were also taken, for the purpose of comparison. The results of some experiments as to the solubility of the P_2O_5 present in the five materials are here given:—

	Soluble in Citric Acid.	Soluble in dilute Acetic Acid.	In 1000 parts of carbonated water dissolved in 24 hours.
Slag I.	3.53	58.07	0.9
Slag II.	3.68	51.23	0.91
Slag III.	4.38	36.34	5.54
Coprolites	1.02	10.95	2.55
Phosphorite ...	1.00	5.64	1.71
—E. G. C.			

*On the Action of the Thomas Slag, when used for Manu-
rial Purposes.* F. v. Maltzan. Chem. Zeit. 9, 1827.

AFTER reviewing investigations which have been made in connection with this subject, the author expresses the opinion that the use of the slag is a makeshift, and that the action of this material has not been sufficiently accurately ascertained. Its low price is, of course, in its favour.—E. G. C.

XV.—SUGAR, GUMS, STARCHES, Etc.

Improvements in the Manufacture of Grape Sugar. Oskar Korschelt. From H. Soxhlet, Munich. Eng. Pat. 7098, June 10, 1885. 6d.

THE improved process relates to the preparation from rice starch of a mixture of maltose and dextrine by the action of malt, and then of the conversion of these substances into glucose, by heating the solution with sulphuric acid, under pressure or otherwise. When working under pressure in closed vessels, sulphuric acid is employed in the following proportions, and the duration of the boiling is regulated as follows:—

No.	Sulphuric Anhydride per 100 gallons of liquid.	Atmospheres pressure.	Hours.
1	20½ oz.	2	4½
2	41	1	5
3	41	2	3
4	82	1	4
5	82	2	2
6	120	1	2
7	160	1	1½

The liquor used in above treatment indicates 10 to 13 degrees on the saccharimeter. When the conversion into glucose is completed, the acid is neutralised by carbonate of lime.—A. J. K.

Improvements relating to Filters, and to Apparatus connected therewith, for Purifying Sugar Liquor. W. R. Lake. From F. O. Mathiesen, New York. Eng. Pat. 1888, February 9, 1886. 8d.

Improvements in Filtering Apparatus for Use in the Purification of Sugar. W. R. Lake. From R. C. Howes, New Jersey, U.S.A. Eng. Pat. 1891, February 9, 1886. 6d.

Improvements in Filtering Apparatus for Purifying Sugar Liquor. W. R. Lake. From E. E. Quindry, New Jersey, U.S.A. Eng. Pat. 1890, February 9, 1886. 8d.

Improvements in and relating to Dischargers for Filtering Apparatus to be used in the Purification of Sugar Liquor. W. R. Lake. From F. O. Mathiesen, New York, U.S.A. Eng. Pat. 1889, February 9, 1886. 8d.

THE above four patents relate to the continuous process of upward filtration of sugar liquor through bone charcoal,

and have special reference to various devices for removing the spent char from the bottom of the char cisterns, either by revolving bottoms or by rocking grates.

—A. J. K.

Improvements in or connected with Triple Effect Evaporating Apparatus, used in the Manufacture of Sugar, and similar Vacuum Apparatus. J. McClure C. Paton, Nottingham. Eng. Pat. 1844, February 10, 1886. 6d.

THE above invention relates to a new way of removing the water of condensation collecting on the lower tube plate, or at the bottom of the calandria or heating drum, of the second and third pans, in a triple effect arrangement.—A. J. K.

Improvements in the Manufacture of Starch, and in Apparatus employed therein. B. H. Remmers. From L. von. Wagner and A. Gillitzer, Buda-Pesth. Eng. Pat. 4758, April 17, 1886. 11d.

THE improved process consists in subjecting maize, rice, or other grain to the following treatment:—(1) Seaking in a weak solution of sulphurous acid; (2) uniformly crushing the softened grain by means of rollers, as set forth; (3) drying and pulverising the grain by means of a disintegrator; (4) soaking the flour so produced in a solution of sulphurous acid; (5) removing the bran, germs and coarser particles from the starch milk by strainers; (6) separating the water and gluten from the starch by centrifugal or other means. The authors also claim improvements in feeding hoppers and other machinery used in above process.—A. J. K.

A Method or Process for the Extraction of Sugar from Saccharine Juices, Syrups and Molasses. Louis Le Franc, of Tracy-le-Val, France. Eng. Pat. 6358, May 23, 1886. 6d.

THE above patent consists of a combination of two known processes for the recovery of sugar from saccharine solutions. In the first process, the liquor, which should contain not less than from 5 to 12 per cent. sugar, is treated first of all with lime in the cold, and then boiled, when the following reaction takes place:— $3(C_{12}H_{22}O_{11} \cdot 2CaO) + 2(C_{12}H_{22}O_{11} \cdot 3CaO) + C_{12}H_{22}O_{11}$. The dilute filtrate from the insoluble tribasic sacrate is then treated in the cold with lime, calcium chloride, and caustic soda, when the remaining sugar is precipitated as insoluble tribasic sacrate, according to the following equation:— $3(C_{12}H_{22}O_{11} \cdot 2CaO) + CaCl_2 + Na_2O = 3(C_{12}H_{22}O_{11} \cdot 3CaO) + 2NaCl$.—A. J. K.

Improvements in Treating Sugar and Like Substances, and in Apparatus therefor. G. M. Newhall and J. H. Tucker, Philadelphia. Eng. Pat. 8843, July 22, 1886. 8d.

INSTEAD of machining raw sugar in the ordinary way, by washing the sugar by hot or cold water in the centrifugal machines, the authors prefer to use a solution made by dissolving a portion of the raw sugar in hot water. About 30 parts of this liquor (36 B.) are added, at a temperature of 200° F., to 100 parts raw sugar, at a temperature of say 60° F. The whole mass is thoroughly mixed in a heater, and then transferred to the centrifugal, when it is machined. By the ordinary process it is impossible to machine, to any advantage, fine-grained sugars especially such sugars as Brazilian, Manillas, etc., which are, in addition, of a gummy nature. By the new process, however, these sugars may be melted and used as a liquor for machining coarser-grained raw sugars.—A. J. K.

XVI.—BREWING, WINES, SPIRITS, Etc.

On the Causes of the Formation of Bad Crude Spirit in Uninterrupted Distillation. Dr. R. Rempel. Chem. Zeit. 9, 1692.

THE author begins his communication by referring to F. Pampé's investigations on this subject (Chem.

Zeit. 9, 1374, 1410, and 1467). Pampe names three causes of the formation of bad spirit: 1. Contamination of the spirit by sulphuretted hydrogen and hydrocarbons, produced by the action of the acids of the mash upon the inner surfaces of iron distillation apparatus; 2. Formation of hydrogen sulphide in consequence of the decomposition of albuminous substances; 3. Production of fusel oil during the operation. The author in the main corroborates Pampe's statements, but dissents from them in certain particulars.—E. G. C.

A New and Useful Process for Preventing from any Possible Alterations the Saccharification of Amylaceous Substances by Malt. Léon Ensinier, Paris, France. Eng. Pat. 7788, June 26, 1885. 6d.

THIS is the application of the well-known fact that chloroform, ether, and anesthetics in general do not affect the action of the soluble ferments, whilst they prevent entirely the growth and action of micro-organisms. The inventor adds 0.01 per cent. of the anæsthetic, preferably chloroform, to the wort; this preserves it for an indefinite time, without retarding the saccharification. The chloroform can be got rid of by boiling. If the process of saccharification is carried on in closed vessels, no loss of chloroform takes place by volatilisation, and the whole can be recovered by distillation.—G. H. M.

Improvements in the Processes of Distilling and Rectification. J. Wright, London. Eng. Pat. 2604. February 23, 1886. 4d.

THESE improvements consist in the employment of a partial vacuum in the still during the distillation, and a consequent lower temperature than would be employed in the usual way. A steam jacket or steam coil is preferred as the source of heat.—G. H. M.

XVIII.—ELECTRO-CHEMISTRY.

Improvements in Coating Copper Printing Plates to render them more durable. H. M. Senhouse, Stoke-upon-Trent. Eng. Pat. 5977, May 15, 1885. 6d.

A COAT of iron is first deposited upon the copper, and then a coat of nickel upon the iron, thereby making the plates more durable, and rendering more easy the removal of the nickel from the copper when partly worn.—W. B.

Improvements in the Continuous Manufacture of Light Metals by Application of Electrolysis, and in Apparatus therefor. P. Jensen. Eng. Pat. 7510, June 19, 1885. 8d.

IN order to produce the light metals on a cheap scale by electrolysis, the author proposes an arrangement of a number of half retorts or bottomless retorts, placed horizontally in a furnace, connected with suitable receivers. The light metals formed in the half retorts, from the halogen compounds with which they were charged, are withdrawn, without interrupting the electric current, and allowed to cool with the air excluded.

—W. B.

Improvements in Electrical Batteries. H. C. B. Chalders and A. J. Thorman, London. Eng. Pat. 7733, June 25, 1885. 4d.

SEAWEED or sea-wrack is used as an exciting agent in primary or secondary batteries.—W. B.

An Improved Carbon Element for Galvanic Batteries. C. R. Goodwin, Paris. Eng. Pat. 8331, July 9, 1885. 8d.

CARBON elements of galvanic batteries, when being moulded, have a metallic screw-threaded rod partly embedded in them, after which they are baked. The conducting wire is held between a washer and nut, which are screwed upon that part of the rod not embedded.

—W. B.

Method of Constructing Electrode Frames for Secondary Voltaic Batteries. A. Khotinsky, Rotterdam. Eng. Pat. 8416, July 11, 1885. 6d.

ELECTRODE frames for secondary batteries are formed with recesses, having ribs or partitions separating them, with inwardly projecting lips or flanges, the electrode material being placed in the recesses.—W. B.

Improvements in Galvanic Batteries. A. R. Upward, and C. W. Pridham, London. Eng. Pat. 9302, August 4, 1885. 8d.

THIS invention relates to batteries which are maintained in an active condition by the passage of chlorine gas through the cells. The gas is caused to be delivered from the generator into the lower part of a high column of vertical pipes open at the top and connected near the bottom by a tube, with the batteries to be supplied. An aspirator, in which a jet of water operates to propel the air, is provided at the outlet of each battery. An electric governor controls the water supply to the aspirator in accordance with the current delivered by the battery.

—W. B.

An Improved Voltaic Battery. S. W. Maquay, London. Eng. Pat. 15,040, December 8, 1885. 8d.

THE chief improvement is in constructing the positive elements used with the battery, of an alloy consisting of zinc, 95 parts; lead, 2 parts; tin, 2 parts; and mercury, 1 part. This alloy having been cast into the desired shape, it is alternately amalgamated, and then heated to 100° F., until it has taken up a very considerable quantity of mercury. Any convenient negative element, such as carbon or platinum, may be used, after it has been dipped into liquid sulphur.—W. B.

Improvements in Smelting Ores by means of Electricity, and in Apparatus or Furnaces therefor. A. H. Cowles, U.S.A. Eng. Pat. 1160, January 26, 1886. 8d.

THE charge to be reduced is contained in a furnace-chamber having electrodes fitted into its opposite sides. The electrodes which are buried in the charge are drawn further apart, according as the resistance diminishes during the reduction of the charge, either by hand, clockwork, or automatically by the current in the circuit. As the heated portions of the electrodes emerge slowly from the furnace, they first pass through copper boxes containing small copper shot, by means of which they are reduced to such a temperature that they are not injured on being exposed to the air.—W. B.

XIX.—PAPER, PASTEBOARD, Etc.

Improved Process for Preparing Paper for Indelible Writing. D. S. Simpson, Edinburgh. Eng. Pat. 3980, March 28, 1885. 4d.

PAPER, cardboard, wood or other material on which writing or printing can be done is impregnated with certain chemicals as follows:—Carbonate of soda or potash, cyanides or any soluble salts having the desired effect of rendering the ink or other writing, printing, or marking material indelible to water. Inventor finds the following salts suitable for his purpose:—Sodium carbonate, or bicarbonate, the corresponding potassium salts, potassium ferrocyanide, with or without the addition of a mordant like alum or tin chloride. Either of these mordants may also be used alone.—H. A. R.

Improvements in Sizing Paper and such-like Material. C. Weygang, London. Eng. Pat. 5585, May 6, 1885. 6d.

THE object of these improvements is the sizing of paper with certain substances of an oily, fatty, resinous, or tarry nature in such a manner as to produce a stronger and more impermeable material than is ordinarily obtained. Any oils, resins, or tar, or any allied substances soluble in alkaline solutions, may be employed. The

mixtures proposed, which inventor terms "size," are incorporated in the beating engine in the usual way. The size is precipitated by an alkaline salt—*e.g.*, nitrate or sulphate of ammonia, either alone or together, with other more energetic precipitating agents, such as an acid, an acid salt, a calcium salt, a salt of chromium in conjunction with another metallic salt. Sometimes the ammonia salt is omitted altogether, and a salt of chromium or manganese is used in combination with another metallic salt, such as sulphate of iron, aluminium, copper or zinc. The following are examples of the kind of mixtures it is proposed to use along with common rosin size such as usually employed by paper-makers.

Rosin	30 parts.
Soap	30 "
Petroleum or Turpentine	10 "
Wood Tar	80 "
Ordinary Soap	20-40 "
Rosin	20-40 "
Crude Carbolic Acid	15-20 "

A great variety of mixings is given, also different modes of applying the same to produce different effects.

—H. A. R.

Improvements in the Preparation of Paper Pulp from Straw, Esparto, Wood, Rags, and like Fibrous Substances. R. C. Menzies, C. F. Cross, and E. J. Bevan, London. Eng. Pat. 6839, June 5, 1885. 4d.

THIS invention consists essentially in subjecting the substances, after they have been pulped and before they have been bleached, to the action of chlorine gas and an alkali or alkaline salt.—H. A. R.

Improvements in Machines for Cleansing Esparto and other Grass used in Making Paper. G. Petrie and F. W. Petrie, Rochdale. Eng. Pat. 7772, June 26, 1885. 11d.

THE main points in this invention are the following:—1. The construction of the beater fan, which is armed with studs or teeth, or with plates or blades. 2. The combination of the same with a dead plate armed with teeth and with one or more grids underneath, and in combination with an exhaust fan.—H. A. R.

Improvements in Apparatus for the Manufacture of Paper. C. J. Richardson. Eng. Pat. 10,543, September 5, 1885. 8d.

THE object of this invention is to afford increased facility for making changes in the width of paper during manufacture without having to stop the machine. The deckle frames are made to move in or out simultaneously under the manipulation of a single man without any stoppage of the paper machine, whilst the action of the same mechanical means rolls up or spreads out the apron as required.—H. A. R.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

Observations and Experiments on Poisoning by Atropine. Chem. Centr. 17, 217.

EXAMINATION of the urine is particularly important, as atropine is entirely absorbed and passes away unchanged with the urine. Although a microscopical examination in polarised light cannot by any means give sufficient evidence for deciding on the presence of atropine, it is nevertheless of interest, as the sulphate crystallises in a characteristic way, and any foreign matter may thus be detected with absolute certainty. It is only by a positive result of a physiological experiment that we are justified in looking upon the presence of atropine as beyond any doubt. The human eye is best adapted for such an investigation owing to its great sensitiveness. Atropine exhibits a striking resistance to decay, and may probably be detected in a corpse, even if months have elapsed since death.—A. R.

Some New Drugs. Chem. Zeit. 10, 433.

ALMOST all parts of the plant *Anona muricata* L. have a medicinal value. Thus a decoction of the root is used as an antidote for fish-poisoning, and the bark serves as an astringent. The leaves are useful in softening abscesses, and as the seeds in the fruit contain tannin, the latter are employed as astringents, or a wine can be prepared from them by fermentation, which is said to be beneficial in cases of diarrhoea.

Several kinds of *anona*, such as *polyalthia*, *xylopia*, *artobotrys*, are also highly prized as medicines. Most of these plants have a sharp aromatic odour and taste. The flavour of the fruit resembles that of oil of turpentine.

Eupatorium.—Many kinds of this species have an aromatic odour and bitter taste, the latter being so intense that *E. amarissimum* is used in Mexico, and *E. villosum* sweet in Jamaica as a substitute for hops. *E. ayupama* is a good remedy for indigestion, and an infusion of it is said to give relief to patients suffering from chest complaints, and has been employed on the Isle of France as an antidote for cholera.—A. R.

Properties of some New Drugs. The Pharmacopœia Commission of the German Chemists' Union. Arch. Pharm. 24, 166.

BESIDES a thorough investigation into the contents of the pharmacopœia, the above commission intend to examine all new medicinal preparations, and of these the following have been recently studied:—

Ammonium ichthyolsulphonate is a thick, clear syrup of a redish-brown colour. It is soluble in water and in a mixture of equal volumes of ether and alcohol. On adding hydrochloric acid to the aqueous solution, a resinous mass is precipitated.

Arbutin.—An aqueous solution is coloured green by small quantities of a solution of ferric chloride, and blue by a larger amount of that reagent. On heating with 1 part of water, 2 parts of sulphuric acid, and 8 parts of manganese dioxide, a penetrating odour of quinone should be observed.

Thallium sulphuricum is a yellowish-white crystalline powder, resembling cammarin in its odour. A dilute solution (1:100) is coloured a deep green by ferric chloride, changing to a dark red after a few hours.

—A. R.

The Artificial Production of Codeia. G. B. Dott. Eng. Pat. 7413, 1885. 6d.

THE patentee produces codeia artificially by the action of methyl chloride, preferably under pressure, upon morphia.—T.

The Preparation of a Colourless or Decolourised Solution of Iodine. H. N. Draper. Eng. Pat. 7527, June 20, 1885. 4d.

THE patentee affects his object by forming combinations of iodine with orcin, phoroglucin, resorcin and similar organic bodies, which are so loose as that, upon evaporation of the solution, the iodine is left in a free or uncombined state.—T.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

Wash-bottle for Quantitative Work. M. Wernecke. Chem. Zeit. 10, 399.

To prevent the water from receding in the exit tube of the wash-bottle, the author constructs it in the following manner:—The exit tube being bent in the shape of a U, the upper limb is cut off short, and a piece of india-rubber tubing attached, closed at the end by a glass rod, and also provided with one of Bunsen's slit valves. Over the india-rubber tubing a piece of glass tubing of

somewhat wider dimensions is passed, and attached to the free end of this by means of an indiarubber ring is

the glass tubing, bent and drawn out to a point as shown in the figure.—A. R.

Determination of Carbon and Hydrogen by means of Copper Oxide Asbestos. E. Lippmann and F. Fleissner. *Monatsh. Chem.* 7, 9.

To prepare molecular copper, a solution of a copper salt is treated with ammonia, then with a sufficient quantity of caustic soda to redissolve the precipitate, and boiled ten minutes with a solution of grape sugar. Thus cuprous oxide is formed, and can be further reduced to metal. The precipitate of this, after decanting the solution, is washed with dilute sulphuric acid to remove any cuprous oxide. The metal is lastly washed with water. Another method is to reduce with zinc dust and to remove excess of the latter by boiling with sulphuric acid. The spongy mass obtained in this manner must be dried and powdered. By shaking 20–30 grms. of the powder, which has been dried over sulphuric acid with some silky asbestos, the copper is made to adhere to the fibre. The combustion tube should be about 70cm. in length and 1.5–2cm. wide. A stopper of silver gauze is inserted at *a* (Fig. 1), then follows a layer of 20cm. of

FIG. 1.

copper-asbestos, another stopper at *b*, similar to the one at *a*, and adjoining the latter a stopper of asbestos. The part *a b* being heated to a dull-red heat, a dry current of air is slowly passed through the tube, and when nearly all the copper has been oxidised, the current of air is replaced by one of oxygen, until this gas is detected at *d*. After cooling, the tube is filled from *c* to *d* with a layer of lead oxide 5cm. in length, previously boiled with nitric acid, an asbestos stopper being inserted at *d*.

FIG. 2.

The authors recommend Kopfer's combustion furnace, with slight alterations (Fig. 2). The front part of the

tube is first heated to a red heat, then the lead oxide to 150–200°, and when sufficient oxygen has been passed through the tube, the boat containing the substance is quickly introduced, a spiral of copper gauze being placed immediately behind it. The latter is now heated with burner *c* and the application of heat gradually extended to the whole tube. Finally, the part where the substance originally was is strongly heated. Solid bodies must be covered in the boat with lead chromate, and cyanogen compounds should previously be well mixed in an agate mortar with one part of potassium chromate and ten parts of lead chromate.

A combustion by this method only takes 1½ hours, even if the body analysed contains a high percentage of carbon. The authors give the results of numerous analyses proving the exactness and the wide range of their method, which they expect will soon be in general use in laboratories, where it is sure to be preferred to any other.—A. R.

Tube for Fractional Distillation. Rud. Rempel. *Chem. Zeit.* 10, 371.

THE author claims that these tubes combine the advantages of those constructed by Linnemann and Hempel on the one hand, and by Winssinger on the other hand—*i.e.*, it serves the purpose of rectification and dephlegmation at the same time. The part A of the tube is filled with glass beads, and the vapour which passes through is partly condensed by means of a fluid which enters B by *a* and is conducted away through *c*. At the same time the condensed vapour, in passing over the glass beads, is rectified again by the rising vapour. It is obvious, from the direction in which the fluid passes through B, that the layers in the lower portion of B are warmer than those in the higher, and a much better separation of the constituents of the vapour is thus effected. This tube is specially adapted for mixtures boiling below 100°, for in that case the water from the condenser may be used for dephlegmation. To effect this, the exit tube of the condenser is connected with *a*, and by increasing or decreasing the supply of water to the condenser, the temperature of the water, which passes into the dephlegmator, can be regulated at will. A certain size of the glass beads is essential to the good working of the apparatus. For fluids which are very

mobile the beads should be 4–5mm. in diameter, whereas in the case of oily fluids which boil with difficulty, the diameter should be 6–7mm. and more. The platinum net *p* must have wide meshes. The author finds the apparatus most serviceable in separating the various constituents of fusel oil.—A. R.

Drying Apparatus. V. Meyer. Ber. 19, 419—420.

This paper is a supplement to a former article (this Journal, 1886, p. 106), in which a drying and heating apparatus devised by the author was described. Attention is called to the necessity of employing perfectly pure heating agents, as mixtures of liquids differing in boiling points indicate temperatures varying with the size of the flame employed.—D. E.

Analysis of Cyanogen Products from Blast Furnaces. H. V. Jüptner. Chem. Zeit. 9, 1805.

THE mass is treated with water and filtered. A part of the filtrate is evaporated to dryness after digestion with aqua regia, and used for the determination of SiO_2 , K_2O , Na_2O , and S. To a second portion of the aqueous solution is added barium acetate, which throws down SiO_2 and CO_2 ; these are determined as usual. To the filtrate is added in excess a measured quantity of AgNO_3 solution. The amount of excess of silver solution is determined. The precipitate is now treated with HNO_3 , which dissolves silver cyanate. The silver in this solution is titrated, and the cyanic acid thus estimated. The residue is dried, ignited, and treated with ammonia. AgCl goes into solution, from which it can be again precipitated by HNO_3 , then weighed as usual.

—E. G. C.

Quantitative Analysis by means of Electrolysis. Alex. Classen and Robert Ludwig. Ber. 19, 323—327.

IN a previous communication (Ber. 14, 1630) it was stated that arsenic could not be deposited by electrolysis either from an aqueous solution or from one containing hydrochloric acid or ammonium oxalate. It has not been found possible, on the other hand, to obtain a deposit of antimony free from arsenic (Ber. 18, 1110). The authors now find that the separation may readily be effected if the arsenic is in the form of arsenic acid or a corresponding compound. The mixture of antimony and arsenic or of their compounds is evaporated to dryness with aqua regia, dissolved in 2 or 3 cc. of water, and treated with concentrated caustic soda until about a gram of NaOH is contained in the solution. About 60 cc. of sodium sulphide solution (Ber. 18, 1110) are added, and the elements separated in the same way as antimony and tin (*loc. cit.*). The arsenic is estimated as usual in the residual solution.

Antimony may be separated from arsenic and tin by the above method, but if the latter elements are also to be estimated, the modified method of Fischer and Hufschmidt, described in the paper referred to, is to be adopted.

Mercury may be deposited from a solution slightly acidified with nitric acid, if the experiment is continued for twelve to sixteen hours at the ordinary temperature by such a feeble current as would liberate 0.5 to 1.0 cc. of oxygen and hydrogen in that time. It is possible to separate mercury in such a solution from the alkaline earths, from chromium and aluminium, from nickel and cobalt, from iron, manganese and uranium, and from cadmium. 2 cc. of concentrated nitric acid are added to about 200 cc. of solution. The mercury is washed with cold water while the current still passes, then with alcohol, and it is dried over sulphuric acid. Mercury could not be separated from bismuth by this method.

The difficulty hitherto experienced in obtaining a coherent deposit of bismuth (Ber. 14, 1626) has been overcome by Herr Eliasberg in the following manner: The bismuth salt is treated in a weighed platinum basin with 10 cc. of potassium oxalate solution (1:3), and to the warmed mixture solid ammonium oxalate is added until the whole is dissolved. The solution is diluted to 150 cc., and a current is passed, at a temperature of 70 to 80°, of an intensity barely sufficient to decompose water. Two Meidinger's elements, with an external resistance of about 60 Ohms., are recommended. After about sixteen hours the solution is acidified with pure oxalic acid and the electrolysis continued. After twenty-four hours a drop of the solution is tested for bismuth with sulphurated hydrogen. When the deposition is complete the

current is stopped and the metal washed with water. In case of partial oxidation of the bismuth it is advisable to dissolve it in nitric acid, and estimate it as oxide. Bismuth was separated from zinc, nickel, cobalt and uranium by this process, but it was not found possible to separate it from iron. Details of numerous analyses are given in this paper.—S. Y.

On the Employment of Hydrogen Peroxide in Volumetric Analyses. S. Eliasberg. Ber. 19, 320—323.

THE method proposed by Classen and Bauer (Ber. 16, 1061) for the estimation of sulphur in sulphides by oxidation to sulphuric acid by means of hydrogen peroxide is a gravimetric process requiring hydrogen peroxide free from H_2SO_4 , which is difficult to obtain.

The author performs the oxidation with carefully neutralised hydrogen peroxide to which a measured volume of standard alkali has been added. The excess of alkali, left uncombined with the H_2SO_4 , is then titrated back with standard acid, using dimethylaniline-orange as an indicator. In the case of sulphides which evolve H_2S on treatment with acids, the determination is made in the apparatus used by Classen (Ber. 16, 1069), the H_2S being passed into the peroxide solution and the analysis completed as above. Thiosulphates (and other poly-thionic acids) are gently heated with the alkaline hydrogen peroxide solution for half-an-hour, and the excess of alkali then titrated back. The quantity of H_2SO_4 found multiplied by the factor 2.5316 gives the quantity of $\text{Na}_2\text{S}_2\text{O}_3 + 5\text{H}_2\text{O}$ which was present. The process is very simple, and the results are fairly accurate.

—A. G. G.

Bacterioscopic Examination of Water. Dr. Link. Arch. Pharm. 24, 145.

IN an article by Professor Koch on the above subject, the following passages occur:—" . . . the presence of numerous micro-organisms denotes that this water is in a state of decomposition." "As far as we can judge at present, the number of micro-organisms in 1 cc. of good water varies between 10 and 150 germs, capable of development. When the number considerably exceeds these figures, the water must be looked upon as suspicious. If there are 1000 and more germs in 1 cc., such water should be declared unfit for drinking." The author claims to have arrived at results entirely at variance with Koch's statements. A considerable number of micro-organisms were discovered in numerous samples of well-water, which could not possibly have been contaminated in any way. Moreover, these waters would have been declared good if judged by the results of a chemical analysis. On the other hand water, which after a chemical analysis would have been considered unfit for drinking, and which was, as a matter of fact, polluted with sewage matter, was sometimes remarkably free from bacteria that had reached development. Numerous reasons are also adduced showing that the dangerous germs could not, as a general rule, be maintained, still less propagated in such water. In summing up, the author thinks no stress can be laid on the results of a bacterioscopic examination of water, which is based on a determination of the number of micro-organisms capable of development and contained in that water. The conclusions which might be drawn from such an examination are, in fact, generally the very reverse of those arrived at by the aid of an analysis, and the latter must, at present, be considered the only criterion in judging of the purity of a specimen of water.—A. R.

Detection of Sulphonated Magentas and Ordinary Magentas by means of Metallic Oxides. P. Cazeneuve. Bull. Soc. Chem. 45, 233.

ON shaking 10 cc. of wine with 0.2 gm. of yellow mercuric oxide, the former is entirely decolourised if natural, while acid magenta is not precipitated, and 0.0001 gm. of the latter in 10 cc. of wine may thus be readily detected. The ordinary magentas are only partially pre-

precipitated, and mercuric oxide is therefore no very delicate test for these colours.

When wine is shaken up with moist lead hydroxide for a few minutes, the normal colouring matter is entirely absorbed by it. 2grm. of the hydrate containing about 50 per cent. of water should be taken for 10ccm. of wine. Acid magenta is partly absorbed but not so the other magentas, and of these the author was able to detect 0.00001grm. in 10ccm. of wine. Moist stannic hydrate is a good reagent both for acid magenta and for ordinary magentas, whereas gelatinous ferric hydroxide cannot be recommended at all.—A. R.

Reactions for the Identification of certain Narcotic Extracts. C. Leuken. Pharm. Zeit. **31**, 105.

As it is difficult to obtain fresh material for the preparation of narcotic extracts, many druggists are compelled to buy them, and it is, therefore, very important to have some trustworthy reactions for their identification.

After acidifying the solution of the extract with hydrochloric acid, potassium mercuric iodide ("Mayer's reagent") is added, the well-washed precipitate suspended in water and treated with alkali. The mixture is then extracted with a suitable solvent, and on evaporating the latter, the alkaloid remains in a sufficiently pure state to make identification possible.

Extr. Aconiti.—A few grams are treated as above described and the precipitate suspended in water and mixed with a few drops of ammonia. After extracting with light petroleum and evaporating the latter, the residue is heated on the water-bath with phosphoric acid, in which a few pieces of glacial phosphoric acid have been previously dissolved; after a short time the mass assumes a distinct violet colour.

Extr. Belladonna treated as above, but extracted with ether, gives Vitali's atropine reaction perfectly. If the residue from the ethereal extract be mixed with a few drops of nitric acid, then heated on the water-bath, and finally mixed with a few drops of a solution of caustic potash in absolute alcohol, a beautiful violet colour is produced.

Extr. Hyoscyami reacts similarly to *extr. belladonna*, but precipitation with "Mayer's reagent" is not so complete, and the colour consequently less intense. To distinguish between the two extracts, the residue obtained by evaporation of the aqueous solution, to which some ammonia has been added, is best examined under the microscope. The crystals of *extr. belladonna* are feathery, whereas in the case of *extr. hyoscyami* the appearance is that of two crystals lying crosswise one over another.

Extr. Digitalis is not precipitated by "Mayer's solution," but may be recognised by dissolving 1grm. in water and precipitating completely with lead acetate. The filtrate is then extracted with chloroform, and the residue remaining on evaporation of the latter gives a red colour on heating with concentrated sulphuric acid.

—A. R.

A Reaction for Cocaine. T. Biel. Pharm. Zeit. **31**, 132. 0.03GRM. of cocaine is dissolved in 1ccm. of concentrated sulphuric acid, heated on the water-bath for 1–2 min. and allowed to cool. On diluting, crystals of benzoic acid appear after some time.—A. R.

Potassium Permanganate as a Test for Cocaine. F. Giesel. Pharm. Zeit. **31**, 132.

ON adding the requisite amount of a solution of potassium permanganate to a solution of pure cocaine hydrochloride a light violet precipitate of cocaine permanganate is formed. If the solution is very dilute, precipitation only ensues after some time, but the deposit then consists of small brilliant crystals of a dark violet colour. This reaction is not very distinct with commercial cocaine, as the impurities contained in it often discolour the solution or the precipitate. It sometimes happens that cocaine permanganate is not deposited at all. In such cases manganese dioxide is precipitated, and on

boiling the solution smells intensely of oil of bitter almonds, these two reactions being a sure sign of the impurity of the cocaine employed.

To test on a small scale, 0.01grm. of cocaine dissolved in two drops of water are mixed with 1ccm. of a solution containing 0.3grm. of potassium permanganate, when a violet precipitate must be formed, and no odour of oil of bitter almonds should be noticeable on boiling.

—A. R.

Quantitative Determination of Methoxyl (OCH₃). S. Zeisel. Monatsh. f. Chem. **6**, 989–996.

THE method consists in heating the compound with hydriodic acid (of sp. gr. 1.68, prepared by phosphorus) and receiving the methyl iodide formed in an alcoholic solution of silver nitrate. From the weight of silver iodide produced the percentage of methoxyl can be calculated, since 1AgI corresponds to 1CH₃O. The substance (0.2–0.3grm.) is boiled in a small flask with 10cc. of aqueous hydriodic acid (sp. gr. 1.68), whilst CO₂ is passed slowly through the liquid; the gases are led through an inverted condenser surrounded with water at 40–50° C., and through a Geissler's bulb apparatus, also kept warm, containing red phosphorus (½–¾grm.) suspended in water, to retain iodine vapours and HI. The methyl iodide is finally absorbed in two flasks, each containing 25–50cc. of the alcoholic silver solution. The precipitated silver iodide is separated and weighed. The analyses given are very satisfactory.—A. G. G.

New Books.

WATTS' MANUAL OF CHEMISTRY: THEORETICAL AND PRACTICAL (Based on Fownes' Manual). Vol. II.: Chemistry of Carbon-Compounds; or, Organic Chemistry. Second Edition (Thirteenth Edition of Fownes). By WILLIAM A. TILDEN, D.Sc., F.R.S., V.P.C.S., Professor of Chemistry in the Mason College, Birmingham. London: J. & A. Churchill, 11, New Burlington Street, 1886.

8vo volume, bound in cloth, containing 646 pages of subject-matter, and Appendix with Tables of the Strength of Spirits of different specific gravities, and some additional matter devoted to Lævulose and Anthracene. The pages are illustrated with some 20 woodcuts, and numerous useful tables are given. The nomenclature has throughout been brought into conformity, as Professor Tilden remarks in his Preface, with the system recognised and adopted by the Chemical Society of London. The arrangement of the matter of this useful work is disclosed in a review of the Table of Contents, the chief headings in which are given as follows:—INTRODUCTION. ELEMENTARY OR ULTIMATE ANALYSIS OF ORGANIC COMPOUNDS. CLASSIFICATION OF ORGANIC COMPOUNDS. ORGANIC SERIES. PHYSICAL PROPERTIES OF ORGANIC COMPOUNDS. DECOMPOSITIONS AND TRANSFORMATIONS OF ORGANIC COMPOUNDS. METHANE DERIVATIVES OR FATTY GROUP. MONOHYDRIC ALCOHOLS AND ETHERS. DIHYDRIC ALCOHOLS AND ETHERS. TRIHYDRIC ALCOHOLS AND ETHERS. TETRAHYDRIC ALCOHOLS AND ETHERS. HEXHYDRIC ALCOHOLS AND ETHERS. AMINES. MONAMINES. DIAMINES. TRIAMINES. PHOSPHORUS, ARSENIC AND ANTIMONY-BASES, ORGANO-BORON COMPOUNDS, ETC., ALDEHYDES. KETONES. CARBOXYLIC ACIDS. AMIDES. BENZENE DERIVATIVES OR AROMATIC GROUP. INDIGO GROUP. DIPHENYL GROUP. NAPHTHALENE GROUP. PHENANTHRENE AND ANTHRACENE GROUP. CAMPHENES AND CAMPHORS. RESINS AND BALSAMS. GLUCOSIDES. BITTER PRINCIPLES. COLOURING MATTERS. ALKALOIDS. PECTORAL SUBSTANCES. BILE CONSTITUENTS. GELATINOUS SUB-

STANCES. PROTEIDS OR ALBUMENOID. SUBSTANCES RELATED TO THE PROTEIDS. BRAIN CONSTITUENTS. The work is terminated by a copious Alphabetical Index.

WATER ANALYSIS: A Practical Treatise on the Examination of Potable Water. By J. ALFRED WANKLYN and ERNEST THEOPHILON CHAPMAN. Sixth Edition, by J. ALFRED WANKLYN, M.R.C.S., etc., etc. London: Trübner & Co., Ludgate Hill, 1884.

In this, the Sixth Edition, an addition on page 58 is made, and an extra chapter entitled "Verifications" is all that distinguishes this from the last edition. This book now comprises an Introduction, 154 pages of subject-matter and an Appendix, and terminates with an Alphabetical Index. The pages are illustrated with some four or five woodcuts, and the chapters are headed as follows: Part I.:—I. Collection of Samples of Water. II. Total Solid Residue. III. Chlorine. IV. Organic Matter, "Free and Albumenoid Ammonia." V. The Moist Combustion Process. VI. Poisonous Metals. VII. The Drawing up of Reports. VIII. Verification. PART II.:—SPECIAL ANALYSIS.—I. The Specific Gravity of Natural Water. II. The Water Residue; The Insoluble Solids; The Soluble Solids; The Degree of Alkalinity. III. Hardness. IV. General Quantitative Analysis of the Water Residue; Statement of Results. V. Gases and Vapours Dissolved by Water. VI. Purification of Water. VII. Urine and Sewage. PART III.: EXAMPLES OF COMPLETE MINERAL ANALYSES.—Water Supply to London and to Manchester, etc.

MILK-ANALYSIS: A Practical Treatise on the Examination of Milk and its Derivatives, Cream, Butter, and Cheese. By J. ALFRED WANKLYN, M.R.C.S., etc. Second edition. London: Trübner & Co., Ludgate Hill, 1886.

This is a small 8vo. volume, bound in cloth, and of similar appearance to the "Water Analysis." It contains seventy-six pages of subject matter, some three or four wood-cut illustrations and a table of contents. The subdivision of the matter is as follows:—I. Introductory—Milk, its Nature and Chemical Composition; Description of each of its Constituents; Constancy of its Composition. II. Instruments and Methods for Testing Milk; Outline of Method of Milk Analysis. III. Milk Solids. IV. The Fat. V. Caseine. VI. Milk-Sugar. VII. Ash. VIII. Calculation and Statement of Results. IX. The Milk Supply of the London Workhouses. X. Cream. XI. Butter. XII. Cheese. XIII. Koumiss. XIV. Condensed and Preserved Milk. XV. Poisonous Milk and Milk-Panics.

TEA, COFFEE AND COCOA: A Practical Treatise on the Analysis of Tea, Coffee, Cocoa, Chocolate, Maté (Paraguay Tea), etc. By J. ALFRED WANKLYN, M.R.C.S., etc. London: Trübner & Co., Ludgate Hill, 1874.

This little volume is bound similarly to the preceding works. The subdivision of the text is as follows:—Part I.: Introduction. II. The Ash. III. The Extract, and the Tea-assay. IV. "Free and Albuminoid" Ammonia in Tea-extract; Estimation of Nitrogen in Tea. V. Theine. VI. Tannin in Tea. VII. Calculation of Results. Part II.: Coffee. Part III.: Cocoa and Chocolate. Part IV.: Maté or Paraguay Tea.

BREAD ANALYSIS: A Practical Treatise on the Examination of Flour and Bread. By J. ALFRED WANKLYN and W. J. COOPER. London: Trübner & Co., Ludgate Hill, 1886.

A book similar in appearance and style to the preceding, and containing 72 pages of subject-matter, a Table of Contents, and an Alphabetical Index. The manner of subdivision of the matter into chapters is indicated by the following headings:—I. FLOUR. Its Composition; Description of its Constituents. BREAD: II. The Water in Bread. III. The Ash of Flour and Bread; Mineral Adulteration of Flour and Bread; Alum. IV. The Gluten Assay; The Nitrogenous Portion of Flour; The Yield of Albumenoid Ammonia. V. The Cold Aqueous Extract; Sound and Unsound Flour. VI. On Food. VII. On Corn Flour.

ANALYTISCHE CHEMIE FÜR DEN GEBRAUCH IM LABORATORIUM UND FÜR DAS SELBSTSTUDIUM. Von N. MENSCHUTKIN, Professor an der Universität zu St. Petersburg. DEUTSCHE AUSGABE UNTER MITWIRKUNG DES VERFASSERS, Uebersetzt von Dr. O. BACH; Zweite verbesserte Auflage. Leipzig: Verlag von Quandt und Händel, 1886. London: H. Grevel, 33, King Street, Covent Garden.

This excellent work, to which no higher commendation can be given than to state that Bunsen recommends and uses it in his laboratory in Heidelberg, has reached its second edition. The volume is of 8vo size, is bound in the usual paper cover, and contains a Preface, a Table of Contents, 459 pages of subject-matter, and an Alphabetical Index. The general scheme of the work may be gathered from the following excerpt from the "Inhaltsübersicht":—Einleitung: 1. Theil, Die Metalle. 2. Theil, Metalloide. 3. Theil, Beispiele zur qualitativen Analyse. 4. Theil, Beispiele zur quantitativen Gewichtsanalyse. 5. Theil, Beispiele zur quantitativen Maassanalyse. 6. Theil, Analyse der organischen Verbindungen.

OILS AND VARNISHES. Edited by JAMES CAMERON, F.I.C., Analyst in the Laboratory, Somerset House. London: J. and A. Churchill, 11, New Burlington Street.

OCTAVO volume, bound in cloth. One of Churchill's series of Technological Hand-books. It contains, besides Table of Contents and Alphabetical Index, 356 pages of subject-matter, 14 wood-cuts, and a useful Appendix containing various tables of value. The Chapters bear the following signatures:—I. Chemistry of Oils, Glycerine, Organic Acids, etc. II. Animal Oils. III. Vegetable Oils—Fixed. IV. Vegetable Oils—Volatile or Essential. V. Empyreumatic, Medicated, Mixed, and Perfumery Oils. VI. Waxes. VII. Mineral Oils. VIII. Purification, Bleaching, and Refining of Oils. IX. Testing of Oils—(i.) Purity; (ii.) Lubricating Qualities; (iii.) Illuminating Efficiency, etc. X. Resins and Varnishes. XI. Testing Resins.

 7958 W. H. Hartland. Improved means for filtering and purifying water. April 27
 8162 W. Hucks. Separation or filtration of solid and liquid matter. May 21
 8199 W. Allen. Acid taps and valves and seats for chemical works. April 30
 9234 M. Coulson. Apparatus for heating, purifying, and softening water for boilers. May 4
 12513 P. Parker. Improvements in construction of water filters. April 30
 11535 R. Dick and R. Kennedy. Mercurial vacuum pumps. May 4

1886.

- 2258 O. W. Bennett. Carburetting apparatus. April 23
 3412 G. H. Moore. Methods and apparatus for refining fluids. May 11
 3857 J. R. Alsing. Improved mode of triturating, and apparatus for such purpose. May 7
 3964 G. F. Redfern—C. A. Johansson. Improved centrifugal separating machine. May 11
 4012 O. Klauhnig. Apparatus for evaporating and drying solutions, etc. April 30

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Specifications thus advertised are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

- 4159 J. R. Alsing. Improved triturating cylinder. May 7
 4656 J. S. Sawrey. Improvements in filters. May 7
 5340 J. R. Alsing. Construction of triturating cylinders. May 18

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

- 5163 H. S. Forbes, London. Improvements in producing and utilising hydrocarbon gas. April 20
 5522 T. F. V. C. Otto and C. Otto & Co., London. Improvements in coke ovens. April 21
 5597 J. J. R. Humes, London. Improved means for preventing "back ignition" in hydrocarbon engines. April 22
 5715 J. Lyle, Glasgow. Improvements connected with the burning of oils or other hydrocarbon fluids for the production of heat. April 27
 5727 T. Nicholson, Abergyle. Improvements in the methods and appliances for obtaining and cleansing gas from coal. April 27
 5801 E. Phillips, London. Improvement in petroleum oils. April 28
 5836 J. Holden, London. Improvements in the application of liquid fuel to the furnaces of locomotive engines; also applicable to the furnaces of portable and other engines. April 29
 5915 W. S. Sutherland, Liverpool. Improvements in gas-making apparatus for producing heating and illuminating gas. May 1
 6059 J. Holden, London. Improvements in the use of liquid fuel as auxiliary to ordinary solid fuel in the fire boxes of locomotives or boilers of similar type. May 4
 6253 P. M. Justice, London—Communicated by La Société de Produits Réfractaires de St. Ghislain, Belgium. Improvements in and connected with furnaces for the manufacture of illuminating and heating gas. May 8
 6347 O. Imray, London—Communicated by J. B. Archer, United States. Apparatus for conversion into gas, and combustion of liquid hydrocarbons. Complete specification. May 11
 6348 O. Imray—J. B. Archer. Boiler furnaces for combustion of gaseous fuel. Complete specification. May 11
 6349 O. Imray—J. B. Archer. A process and apparatus for manufacturing water-oil gas. Complete specification. May 11
 6362 H. J. Haddan, London—Communicated by H. Welsh, United States. Improvements in apparatus for promoting the combustion of fuel. Complete specification. May 11
 6511 F. W. Clark, London. Improvements in machinery or apparatus for the manufacture of gas for illuminating and heating purposes. May 11
 6531 W. Foulis, Glasgow. An improved apparatus for heating by gas. May 15
 6551 J. Wright, T. Charlton, and T. S. Wright, London. Improved methods for combining atmospheric air with petroleum or other liquid or gaseous hydrocarbons; and also improved appliances for using the said combinations for the production of motive power, being, more briefly, improvements in petroleum and such-like engines. Complete specification. May 15
 6620 H. J. Haddan, London—Communicated by L. von Wohlfahrt, S. Heumann, and E. Heumann, Austria. Improvements in candles. May 17
 6647 E. Mansfield, Manchester. Improvements in apparatus for manufacturing gas from oil. May 18
 6811 J. Mactear, Glasgow. Improvements in the combustion of gas for illuminating purposes. Complete specification. May 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 7157 C. J. C. Bailey and S. C. Dean. Making and utilising water- and oil-gas. May 11
 7643 L. A. Groth (F. Garavagnoe & Co.). A new or improved gas carburetting apparatus. May 11
 7815 H. Dempster, jun. Construction of stand-pipes for gas retorts. May 7
 12686 S. F. Smith. Apparatus for carrying off the products of combustion of gas or other lights. April 30
 13014 N. H. Henderson. Apparatus for distilling shale or other mineral oil or petroleum. April 30

1886.

- 4016 W. P. Thompson—A. I. Ambler. Apparatus for the production and utilisation of vapour fuel. April 23
 4091 W. M. Fraser. Apparatus and arrangements for distilling mineral oils. April 27
 4099 A. Dempster. Apparatus for purifying and enriching coal-gas. May 7
 4169 B. Loomis. Processes and apparatus for manufacturing gas. May 18
 5024 H. H. Lake—L. Cline. Improved artificial fuel. May 14

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

APPLICATIONS.

5944 J. Yates, London. Improvements in apparatus for the distillation of tar, and for heating other heavy or semi-fluid matters. May 1

COMPLETE SPECIFICATION ACCEPTED.

1885.

7079 J. Hardman. Improvements in, and apparatus for, obtaining carboic acid and other tar acids from tar oils. May 11

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

5846 J. Y. Johnson, London—Communicated by The Farbenfabriken vormals, F. Bayer & Co., Germany. A process for producing a new sulpho-acid and obtaining azo-dyes therefrom. April 29

5938 R. Barringer, J. H. Wallis, and W. Barringer, London. Improvements in the manufacture or preparation and application of blue colouring matters for laundry purposes. May 1

6000 H. Baum, London. A process for the production of para-resanilin and its homologues, as well as monoditrialkylised, phenylised, or naphthylised derivatives thereof. May 3

6001 H. Baum, London. A process for the production of chloride or bromide of nitro-benzyl. May 3

6070 H. H. Lake, London—Communicated by C. N. Waite, United States. Improvements in and relating to mordants for use in dyeing or printing calico and other fabrics. Complete specification. May 1

6190 L. Landsberg, London. Processes for the preparation of *m*-methoxy-*p*-nitrobenzaldehyde for use in the manufacture of vanillin. Complete specification. May 7

6143 J. H. Johnson, London—Communicated by The Badische Anilin and Soda Fabrik, Germany. The preparation from gallic acid of a yellow colouring matter suitable for dyeing and printing. May 12

6124 L. J. B. A. J. Bouillet, London. Manufacturing ultramarine-blue in blocks by special ovens for baking and colouring same, with recuperation of sulphurous vapours. May 13

6631 J. H. Johnson, London—Communicated by The Badische Anilin and Soda Fabrik, Germany. Improvements in preparing printing colours and solutions of colouring matters suitable for printing and fixing aniline colours upon cotton or similar vegetable fibre. May 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

8211 T. Frusher. Manufacture of ink from waste dye liquors. May 21

9510 H. J. Haddan—Farbenfabriken vormals, Bayer & Co. Manufacture of violet and blue azo-dyes. May 21

11424 J. Y. Johnson—Farbenfabriken vormals, Bayer & Co. Manufacture of azo-dyes. May 7

V.—TEXTILES: COTTON, WOOL, SILK, ETC.

APPLICATIONS.

5550 J. H. Charnley, Horsforth. An improvement in the manufacture of spun silk yarns. April 22

5911 W. Saunders, London—Communicated by R. H. Collyer, United States. Improvements in machinery for the preparation of fibrous vegetable substances for textile purposes. May 1

5987 E. Edwards, London—Communicated by C. Welté, France. An improved composition for dressing cotton, wool, linen, hemp, or other fabrics. May 3

6205 L. Turner and A. Turner, London. An improved manufacture of elastic fabrics. May 7

6638 A. Dronsfield, Manchester. An improvement in or applicable to machinery used in the preparation of textile materials. May 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

8402 J. F. Giraud. A new or improved size for sizing raw silk. May 11

8792 W. Mather. Apparatus for treating textile materials with liquids, gases, or vapours. May 21

1886.

4323 B. Fiegel. Removing gummy, resinous, and oily matters from fibrous spun or woven materials. May 21

4471 H. H. Lake—T. J. Waring. Preparation of animal fibres for felting. April 30

4780 E. Tweedy, H. L. Brevoort, and I. L. Roberts. Preparing fur for felting. May 7

4781 Tweedy, Brevoort and Roberts. Preparing fur for felting. May 7

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

6116 A. M. Clark, London—Communicated by J. Hanson, United States. Improvements in machinery for dyeing yarns. Complete specification. May 5

6435 H. Broadbent and A. E. Hawley, Halifax. Improved machinery for dyeing or otherwise treating hosiery and other like goods or fabrics. May 13

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

8794 W. Mather. A process for bleaching vegetable textile fabrics. May 18

9690 T. Salt and W. Stead—F. Pasquay. Apparatus for washing, scouring, bleaching, dyeing, etc., fibrous material in the form of slivers, slubbings, rovings, yarns, or fabrics. May 21

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

5156 T. T. Mathieson and J. Hawliczek, Liverpool. A method for purifying crude carbonate of soda, termed "black ash," and the recovery of ammonia therefrom. April 20

5542 D. G. Fitzgerald, London. The regeneration or production of chromic acid from exhausted battery and other solutions. April 21

5673 J. Hargreaves, T. Robinson and J. Hargreaves, Liverpool. Improvements in treating hydrochloric acid to obtain chlorine, using the said chlorine in the manufacture of bleaching powder, and in apparatus employed. April 27

5681 J. Hargreaves, T. Robinson, and J. Hargreaves, Liverpool. Improvements in treating pyrites, and in apparatus employed therein. April 27

5682 J. Hargreaves, T. Robinson, and J. Hargreaves, Liverpool. Improvements in the manufacture of sulphates of soda and potassa, and in apparatus therefor. April 27

5683 J. Hargreaves, T. Robinson, and J. Robinson, Liverpool. Improvements in obtaining carbonate of soda and sulphur from sulphate of soda, and in apparatus employed therein. April 27

5838 J. Hepworth and E. Marriott, Manchester. Improvements in the removal of ammonia from coal gas, and in the manufacture of ammoniacal salts therefrom, and in apparatus employed in such process. April 30

6386 G. Chapman, Glasgow. Improvements in the method of manufacturing soda by what is called the ammonia soda process. May 12

6468 W. Simon, London. Improvements in the manufacture of bicarbonate of potash. May 13

6492 W. H. Munns, London—Communicated by P. Farinaux, France. Apparatus for producing carbonic acid under constant pressure. May 14

6573 R. Weiss, London. Process for the production of alumina compounds applicable for bleaching. May 15

6734 R. H. Wilson, Durham. Improvements in the manufacture of anhydrous sulphuric acid, and in apparatus therefor. May 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

5544 B. H. Thwaite and J. Pedder. The utilisation and method of using liquid hydrocarbons as carbonising and neutralising agents in the alkali processes and for reducing pyrites. April 27

7285 R. Oxland and C. Oxland. Apparatus for burning or calcining ores and minerals containing sulphur or arsenic, for the manufacture of sulphuric acid or arsenious acid, or white arsenic. May 4

7831 T. Copper—Dr. S. Pick. Apparatus for making bicarbonate of sodium. May 4

8282 H. Richardson. Manufacture of hydrate, sulphate, and other salts of alumina. May 4

8502 N. Glendinning. Treatment of copper liquors. May 21

8723 W. P. Thompson—Solvay & Co. Filters applicable for caustic soda solution. May 7

8933 F. Brunjes. Production of carbonate of potassium from chloride of potassium or sulphate of potassium. May 21

1886.

1915 J. Maetear—J. Kolb. Obtaining chlorides of barium and strontium. May 4

3220 A. Dempster. Apparatus for distilling ammoniacal liquor for producing sulphate of ammonia. April 23
 3222 B. J. B. Mills—Verein für Chemische Industrie. Producing chlorine, and chlorine and ammonia. April 30

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

5698 H. Forrester, Stoke-on-Trent. Marbling earthenware and china in enamels by means of oiling and dusting. April 27
 5748 W. W. Pilkington, Liverpool. Improvements in apparatus for use in casting plate glass. April 28
 5978 F. Winterhoff, Hammersmith. A new or improved process for producing ornaments, lettering, etc., on glass or other round or flat substances, for decorating and advertising purposes. May 3
 6114 R. Young and R. Jex-Long, Glasgow. Improvements connected with the manufacture of fireclay tuyères, and in the machinery or apparatus employed therefor. May 6
 6681 J. French and J. Craig, London. Improvements in the process of manufacturing rolled plate glass, and in the machinery employed therefor. Complete specification. May 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

4060 F. G. Johnson and A. Johnson. A "link press" for making earthenware, etc. April 30
 7341 E. S. Tucker and D. F. Tucker. Manufacture of various articles from spar, refuse marble, glass, and the like. May 11
 11351 J. Slater. Ornamenting glass, china, or other vitreous surfaces. May 1
 12762 J. C. Belfield. Furnace for burning dross or slack in the firing of all kinds of earthenware. May 11

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

5843 C. J. Howe, London. Improvements in the manufacture of cement or plaster. April 29
 5844 C. J. Howe, London. Improvements in the manufacture of cement or plaster. April 29
 5975 A. J. Boulton, London—Communicated by A. Grasset and A. C. Mallat. Improvements in the manufacturing of cement. May 3
 5991 J. H. Edge and J. Edge, London. Improvements in dies for the manufacture of roofing, flooring, and other tiles, bricks, and other like articles made of clay. May 3
 5991 G. Mancion, London. An improved process for preserving timber. Complete specification. May 3
 6061 L. A. Groth, London—Communicated by F. L. Perrière, France. Improvements in roofing tiles. Complete specification. May 4
 6212 E. Edwards, London—Communicated by C. Hubert and H. Gennari, France. Improvements in apparatus for forming compressed blocks for building and other purposes. May 7
 6221 C. S. Williams, London. Improvements in the construction of fire-proof floors. May 7
 6520 G. R. Redgrave, London. Improvements in the treatment of sewage-water by the lime process for the production of cement. Complete specification. May 15
 6533 T. Smith, London. An improved method of utilising metallic and other cements, plaster-of-Paris, and such like substances. May 15
 6698 L. White, London. Improvements in the manufacture of cements and plasters. May 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

6813 C. Kingsford. Drying and evaporating apparatus for use in the manufacture and treatment of cement, etc. May 18
 8139 G. F. Redfern—R. Tanczos. Process for rendering wood incombustible. May 11
 8361 J. Matthew. Treatment of stone to produce a glazed surface thereto. April 23
 8508 R. Stanley. Machinery for pressing and moulding bricks, tiles, etc. May 4

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

5527 A. de Laude Long and R. Howson, London. A new manufacture of fibrous iron. April 21
 5560 F. Burklam, Wellingborough. The substitution of sheet steel as a material for the making of pig (and other) patterns, instead of wood or other material now in use. April 22

5762 H. B. Fulton, Kirkintilloch. Treatment of copper precipitate, regulus or ore, for the purification thereof. April 23

5832 J. Y. Johnson, London—Communicated by La Société Anonyme Le Ferro-Nickel, France. An improved manufacture of alloy of nickel, copper, and aluminium. April 29
 5921 F. J. R. Canilla, London. Improvements in the manufacture of steel and ingot iron. May 1

6002 W. Perrott, London. Lining steel converters or open hearth furnaces, also forming blowing plugs with a new material locally called "curlstone," which material is distinct in its features from any previous material used for such purpose. May 3

6066 J. H. Johnson, London—Communicated by A. de Meritens, France. A process for preserving iron and steel. May 4

6128 G. Craig, Glasgow. A new or improved treatment of blast furnace or other slags for subsequently obtaining useful products therefrom. Complete specification. May 6

6145 A. C. Henderson, London—Communicated by L. T. Heroult, France. An improved process for the preparation of aluminium by electrolysis. May 6

6217 H. Johnson, London. Improvements in blasting and getting coal and other materials, and in tunnelling, and in apparatus employed for those purposes. May 7

6251 W. D. Allen, London. Improvements in casting iron and steel ingots. May 8

6281 T. Doughty and A. Doughty, Glasgow. Soaking mould for steel ingots. May 10

6300 J. M. Bennett, Glasgow. Improvements in smelting and refining of gold, silver, copper, zinc, lead and tin ores, and in furnaces therefor. May 10

6367 P. A. Newton, London—Communicated by C. A. Pailard, Switzerland. Improvements in metallic alloys. Complete specification. May 11

6372 H. H. Lake, London—Communicated by E. E. Wood, United States. Improvements relating to the rolling and welding of iron and steel, and to fluxes therefor. Complete specification. May 11

6401 A. Gutensohn, London. Improvements in the process for coating the surface of iron or other metals with tin, lead, or terno. Complete specification. May 12

6405 A. Gutensohn and A. Cox, London. An improved flux to be used in the process of coating iron or steel with lead. May 12

6545 J. H. Goodwin and F. James, Sheffield. Improvements in the manufacture of compound ingots and in apparatus used therein. May 15

6550 T. Slater, London. Improvements in the manufacture or production of metallic alloys. May 15

6571 W. D. Houghton and A. M. Walker, London. Improvements in the manufacture of steel in Bessemer converters and open hearth furnaces. May 15

6572 W. D. Houghton and A. M. Walker, London. Improvements in the manufacture of steel in Bessemer converters and open hearth furnaces. May 15

6609 E. Fox and L. Regnier, London. Improvements in furnaces for use in heating or melting metals. May 17

6717 A. M. Clark, London—Communicated by La Société Anonyme de Produits Chimiques de St. Denis, France. Process and apparatus for the treatment of iron ores for the manufacture of steel. May 19

6786 J. Thomas, H. Lewis, E. W. Lewis, and T. L. Thomas, London. Improvements in the method of and apparatus employed in galvanising (coating with spelter) sheet metal. May 20

6803 E. Edwards, London—Communicated by M. Ramos-Garcia, France. An improved process for the separation of metallic tin from tinned plates, or from alloys or salts of tin. May 20

6810 J. Noad, London. Improvements relating to the extraction or separation of gold, silver, and platinum from ores and other substances or products containing such metals. Complete specification. May 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

5110 J. Gilligan. Manufacture of puddled iron and steel. April 23

5669 T. Timothy. Improvements in annealing pots. May 4
 5702 D. Edwards, R. Lewis, and P. Jones. Coating metal plates with tin or other metal. May 7

6018 H. Aitken. Treatment of carbonaceous, bituminous, calcareous and other substances, such as ores, to obtain products therefrom. May 4

6674 A. E. Scott. Process and apparatus for separating metals from their ores. May 21

6711 W. R. Lake—B. Atha. Manufacture of metal ingots, and apparatus therefor. April 23

6718 B. D. Healey and B. H. Thwaite. Application of gaseous fuel for smelting ores, and furnace crucible and other plant therefor. May 7

7012 H. H. Lake—H. E. Cahen. Manufacture of steel. May 21

7538 D. Hickie. A "miner's knife," with appliances combined for preparing charges of explosives for mining and blasting operations, and for lessening risks in the manipulation of such charges. May 11

8677 J. Riley. Manufacture of steel in regenerative open-hearth furnaces. May 21

8756 H. White. Manufacture of steel and iron, and converters to be used in such manufacture. May 11

8981 T. Hampton and J. Facer. Improvements in method of casting steel ingots. May 11
11311 J. Robb. Methods and composition for case-hardening metals. May 11

1886.

3389 J. E. Craig. Manufacture of polished sheet iron. April 23
3985 C. E. Steinweg. Plating metals and alloys. April 23
4034 C. L. Hartsfeld. Portable blast furnace plant. May 11
4402 B. Ford and J. Moncur. Regenerative hot-blast stoves. May 7
4750 J. W. Hall—G. T. Lewis. Process for treating lead and other ore for obtaining the metal therefrom, and for the manufacture of white pigment. May 7
4956 H. Kesterton. Manufacture of metallic alloys. May 11
5222 J. Heath and W. Frost. Blasting and shot firing in mines, and appliances relating thereto. May 18.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

5769 T. Rockliffe and G. J. Bowes, London. Improvements in soap making machinery, partly applicable for use in moulding other plastic materials. April 28
5792 A. J. Boulton, London—Communicated by E. Oppelt, Spain. Improvements in apparatus for the extraction of oils or other vegetable juice. April 28
6170 W. Green, London. Improvements in the manufacture and treatment of soap. May 6
6172 F. P. Warren, Cosham. Improvements in lubricants. May 7
6210 H. W. Langbeek and R. E. Mitsert, London. Method for the separation of cholesterol fats from commercial wool fats, and from the leys of wool-washing works. May 7
6465 E. P. Chauvet and E. A. Delrieu, London. An improved receptacle or device chiefly designed for containing oleaginous seeds during the expression of oil therefrom. May 13
6736 J. S. Edwards, London. Improvements in the treatment of fish and other matters to extract oil therefrom, and in apparatus to be employed therein. May 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

8230 F. Walton. Manufacture of oxidised or solidified oil and in the application of the same to wires and strands. April 23
8403 A. Michel. Apparatus for treating fatty matters, in order to obtain fatty acids and glycerine therefrom. April 23

1886.

3987 J. Townsend. Improvements in making soaps. April 23
4936 T. E. Gardner. Improvements in marking soap. May 11
4994 J. Higson. Manufacture of soap for the removal of warts. May 14

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

5820 J. Warwick, Newcastle-on-Tyne. Improvements in the manufacture of white lead. April 29
6370 R. Lavender, London. Improvements in the manufacture of oxide of iron pigment colour. May 11

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

5476 P. Haddan, London—Communicated by The Dobson Patent Tanning Process Co., United States. Improvement in tanning hides. Complete specification. April 20
5491 N. A. Alexanderson and L. Hvass, Stockholm. A mode of tanning hides and skins. Complete specification. April 20
5619 J. Hall and A. Hall, Leeds. Improvements in machinery employed in the manufacture of leather for setting, scouring, striking or pinning, printing, rolling, slicking, fleshing, un-hairing, whitening, shaying, and brushing. April 24
6011 F. R. Maggs, Yeovil. The preparation of leather and skins by a substitute for "urine" or "sig" in the process of brushing leather and skins preparatory to dyeing. Complete specification. May 4
6438 R. Baker and W. Baker, London. Improvements in the manufacture of seal splits or fleshings. May 13

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

10147 J. C. Mewburn—J. Marchal and L. Bories. Process of treating tannic extracts or juices. April 27

1886.

5049 H. S. Barrow. Machines for grounding and softening skins or leathers. May 14
5476 P. Haddan—The Dobson Patent Tanning Process Co. Improvements in tanning hides. May 21

XIV.—AGRICULTURE, MANURES, ETC.

APPLICATIONS.

5686 H. J. Allison, London—Communicated by W. S. Pierce, United States. Improvements in fertilising compounds, and in the process of manufacturing the same. Complete specification. April 27
5864 W. H. Keys, West Bromwich. "Cresylline"—destroying wire-worms and other insects in gardens and land. April 30
5732 T. H. Cobley, London. Improvements in the treatment of sewage sludge, and the preparation of a fecal guano therefrom. May 19

XV.—SUGAR, GUMS, STARCHES, ETC.

APPLICATION.

5735 J. Guardiola, London. An improved evaporating apparatus for saccharine and other juices. April 27

COMPLETE SPECIFICATION ACCEPTED.

1885.

4516 P. Jensen—M. C. P. Barbe. Apparatus for the manufacture of refined sugar. May 4

XVI.—BREWING, WINES, SPIRITS, ETC.

APPLICATIONS.

5457 W. S. Squire, London. Improvements in the manufacture of yeast. April 20
5511 W. S. Squire, London. Obtaining useful products from distillers' spent wash. April 21
5772 F. Faulkner and W. Adlam, London. Improvements in treating brewers' wort. April 28
5796 J. Painter, Malmesbury. The manufacture of a new article entitled "Maltina," aerated or non-aerated. April 28
6069 S. A. W. Howmann, London. Improvements in manufacturing compressed yeast. May 4
6401 H. Schaarwachter, Barmen. An apparatus for Pasteurising (d'asteriser) beer, wine, and other suitable fluids. May 12
6658 J. Luth, Glasgow. Improvements in apparatus for cooling beer and other liquids or fluids. May 18
6686 R. Jones, London. Improvements in the treatment of alcohol and other fermented or fermentable liquids. May 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

7736 T. J. Canty. Self-acting apparatus for heating and circulating worts in brewers' mash tins. April 23
8908 G. J. W. Peters. Improved process of purifying yeast. May 11
8925 A. Ralu, jun., J. Grathwohl, and H. A. Browne. Preparation and treatment of sweet potatoes, yams, and arums, and manufacture of spirit therefrom. May 14
9068 R. C. Sinclair and J. Hodson. Apparatus for effecting the turning of malt, etc., on the drying floors of kilns. May 11
11125 J. Hodson. Improvements in and apparatus for tuning or cleansing beer. May 11

1886.

1461 F. Faulkner and G. R. Wilson. Method and apparatus for treatment of beer returns and other like alcoholic liquids. May 18
5152 N. Pigeon and W. L. Flanagan. Manufacture of ale, beer, and porter. May 11

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

APPLICATIONS.

A.—CHEMISTRY OF FOODS.

5484 R. T. Strangman, London. Improvements in apparatus for the reception, preservation, and conveyance of food, liquids, and perishable articles generally. April 20
5658 H. W. Hart, London. Treating chocolate to render it digestible. April 21

5833 J. C. Benit, Peckham. The preservation of milk or cream without the addition of any ingredient. April 29
 5916 S. Preston, London. Improvements in the manufacture of bread. May 1
 6332 E. J. T. Digby, London. The preparation of a nutritious and hygienic biscuit for horses and other animals. May 11

B.—SANITARY CHEMISTRY.

6067 G. D. Robertson, London—Communicated by R. James, United States. Improvements in filtering sewage. May 1
 6283 F. Kingdon and G. Wilde, Bradford. Improvements in destructors or furnaces for destroying refuse. May 10
 6306 J. S. Edwards and J. Edwards, London. Apparatus for drying waste animal matter, and for like uses. May 10

C.—DISINFECTANTS.

1886.

723 R. Kennedy. Electro field magnets for dynamo-electric machines and electro motors, etc. May 18
 4523 H. Muller. Improvement in induction apparatus or secondary generators. May 7
 5273 H. P. Holt. Arrangement for mounting and driving dynamo-electric machines. May 21

XIX.—PAPER, PASTEBOARD, ETC.

APPLICATIONS.

5563 W. E. Heys, Manchester—Communicated by E. G. H. Ladewig, Prussia. Improvements in the manufacture of water and fireproof paper, millboard, and similar materials. April 22
 5929 J. Collins, London. Improvements in the manufacture of diaphanous and air-tight paper. May 1
 6385 J. G. Dunbar and A. McKenzie, Glasgow. Improvements in apparatus for regulating the supply of pulp or stuff to paper-making machines. May 17
 6654 W. Tijen, London. Improvements in steam jacketted boilers for converting wood and other fibre into pulp suitable for manufacture into paper or other articles prepared from pulped fibre. May 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

7158 H. H. Lake—A. D. Beaunier. Manufacture of cardboard or pasteboard, and apparatus therefor. April 30

1886.

3111 H. Watson. Strainer plates used in the manufacture of paper. April 23
 3172 J. D. Tompkins. Process for making paper stock or pulp. May 21

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

5936 E. Edwards, London—Communicated by E. A. Viteau, France. An improved process for the complete purification or perfumes in the manufacture of which sulphuret of carbon has been used. May 1
 6250 C. D. Abel, London—Communicated by La Société Anonyme des Parfums Naturels de Cannes, France. Improvements in the extraction of perfume essences. May 8
 6588 C. E. Landon and J. Wilson, Birmingham. An improved method of mixing chloroform with water. May 17
 6696 P. Joske, London. The preparation of medicinal extracts from the Kava or Yagona plant, scientifically known as the "Piper methisticum," and the preparation of beverages from, and the treatment of spirit with such extract. May 18

COMPLETE SPECIFICATION ACCEPTED.

1885.

8810 G. Brownen. The preparation of extracts and beverages from the leaves of the coca plant. April 23

XXI.—EXPLOSIVES, MATCHES, ETC.

APPLICATIONS.

5491 B. von Schenk, London. Improvements in the manufacture of substances for igniting matches, and in articles made of such substances. April 20

5788 H. E. Newton, London—Communicated by A. Nobel, France. Improvements in the manufacture and use of explosive compounds. April 28

6015 W. Brampton, Birmingham. An improved method of igniting matches, applicable to match boxes. May 4

6222 J. Macnab, London. Improvements in and connected with explosive cartridges for blasting purposes. May 7

6258 C. D. Abel, London—Communicated by F. Gaens, Germany. An improved explosive compound for blasting purposes. May 8

6340 E. L. Zalinski, London. Improvements in fuses for explosive shells and torpedoes. Complete specification. May 11

6632 T. Boek, London—Communicated by C. Libbrecht, Belgium. Improvement in gunpowder. May 18

6664 H. Schöneweg, London. Improvements in explosive compounds. Complete specification. May 18

COMPLETE SPECIFICATION ACCEPTED.

1885.

8951 D. Johnson. Manufacture of explosives. May 18

NOTICES.

ANNUAL GENERAL MEETING.

The next annual general meeting of the members of the Society of Chemical Industry will be held in Liverpool on Wednesday, Thursday, and Friday, 14th, 15th, and 16th July next.

PROGRAMME OF PROCEEDINGS.

At 11 a.m. on the morning of Wednesday, 14th July, the members will meet in the new Chemical Theatre of the University College, Brownlow Street, to transact the ordinary business of the Society, to elect office-bearers, and to hear an address by the President. By permission of the College authorities, members will have an opportunity of inspecting the new laboratories both before and after the meeting. In the afternoon alternative excursions have been arranged to the following places of interest: (a) The International Exhibition; (b) The Liverpool Gasworks; (c) Messrs. Crofield, Barrow & Co.'s Sugar Works. Particulars will be found in the Circular sent to each member with this Journal. In the evening, at 7 p.m., the Annual Dinner will take place at the Adelphi Hotel. Dinner tickets, 10s. 6d. each (exclusive of wine), may be obtained on application, accompanied by remittance, to the Honorary Secretary of the Liverpool Section, Mr. W. P. Thompson, 6, Lord Street, Liverpool. Application before July 9 is requested.

On Thursday, July 15, at 10 a.m., the members will embark at Princes' Landing Stage for a sail on the river, visiting the New North Docks, New Floating Docks, Graving Docks, Hydraulic Works, Grain Silo Warehouse and Elevator, a Transatlantic Steamer, and either the Albert Dock Warehouses or Messrs. Laird's Shipbuilding Works, as preferred by individual members. In the evening, at 8 p.m., there will be a Conversazione and Reception by the President at the Walker Art Gallery, for which each member can obtain a ticket for himself and a lady on application to Local Secretary.

On Friday, July 16, at 9 a.m., two alternative excursions start for Widnes and St. Helens, the first to visit Messrs. Gaskell, Deacon & Co.'s Alkali Works, or Messrs. Gossage & Sons' Soap Works (by ticket of admission), or the works of Messrs. The Tharsis Sulphur and Copper Co., Limited (by ticket of admission). The St. Helens excursion to visit Messrs. Bourne & Robinson's Collieries, and Messrs. Bishop & Co.'s Glass Works (by ticket of admission). A special train will take both parties on to Crewe, arriving at 12.55, and in

the afternoon the Crewe Steel and Railway Works will be visited. At 6.30 there will be an Informal Wind up Dinner in the Adelphi Hotel, Liverpool, at 3s. 6d. a-head.

Members are earnestly requested to fill in, sign, and return as early as possible to Mr. W. P. Thompson, Hon. Secretary, Liverpool Section, the Circular giving the list of works and meetings they intend to visit, as the Local Committee has undertaken to send in beforehand the names of members who will visit the various works, etc.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members of Council whose names are placed in italics in the annexed list, will retire from their respective offices at the forthcoming Annual General Meeting.

PROPOSED AMENDMENT OF BYE-LAWS.

Notice is hereby given, in accordance with Rule 54, that it will be proposed to the forthcoming Annual General Meeting to further amend the Society's Bye-laws as follows:—

Bye-law 1.—That the words "and is established in accordance with the provisions of the Literary and Scientific Institutions Act, 1854," be added after the word "Industry."

Bye-law 5.—That the word "or" be inserted in the third line thereof between the words "Council" and "a professional."

Bye-law 27.—That the words "One Guinea" in the first line thereof, be replaced by the words "Twenty-five Shillings."

Bye-law 29.—That the words "is more than four months in arrear," in the second line thereof, be replaced by the words "has not been paid."

Bye-law 37.—That the word "President" in the second line thereof, be replaced by the word "Chairman."

Bye-law 42.—That the words "is in arrear with" be replaced by the words "has not paid."

Bye-law 49.—That the date "31st of December" be replaced by the date "15th of June."

Bye-law 54.—That the word "given" in the last line but one thereof, be replaced by the word "posted."

The supply of copies of the Journal for January, 1882, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of that number, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the number will be reprinted.

CHANGES OF ADDRESS.

J. Beveridge, 1/o Russia; 19, Rectory Road, Cardiff.
F. C. Blythe, 1/o Adswode; Newholme, Victoria Park, Manchester.

G. S. Bowler, 1/o Kensington; Crystal Palace District Gas Company, Limited, Lower Sydenham, S.E.

H. E. Bunker, 1/o South Hackney; 53, Stocks Street, Cheetnam, Manchester.

Spencer Collyns, 1/o Salford; 61, Barton Street, Moss Side, Manchester.

Wm. Donald, 1/o Salcoats; New Explosives Company, Limited, Pembrey, South Wales.

C. Hinfrey, 1/o Chester; The Villas, Parkgate, Cheshire.

A. P. Laurie, 1/o Edinburgh; 29, Artesian Road, Bayswater, W.

J. Walter Leather, 1/o Bonn; 13, Redcliffe Street, South Kensington, S.W.

J. H. Macmahon, 1/o Desoto Alkali Company; Lancashire Alkali and Sulphur Company, Widnes.

J. C. Major, 1/o Monniere Green; The Blyths, Compton, Wolverhampton.

J. A. Meynier, 1/o Rue Pare Royale; 19, Rue Baudin, Paris.

W. M. Miller, 1/o Glasgow; Tuschen den Vrienden, Demerara, West Indies.

E. Milner, 1/o Warrington; Hartford Manor, Northwich.

J. E. Riley, 1/o Hapton Chem. Co.; Arden Hall, Accrington.

E. Scott; Journals, etc., to 11, Argyle Street, Sunderland.

H. C. Shorten, 1/o Uxbridge Road; 3, Addison Road North, Kensington, W.

W. W. Staveley, 1/o West Bromwich; Baghill, Pontefract.
E. Sykes, 1/o Hill Street; 27, Nursery Street, Pendleton.

W. J. Taylor, 1/o Holborn Viaduct; c/o Prentice Bros., chemical works, Stowmarket, Suffolk.

G. I. J. Wells, 1/o Liverpool; 11 Francis Terrace, Victoria Park, London, E.

C. F. Young, 1/o Middleton; New Islington Chemical Works, Baker Street, New Islington, Manchester.

LIST OF MEMBERS ELECTED, 23rd JUNE, 1886.

J. Kinniburgh Brown, 5, Saxe Cobourg Place, Edinburgh, insurance fire superintendent.

Emmanuel Kur, 13, Bath Buildings, Huddersfield, dyer and colourist.

J. F. McFarlane, 6, Ham Frith Road, Stratford, E., chemist.

J. B. Mercer, 322, Lower Broughton Road, Manchester, manager.

G. H. Scott, Hague Bar, New Mills, near Stockport, chemical manufacturer.

Henry Sharp, Loseley Hurst, Bournemouth and Poole, firebrick manufacturer.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.

H. E. Armstrong.

W. Lant Carpenter.

W. Crowder.

C. Graham.

S. Hall.

A. K. Huntington.

R. Messel.

B. E. R. Newlands.

John Spiller.

G. C. Trewby.

J. Williams.

Local Sec. and Treasurer: Thos. Tyrer.

Garden Wharf, Church Road, Battersea, S.W.

July 11, 15 and 16.—Annual Meeting at Liverpool.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held Tuesday, June 8, 1886.

MR. DAVID HOWARD IN THE CHAIR.

THE CHEMICAL TREATMENT OF SEWAGE.*

BY C. MEYMOTT THOY, M.B., M.A., F.C.S., F.I.C.

It will probably be within the knowledge of some that a few weeks back I gave an address upon Sewage at the Society of Arts. I have no intention, however, to-night, of following the same lines of thought or of treatment that I followed then. As far as I am able, I shall address myself to the special chemical aspects of the sewage question.

At the Society of Arts I ventured to give a general history of the sewage question; I do not propose to repeat that story to-night. I am compelled to admit that the subject of sewage generally is in a frightful mess. If we turn to the scientific history of the question we may find, I think, some cause for the mess. It would be very interesting to trace the subject through its many phases, but for the serious results. I have tried to follow the history, and I hope not many more of you will attempt it. Report upon report, blue book after blue book has appeared, blue book No. 2 always seeming to do its best to undo any good that might have been done by blue book No. 1, and both vieing with one another to bewilder us with facts and figures. Royal commission upon royal commission has been appointed, the members of which can scarcely have been said to have been discreetly chosen. Thus a commission was appointed to inquire into the pollution of rivers and the diseases resulting from such pollution, without any medical man having a place

* The address is from shorthand notes.

on the commission. So much for the past. Is the future brighter? Not much. The prospect looked better a few months ago, but very dark clouds have gathered lately.

Let me ask, in the first place, what is the nature of this material about which commissions have inquired and experts reported *ad nauseam*? Sewage is (in few words) the refuse of communities, their habitations, streets, and factories. That is a broad and general definition of sewage. As to its composition, it contains (1) the solid and liquid excreta of the population, (2) the washings of the streets, and (3) the fluid refuse of every branch of industry. It contains commonly a large volume of subsoil water. Sewage therefore has a complex nature. When called upon to advise upon sewage schemes, it is necessary that we should know exactly what it is with which we have to deal. So far as the excreta of the population is concerned, the question is reasonably simple. The composition of the excreta is fairly constant, as shown by the researches of many authorities, like Lawes and Way in this country, and Wolf and Lehman on the Continent. A thousand people in a mixed population contribute about 2640lb. of liquid and moist excreta per day, or 141lb. of dry deposit to the sewage; in other words, about 2½ oz. per head daily of dry matter. These results agree fairly well with the average records of a very large number of observations of different observers. Combined results are of much greater value than individual results. That, then, is the nature of the excreta. The washings of the streets is the next branch of the subject. The conditions under which observations are taken should be as nearly as possible identical, and perhaps preferably be made at the time of storm following a period of drought. On a granite road, after a heavy shower, the discharge into the gullies will contain an average of 800grs. per gallon of solid matter, of which 280grs. will be in solution, and 520grs. in suspension. I must point out that this quantity is enormously influenced by the traffic and by the character of the road. Taking an average of observations made on all sorts of roads during a heavy storm, the solid matters present were found to be 280grs. per gallon, of which 120 was in solution and 160 in suspension. The granite roads are found generally to yield the largest quantity of matter to our sewers. In the case of a wood pavement, during a heavy storm, the discharge contained a quantity of solid matter not exceeding 50grs. per gallon, of which 40 was in solution and 10 in suspension.

The excreta of the population, it will be noted, is fairly calculable, whilst it is possible to estimate the solid matter in the washings of the roads. But as to the rest of the data—they are uncertain. When you are consulted by local authorities, you will be asked to let them send you up a sample. A single sample won't tell you much. If a specimen sample is to be of any good it must be a mixture of samples taken every half-hour during the twenty-four hours. It may then probably be of some value, but even it will not go very far. There is still an important piece of information which you require. It is necessary to have the clearest information as to the place where the sample of sewage was collected, and the conditions under which it was taken. The sewage, for example, at a stagnant spot, or in a branch sewer, may be very foul, whilst the sewage ordinarily is not foul. But when all possible care has been taken in the collection of the samples, you will want to know more than any one sample of sewage can tell you. The weather has an important bearing on the quality. The first sewage after a storm usually contains an extraordinary quantity of impurity. It is important, therefore, that a second sample, taken an

hour or one hour and a-half after the storm, should be collected. It comes to this, that a sample of sewage may be submitted for your examination, which, for want of many necessary data, affords you no information upon which you can report. You cannot estimate factory refuse, except by experiment on the spot, for it varies from hour to hour. I do not intend to enter on the difficult or contentious subject of Metropolitan sewage; but, taking a large number of samples of London sewage, not collected during a storm, the quantity of solids found was on an average 94grs. per gallon, of which 56 were dissolved and 38 in suspension. At night the results gave 78grs. per gallon, 64 dissolved and 14 in suspension. The average is 90grs., 60 dissolved and 30 in suspension, and of organic matters 15grs. in suspension and 15grs. dissolved. In making an analysis of sewage, it is advisable to make an analysis of the sample (1st) as delivered, (2nd) of the liquid after the sediment has been removed, and (3rd) of the sedimentary matter. The physical qualities of sewage have a very practical bearing. The analysis will show that the clear liquid contains, besides amorphous organic matter, filaments of various fungi and the lower forms of animal life (monads, vibrios, etc.). If you expose the clear liquid to air, you then obtain the higher forms of infusoria (vorticellæ, rotifera, etc.). When the sewage decomposes and gives off sulphuretted hydrogen and marsh-gas, you will find animal life disappear, and if you dilute the sewage in this state with water and expose it to air, the bad odour goes, and the higher infusoria, the vorticellæ and the rotifera appear. That illustrates the salutary effects of air and dilution on sewage. If you have to examine a river containing sewage matter, you can get very different results according to the place from which you take the samples. A sample taken near the edge of the river, where the sediment collects and foul gases are likely to be evolved, the water will probably exhibit only the lowest forms of organic life, but if the water taken in the middle of the stream, where air has free access and the water is abundant, the higher forms of infusoria will abound. You can tell in many cases by the character of the infusoria from what part of a river a given sample has been taken. Again, as regards river water, the only way to get a fair sample is to take a series of samples across the river from the one side to the other.

In the sediment, besides a great deal of black amorphous matter, there will be found—(1) the remains of undigested food, muscular fibre, husks and hairs of wheat, fibres of wool, and tissues of vegetables; (2) the products of secretions, such as yellow biliary matter, intestinal mucus and crystals of uric acid; (3) the debris of the streets, such as particles of granite, flint, carbonate of lime, etc. There are two things, however, which are specially characteristic of sewage. It is very important to know them, because their presence or absence will enable you to say with certainty whether matter found in a water is of sewage origin or not. You will almost certainly find hairs of wheat and free spirals—that is, vegetable spirals without their investing membrane. In the case of vegetable tissues passing through the alimentary canal, the fluids of the digestive tract have the power of dissolving the investing membrane, but not the spiral. Nothing that I know of is so characteristic of sewage as these free spirals and hairs of the wheat.

And now comes the question, What are we to do with the sewage? The voice of authority is not very unanimous on this question, but authorities are fairly well agreed on two points, (1) that if sewage contains anything of value to the agriculturist it is in solution,

and (2) that the matters in sewage likely to cause a nuisance, are in suspension. What is the value of sewage? Has it any value? Of course it has, you answer. It contains nitrogen, phosphoric acid and other constituents valuable to the soil. The calculation of its value is very easy to some people. You have only to find out what is the population, and then determine the quantity of the sewage. Taking the value of the excreta at six or seven shillings per head, of course (they will tell you) you have all the data you want for the calculation.

Years ago, when the population of London was only about 3,000,000, some very wise people said the Metropolitan sewage was worth from one to four millions sterling. That they were rather wide in their estimates is certain.

Suppose a local authority consults you about their sewage, the first thing they will do will be to refer you to the teachings of science. They will tell you that it is our duty to return to the soil those matters that have been taken from it—that it is a shame to waste sewage. No doubt they are right. But the authorities will press you further. They will ask—Can you tell us how to make our sewage pay the rates? Science has told them that the proper way is to apply it to the land, and they ask you to advise them how to do it advantageously. Having already discussed this branch of the subject at the Society of Arts, I only now note, *quâ* irrigation—1st, That the real value of sewage is not its theoretical value; and, 2nd, That there are definite obstacles against the application of crude sewage to land. Sewage comes to the works at all times—day and night. Sewage is no Sabbatarian. It must be taken Sunday and week day—in all weathers—in the heat of summer when the ground is liable to crack, and in time of frost when the ground becomes so hard that nothing can permeate it. You must take the sewage whether the ground wants it or not. You must take it in all conditions of your crops—in seed time and in harvest—all the year round. But another difficulty presents itself—namely, rival interests—call it, if you will, the antagonism of parties. The farmer naturally wants to make something out of the sewage. The local authority says to the farmer—I don't care whether you do or do not make anything out of it, but two things we demand—1st, That no nuisance shall result during the operation; and 2nd, That you should produce a pure effluent. Now, you see why local authorities, in order to obey the teachings of science, are compelled to be their own land proprietors. But now a fresh series of difficulties present themselves—1st, The soil must be porous enough for sewage to filter through it, but not too porous, lest the sewage pass through without purification; 2nd, The land must be sufficiently near a town to ensure a market for its only merchantable produce—Italian rye grass—but not so near the town as to pollute the air with miasms, or infect the wells by subsoil drainage; 3rd, The land must be of such a level as to receive the sewage by gravitation, but also of such a level as to allow the effluent to flow away from it by drainage.

The question of the land is in itself one of enormous difficulty. The more sewage you have to treat the more land you require, whilst as the population of your town increases, the difficulty of obtaining land also increases, and the higher becomes its price. But suppose science wins the day, and the land is procured and the sewage turned on. The results, next to certain, will be (1st) that your land becomes a fetid swamp—an offensive morass, and (2nd) that a nuisance results dangerous to the public health. If you may put sewage on land—undefecated sewage, I mean—with impunity, what is the good of all our elaborate

machinery for getting rid of sewage from our houses, and for preventing the escape of noxious emanations? If the principle of broad irrigation is sound, why should we bother ourselves about untrapped drains or overflowing cesspools? The sewage matter may percolate through the soil. Then how about the neighbouring wells? Did not Dr. Frankland think a certain chalk well at Croydon was polluted by foul matters from the irrigated farm at Beddington? Pettenkofer may be right, too, in regard to his theory that fluctuation in the levels of ground water is an active agent in the production of fever and cholera. I omit all reference to the question of the deterioration of the land by constant irrigation, and the difficulties resulting therefrom. But, it may be said, you admit that you may get a good effluent by irrigation. Well, suppose I admit that you may get a better effluent by such means than by a precipitation process. Still, that does not go very far. Let me give you a warning. Suppose an inspection of a sewage farm is arranged. The effluent water, you will be told, and will see for yourself, is not only pure but drinkable. I grant that under proper management you can rely upon obtaining good results. But that is not the question. Are such results obtainable at all times, and under all circumstances? I reply they are not, because they depend on too nice an adjustment of the quantity of the sewage and the weather. The nice balance requisite is not susceptible of mechanical adjustment. You cannot turn a screw and lay on the proper amount of sunshine. Local authorities, I have found, always like to have due notice of inspections of sewage farms, and that such appointments should be made subject to telegrams. Let me draw this conclusion. Do not give any notice when you propose inspecting a sewage farm. And when you go it is advisable to inspect the whole district. It is not at all uncommon to find very convenient byways for the disposal of sewage, which the land will not take.

I think you will now see why the difficulties of irrigation have led to the proposal of other methods of treatment. The solid matters, it is agreed, are the chief cause of nuisance, and these must be got rid of. I suppose the idea of making money, or of paying the rates out of sewage, is nearly given up. But in order to get the solid matter out, I say at once, you cannot stram sewage and you cannot filter it. The most effective strainer soon gets so clogged with aluminous matter that it fails to act. Subsidence or filtration methods equally fail.

Then you turn to chemicals. What are the points to be considered in the chemical treatment of sewage? They may be stated under five heads:—

1. That, consistent with good results, the chemicals should be cheap.
2. That they should act, not only as precipitants, but as deodorisers.
3. That it needs to be decided, by experiment, what is the minimum quantity of chemicals required to produce the maximum purity of effluent.
4. That the precipitated matter should subside rapidly.
5. That the sludge should part readily with its water.

Now comes the question, What chemicals are we to use? I have no patent. I never took out a patent in my life, and I don't mean to do so. I have no system to advocate. One system may answer best in one place, and a different one in another. Prof. Dewar and myself, it is true, have been called upon to report on the A B C process, as we have on other systems, and it is right that I should say for him and myself that our obligations entirely ended with the

report. I am not here to advocate the A B C or any other process. Further, I have no precise answer to give to the question of what chemicals to use. A precipitation process advisable at one place, may not be the process to be recommended at another. It is of no use to tell an authority at A to see how a process works at B, as if it would therefore work well at A. Nothing is a greater nuisance than show chemical precipitation works. A chemical adviser must have no hobby, or if he has, must be prepared to sink his hobby when the conditions are against him. With regard to the value of sludge, I advise that we give no scientific authority in support of any value. The enemies of precipitation schemes have been the advocates of sludge value. The public weighed the claims that have been advanced against the facts, and came to the conclusion that there was not much in the claims. Sludge may have a value, but it is one that chemistry is not able to take cognisance of. I may here quote an opinion expressed in the report by Professor Dewar and myself on the A B C process already referred to:—"As to the manurial value of native guano, we are strongly of opinion that this must be judged rather by the practical results of agriculturists than by presumed theoretical values based on analytical data, and on the price of ingredients not necessarily in the same physical or chemical condition."

To test a chemical process, it is of no use trying experiments on a small quantity of sewage like a tenth of a gallon. The smallest quantity that will be of use for the purpose is about five gallons. One of the first precipitants suggested was lime. Taking the sewage of a large town (not London), where I had to investigate the precipitating action of lime (it was a town where the sewage was about 30 gallons per head of population), I found that 20 grains of lime per gallon not only removed all suspended matter, but also one-fourth at least of the dissolved organic matter. The precipitate settled from 6 feet to 2½ inches with this quantity of lime in about one minute. The effluent had no smell. I am free to admit that there are great objections to the use of lime. 1st. When used in sufficient quantity the sludge is very large in amount and very valueless. If too little lime be used, its use is worse than useless, because a small quantity of lime renders the sewage ten times more offensive. 2nd. When lime is used the effluent is alkaline, and is accordingly liable to putrefy. 3rd. Free lime is injurious to fish life. I know of places where lime can be used, but it is not, I am convinced, universally applicable.

The second precipitant to which I may refer, is a salt of alumina. We know that compounds of alumina fix ammonia and phosphoric acid. Further, alumina combines as a mordant with organic matter in solution. The flocculation of sewage, treated by alumina, is very great. I have obtained excellent results from alumina, but the precipitation is slow.

Salts of iron are undoubtedly valuable both for precipitation and purification. They were suggested by Frankland and Hoffman for London sewage, and the reason why it was condemned was that a great deal of black deposit would result, which collecting on the banks would lead the people to think that the river was foul and would necessarily smell. The use of salts of iron makes the sludge very black from the formation of iron sulphide. Iron salts are not so good as sewage precipitants as sulphate of alumina. There are numerous other processes in which chloride of lime, magnesium salts, etc., are used, but most of them depend on one or other of the precipitants I have named.

Now, there are two points which in dealing with sewage it is desirable we should bring clearly

before local authorities. 1st. We can't produce a sludge having the value of Peruvian guano; and 2nd. We can't produce an effluent sufficiently pure to be employed as drinking water. As regards value of sludge, I discard at once all processes where phosphoric acid in any form is used to enrich the sludge by the formation of phosphates. Phosphates in an effluent are objectionable because they enormously assist the development of sewage fungus. Taken altogether, I am disposed to think that the use of an amount of lime sufficient to render the sewage alkaline, and the after addition of a salt of alumina, produces the best result.

The chief points to be attended to in the treatment of sewage by chemicals are:—1st. That the sewage should be treated fresh—*i.e.*, before actual putrefaction has set in. If within 24 hours, so much the better. The various organic matters in sewage possess different degrees of putrescibility. Fresh sewage has very little smell. Straining the sewage in the first instance with such mechanical contrivances as Baldwin Latham's extractor, has its advantages, but is not essential. 2nd. Sufficient chemicals should be added to effect complete purification. It is a great mistake to starve the chemicals. Local authorities are always ready to starve chemicals. They will build works, and spend large sums of money upon them. Works are something to look at and to admire, but when it comes to spending a considerable sum every week and every day in the treatment of their sewage, then comes the rub. Local authorities must be taught that, if they are to treat sewage properly, it means an every-day expenditure. With regard to the calculations, it is better to take population as the basis of the calculation of the quantity of chemicals needed rather than quality of sewage. 3rd. After you have added your chemicals, you must stir the mixture thoroughly if you wish to obtain the maximum result of the chemicals. You all know the value of the stirring rod. 4th. A very important matter is sufficient tank accommodation. Large tanks, or enough tanks, are necessary in order that the flocculent matter may subside perfectly, and that the sludge can be easily and frequently removed. If you have a quantity of old sludge in the tanks it putrefies and contaminates your freshly-treated sewage. It is not sufficient merely to empty the tanks, but you must wash them. It is a very hard thing, in my experience, to teach local authorities these things. It is very hard to teach them that they must not only have good works, but that the good works to be efficient must have constant attention. When all this has been done, two important questions arise: 1st. Have you produced an effluent that will not pollute the water course? and 2nd. Is not the sludge an inevitable cause of nuisance? In regard to the first, I answer, a precipitation process will produce such a good effluent, and that it may be made efficient at all times, but I know of no precipitation process by which you can remove entirely a certain peculiar odour of the effluent. There is always some smell left, and I don't know what it is. It will be asked—Can we do anything to get rid of this peculiar smell of a chemically produced effluent? There is only one thing to be done—*i.e.*, to let it flow over a little piece of land or through properly prepared filters. This constitutes the combined system of treatment. It cannot, as a defecated effluent, cause a nuisance. A very small quantity of land is sufficient. I have seen it done effectually with an acre to 10,000 of the population. As to the sludge being an inevitable nuisance, I think it need not be. Formerly it was, no doubt, a great nuisance; I am not sure, in fact, that the solid matter was not a greater nuisance when

taken out of the sewage than when left in it, but by the process of pressing the sludge now in use, you can remove its obnoxious character altogether.

Very excellent papers have been read in this room by Mr. C. C. Hutchinson and Dr. Monro upon this subject. Many very important facts were referred to in these papers, but there is one to which they did not refer. The liquor that is expressed from the sludge is clear and bright, but uncommonly offensive. The old method was, to return the expressed liquor to the raw sewage, but that inevitably renders the remainder of the sewage difficult to treat. The best way of dealing with expressed liquid is to treat it separately with a rather large dose of chloride of lime and then afterwards add lime.

I told you when called to advise upon a sewage process not to volunteer too many opinions. You will be asked to analyse a sample of effluent. I advise you to do no such thing. Take care to have half-hour samples of effluent, and take care, moreover, to have with the samples of effluent a sample of sewage taken similarly in order that you may compare the analysis of the raw sewage with the effluent with precision.

We have got ourselves into a terrible mess with this water-carried sewage. The advocates of the water carriage system tell us that water as a means of getting rid of our sewage difficulties commends itself on the ground of cleanliness and cheapness. I admit that, at first sight, all the advantages and all the arguments seem to be on one side, but I am disposed to think that the facts are for the most part on the other. Of the thirty gallons of water per head, brought at a vast expense daily to our homes, only about one-ninetieth part is used for drinking, much of the remainder being required for the carriage of the sewage. The water carriage system is an ingenious contrivance to occupy the time of local authorities, to increase the taxes of the people, and to assist the practices of chemists, counsel, and engineers.

After offering an apology for having detained the meeting so long, Dr. Tidy concluded with an eloquent appeal to men of science to address themselves to the study of this question. The sewage question, he said, is emphatically a question for the chemist. It is a question for those who, admitting the grandeur of scientific research, when it is research and when it is science, are yet not unmindful of the fact that it is a part of their duty to apply their science to the daily requirements of daily life and to the common wants and common needs of our common humanity.

DISCUSSION.

The CHAIRMAN said, in listening to the very interesting and instructive address which Dr. Tidy had delivered, the reference to the schemes of inventors who, starting out with sanguine anticipations of profits, so often missed the hoped-for success, had awakened a reminiscence of his early days. His father had shown him a sample of Welsh ore containing a small quantity of gold, but it proved on examination that it would never pay to get it out. This circumstance strongly impressed his mind at the time, and perhaps he owed it to that incident that he had in later life kept aloof from visionary schemes. Dr. Tidy had brought the matter before them so clearly that they would be disposed, perhaps, to exclaim, What on earth are we to do with our sewage? He hoped that an interesting discussion would follow.

Dr. DUPRÉ said he had listened to the paper with a great deal of pleasure. He thought that if sewage wanted a good deal of stirring it had that night been

very thoroughly stirred. Dr. Tidy had treated the subject so fairly and judiciously that it would be a great sin to begin a discussion at that late hour. Those who knew most of the subject of sewage, would know how well its difficulties had been described, and that they might have been extended to more than the two points selected. He was glad to hear reference made to the idea of local authorities that sewage would pay the rates. Local authorities were always disposed and ready to lay the blame of every failure on the chemist. The first duty of the chemist was to dismiss from his mind all idea of making a profit out of the sewage. There was one difficulty which every man who had experience in the chemical treatment with sulphates and by filtration would have met with. It was where the effluent had to be discharged into a small quantity of water. It sometimes happened that a stream which might, perhaps, be called a river in winter, was in summer nothing but a dry watercourse. He expressed hearty concurrence with Dr. Tidy on most points.

Mr. GROVES could offer some little testimony in favour of the lime and alumina process. In the case he was about to refer to, lime, then sulphate, and then small quantities of chloride were employed, and the effluent was discharged over a bed of charcoal. It passed into a canal, and fifteen months after the commencement of the works not the slightest deposit or disagreeable odour could be discovered. He thought that spoke strongly in favour of the process recommended by Dr. Tidy.

Mr. BISCHOP thanked Dr. Tidy for his interesting paper, but would like his opinion upon the increasing difficulty of disposing of sewage to the farmer caused by its fall in value. It was universally stated that a certain proportion of the value had to be taken off the process, and some people put the restriction at as much as five-sixths. Would not the value to agriculture proportionately decrease? Would it not be more and more difficult to get farmers to take the sewage, and would not local authorities be compelled to purchase land? He concluded by reading an extract from a letter he had received from the engineer of the Rochester (U.S.A.) Board, which recorded some excellent results of the system adopted in that country.

Mr. C. N. CRESSWELL was of opinion that the meeting owed a debt of thanks to Dr. Tidy for the fearless way in which he had expressed his views on a much-vexed subject. When Dr. Tidy stated that he had arrived at an important epoch in the history of sewage, he expressed an opinion with which he (Mr. Cresswell) entirely concurred, and he found it a very difficult thing to make a speech when he agreed with his adversary from the beginning to the end of his argument. He especially agreed with that portion of his address where he described the evils which we suffer from the water-carriage system. Some years ago, in a paper read before the Society of Arts, he described the evils resulting from the almost universal adoption of the water closet in rural districts, as well as in the towns. Nevertheless he had felt some measure of disappointment that they were asked not to discuss a measure which so much agitated the public mind at the present time—the question of Metropolitan sewage. The world of sanitary science had been startled by an alleged discovery, which, if true, was the most beneficent discovery of the age. They were told that Thames sewage could be treated by lime and salts of iron in such a way that for nine months out of the twelve they could get an effluent without danger to those who lived on the river and its banks, but that at certain times gaseous matters might be evolved which were offensive and

unsalubrious; that at length a means had been found which would enable the authorities of the Metropolis to overcome all their difficulties. They were told that permanganate of soda, with a certain proportion of sulphuric acid, would work that miracle. For the last forty or fifty years they had only known one method of dealing with sewage—applying it to the land. There was scarcely a community within 300 miles of London who had not spent a large sum of money on experiments in this direction; if the supposed discovery were true, it seemed a melancholy reflection that all their arguments and efforts must have been futile. When told that we were only in the infancy of the science, and that we must do nothing until we knew more about it, he had always thought it argued a dull and stolid mind; but if what they were now taught were sound, it went far to justify what was then called stupidity. It made those seem wise who had always said, "Don't let us spend thousands and thousands on these experiments, when, perhaps, in a few short years some inspired prophet of the day will relieve us of all our doubts and difficulties." It seemed to him (the speaker) of the greatest importance that they should be allowed to discuss a subject which so virtually affected the welfare of so many of the inhabitants on the banks of the Thames. Were they to continue to spend thousands of pounds annually in providing a proper outfall, or in the purchase of land, owing to their want of knowledge of the most fortunate discovery in this wonderful age?

Dr. Tidy then replied. He had had the pleasure of meeting Mr. Cresswell when their opinions were not in such absolute accord as they appeared to be that evening. They had been sometimes on opposite sides, and they, therefore, knew each other's views. In the address, he had carefully avoided the question of Metropolitan sewage, not because he had nothing to say upon the subject, but because he would rather deal with it as a whole. With regard to the alleged discovery which Mr. Cresswell had mentioned, he might point out that the three distinguished chemists who sent in the report containing the idea, had all given evidence that nothing more was wanted in the treatment of sewage. He wished to speak with all respect of those gentlemen, two of whom, Sir F. Abel and Dr. Odling, were old friends of his own; but he felt bound to point out that they had all given evidence before the Royal Commission that no treatment of sewage was required. He might claim to know something of the Metropolitan Board (having fought with them a fight lasting many days), and he could not help thinking that a Board which so completely agreed with this evidence, and who thought themselves great benefactors to the community in putting sewage into the Thames, were not perfectly justified in proposing to spend a sum of money in treating that sewage which was doing so much good. Mr. Cresswell, with his trained lawyer's mind, might perhaps divine what his (Dr. Tidy's) opinion was on the subject. He could only say that he considered it a very sad thing—he wished to speak generally—when processes were adopted which it was known must be a failure.

DR. SPRENGEL, F.R.S., exhibited some objects connected with the Hell Gate explosion, near New York—viz.: (1) Photographs (taken at the moment of explosion, 11.13 a.m., October 10, 1885) of the immediate surroundings of the mine, charged with 22 tons of dynamite and 107 tons of one of Dr. Sprengel's safety explosives (*Jour. Chem. Soc.* 1873, p. 806); (2) A sample of this safety explosive (79 per

cent. potassium chlorate and 21 per cent. nitrobenzene) possessing the power 109 (General Abbot, U.S. Army), dynamite No. 1 (containing 75 per cent. nitroglycerine) being 100; (3) Effects on lead produced by the explosion of equal weights of another series of safety explosives—the nitric-peroxide mixtures—demonstrating their greatly superior power over that of nitroglycerine.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held Wednesday, May 5, 1886, at
University College, Ashton Street.

PROF. CAMPBELL BROWN IN THE CHAIR.

THE CHAIRMAN called the attention of the meeting to the recent death of Mr. James Muspratt, father of the President of the Society, and moved the following resolution, which was seconded by Mr. A. Norman Tate, and carried unanimously:—"That the Liverpool Section of the Society of Chemical Industry has heard, with great regret, of the death of Mr. James Muspratt, and desires to offer its condolence to his family, and to record its profound respect for his memory, recognising the great work which he accomplished in initiating and developing chemical industry."

MR. ALEX. WATT exhibited a sample of Fahlberg's so-called "Saccharine," an account of which was recently given at the Manchester Section by Mr. Levinstein (see *Journal*, vol. v. p. 75).

THE CHAIRMAN hoped that the recent remarks of Sir Lyon Playfair would not render this substance too popular, unaccompanied as they were by even a word of warning. It must not be forgotten that this nitrogenous body was in no sense sugar, nor nutritious like sugar, although in some senses Sir Lyon Playfair might consider this a recommendation. Nitrogenous bodies were uncertain in their action, and were often poisonous without apparent reason.

MR. BRUNNER inquired as to the therapeutic action of saccharine.

MR. ALEX. WATT stated that it was held to be harmless.

THE CHAIRMAN required further evidence of this.

MR. TATE said that he was making an experiment, and would communicate the results to the Society.

DISCUSSION ON MR. T. ANDERSON REID'S PAPER ON "WOOD AS A PAPER-MAKING AGENT."

MR. NORMAN TATE said the Society was much indebted to Mr. Reid for his very practical paper, which showed what might be done, as a matter of chemical industry, in dealing with what would be

otherwise waste matters. He would like to ask whether the "teasing" process was simply a mechanical process, or was the wood in any way treated by chemical agents? On examining a substance made from wood pulp a short time since, he found in it small amounts of resinous and other matters which existed in natural wood. The substance was in the form of very thin sheets, and had apparently been made by rolling wood pulp, and subjecting it to very great pressure, until something similar to Kamptulicon and other floor coverings was obtained. An important suggestion made by Mr. Reid was, that during the recovery of the soda by evaporation, drying, etc., the volatile matters that were now wasted might be collected. In some places the recovery process had been so conducted as to become quite a nuisance to the neighbourhood in which it was carried on. In investigating the cause of this nuisance for legal purposes, he (Mr. Tate) noted that much of the strongly smelling volatile matter could be collected, but whether the character of the substances was such, and the quantity sufficient to pay for collection, he thought required further investigation. Many of the samples of marketable wood pulp he had examined contained as much as from 40 to 50 per cent. of moisture. He supposed there must be some reason based upon inferior texture of the pulp, if dried too much, that rendered it desirable that so much moisture should be left in, as the cost of carriage was thereby much increased. With regard to the sulphite process it appeared not to act satisfactorily unless the wood was brought into a finer state of division, and knots, etc., removed; whereas the caustic process appeared to deal more readily, and in an efficient manner with all refuse wood. Against this it must be remembered that by the sulphite process the yield of pulp on the wood actually employed is greater than by the alkaline process. Therefore, it seemed to be necessary to consider how far extra yield compensated for the extra cost of the process.

Mr. REID, in reply to a question from Mr. Brunner, said that the pulp was bought as air-dried, and was found to suit the paper makers in that condition.

Mr. W. P. THOMPSON reminded the meeting that, at the time of the South Sea Bubble, a company was actually floated for grinding down chips into sawdust and rolling it into boards. The intention seemed to be nothing more than to make paper pulp and solidify it by heavy pressure. When the author stated that hard woods yielded more pulp than soft woods, did he mean by weight or by bulk?

Mr. REID: By weight.

Mr. THOMPSON continued: American rock elm had such a strong fibre that it was used by lumbermen to tie their rafts together. Basswood was softer, but seemed all fibre. He would like to know how these two woods compared for pulp making. His idea was that basswood would give a larger quantity, and rock elm a stronger quality of fibre. The resins might be removed before bleaching by a treatment with hydrocarbons or carbon disulphide.

Mr. REID replied that the soda process saponified the resins, but the sulphite process rather tended to fix them in the form of an orange stain.

Mr. THOMPSON suspected that the pulp which Mr. Tate had found so resinous was a sample sent from Norway for a particular purpose, in which the resin was to serve as a kind of cement when the pulp was pressed into heated moulds. Blocks and medallions of imitation wood were often made in this way, surfaced with a veneer, or moulded into the appearance of carving. The veneer might even be of metal, and would firmly adhere to the pulp if a layer of glue

were interposed. He was not sure if this class of resinous pulp was ever used for paper making.

Mr. REID: The mechanical pulp which came from Norway and Sweden was only worth about £5 a-ton, and was quite useless for paper making, while chemical pulp was worth from £16 to £20 per ton.

Dr. HURTER, while regretting that they had not been furnished with some figures to illustrate the comparative cost of the alkali and sulphite processes, said that the cheapness of sulphurous acid, as compared with soda, would always be an inducement for them to try to render the former effective. It was evident that the sulphite process was not all that could be wished, or Messrs. Cross and Bevan would not have tried to combine it with the use of alkalis. If, for instance, pulp prepared by the sulphite process were incapable of being bleached, as had been stated, then none of the higher classes of pulp could be made by it. He was much interested in the author's remarks about the recovery of alkali in the soda process, because the recovery of 90 per cent. of the alkali would materially reduce its cost. It would be a further inducement to use the process if other products, such as acetic and oxalic acids, which were worth many times the price of alkali, could also be removed by subjecting the residue to dry distillation.

The CHAIRMAN quite agreed with the remarks which had fallen from the various speakers. It was true that the recovery of alkali from these processes was often accompanied by a disagreeable smell, but it was quite easy to prevent this by thorough combustion. At the same time the possibility of recovering valuable by-products must not be overlooked. He would like to point out that, for the class of resinous bodies present in wood, alkali was a far better solvent than bisulphide of carbon. As to the question of oxalic acid, one must remember that the object of the pulp maker was to free the cellulose as much as possible from extraneous matters without destroying the cellulose itself. If much oxalic acid were formed, it could only be at the expense of the cellulose itself, and would hence cause loss to the paper maker. Action on the cellulose was more likely by the soda process than by the sulphite process, and would account for a smaller yield of pulp in the former case. As regarded distillation products, they were quite as likely to be valuable whether derived from the deposits on the cell walls, or the cellulose itself.

Mr. THOMPSON stated that he had recently seen samples of artificial cork which looked very much like mechanical pulp with the resin taken out, and were of a pale yellow colour.

Mr. REID said that ordinary bark when treated with alkali gave a body like that described by the last speaker.

MEETINGS, SESSION 1885-86.—First Tuesday in each Month, at 7 P.M.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

ALDERMAN W. H. BAILEY IN THE CHAIR.

NOTE ON MR. PETER HART'S PAPER ON CAUSTIC SODA.

BY GEORGE E. DAVIS.

I SUPPOSE it is universally admitted that caustic soda came into existence by reason of several manufacturers requiring to produce a highly carbonated soda-ash. The old-fashioned way of making soda-ash was to boil down the crude black-ash liquor in what was called a dandy-furnace, thereby producing a soda-ash containing about 48 to 50 per cent. of alkali, of which from 8 to 10 per cent was in the caustic state. This article was not suitable for many industries, notably wool scouring, and many attempts were made to carbonate the caustic alkali, and by others to remove it. In those days, however, the demand for caustic soda was extremely limited; and, moreover, the alkali-makers of that day were strongly impressed with the idea that caustic soda was of such an extremely corrosive nature that nothing would withstand it. I have been told, however, that small quantities of caustic were made about the date mentioned by Mr. Hart at the St. Rollox Works, in Glasgow, but it is equally certain that the quantity produced was not very great. I think the credit for producing it in quantity should be accorded to Mr. Gamble, of St. Helens, who was the first to work out Mr. Gossage's process for the separation of carbonate and caustic alkali from the same liquors; the carbonate was fished out, and the caustic remained behind in the mother-liquor, which was eventually boiled down and fused in cast-iron pots.

With regard to the manufacture of white caustic soda, there is no evidence whatever to show that it was made, even in small quantities, before it was produced by Dr. Pauli and Messrs. Evans & McBryde, at St. Helens, in 1862. Even in that year, most of the good coloured caustic soda was made by the causticisation of soda-ash with lime, and it will be known to most of you that Messrs. Roberts, Dale & Co., of this city, excelled as early manufacturers of this article.

OBSERVATIONS AND SUGGESTIONS ON THE PRESENT POSITION OF THE BRITISH CHEMICAL INDUSTRIES, WITH SPECIAL REFERENCE TO COAL-TAR DERIVATIVES.

BY IVAN LEVINSTEIN, ESQ.

IN the year 1878, Professor Bayer, the discoverer of artificial indigo, made the following remarks in a speech delivered on a special occasion:—*

"Germany, which, in comparison with England and France, possesses such great disadvantages with reference to natural resources (raw materials), has succeeded, by means of her intellectual activity, in wresting from both countries a source of national wealth. Germany no longer has to pay any tribute to foreign nations, but is now receiving such tribute from them, and the primary source from which this wealth originates has its home, not in Germany, but in England.

"It is one of the most singular phenomena in the domain of industrial chemistry, that the chief industrial nation, and the most practical people in the world, has been beaten in the endeavour to turn to profitable account the coal-tar which it possesses.

The numerous German colour works purchase from England the greater portion of the products of the distillation of coal-tar, and they supply three-fourths of the world with the colours made from it. However, we must not rest on our laurels, for we may be sure that England, which at present looks on quietly while we purchase her tar and convert it into colours, selling them to foreign nations at high prices, will unhesitatingly cut off the source of supply as soon as all the technical difficulties have been surmounted by the exertions of German manufacturers, etc."

Eight years have elapsed since these remarks were uttered, and what is our position in England to-day? We have not cut off from Germany the source of supply; we still supply Germany with three-fourths of the hydrocarbons which she requires; and we still allow Germany to supply us with at least three-fourths of the colouring matters which we use.

It might be argued that, after all, trade is in principle only an exchange of commodities, and as long as we supply Germany with the raw material, and it pays us to purchase from her the colours manufactured from it, there is no ground for complaint. This sounds plausible, and the assertion might be true if we got twenty shillings in exchange for a sovereign, or if the profits realised on our raw material were equal to those obtainable by turning the latter into finished products. But neither of these positions is correct. Our tar distillers are by no means so favourably situated as the German colour manufacturers. Instead of getting twenty shillings in exchange we do not even receive five shillings in return for our sovereign, and yet the natural advantages are all on our side.

Some little time ago an attempt was made to fulfil, in some measure, the prognostications of Professor Bayer, not exactly by cutting off the source of supply, but by endeavouring artificially to inflate, or at least control, the prices of some of the most important hydrocarbons; but experience taught, in this case as in all previous instances, that such attempts, however successful they may appear for a short time, end, as a rule, sooner or later, in heavy losses to the promoters and disaster to the participants. Trade does not admit of coercion; it must expand on natural bases. And there is only one sound way of stopping the supply to competitors of our raw materials, and that is by using them ourselves, and thus turning them to profitable account. Only thus can we secure to ourselves their full value, and benefit not only the industry more directly concerned, but also other collateral industries.

The productive capacity of the United Kingdom in benzene-toluene may be put down, without reckoning gas benzene, at nearly 3,000,000 gallons, of which quantity Germany takes about half—namely, 1,500,000 gallons, England half a million, the remainder going to France, Switzerland, and other countries, or constituting, as at present, floating or surplus stock. The home production of Germany and France does not exceed one million gallons, about equally divided between the two. Of the half-million gallons required by this country, only about half is converted into colouring matters, the other quarter of a million is exported as aniline-toluidine, pure aniline, or aniline salt. The entire consumption of benzene-toluene in Germany will be about 2,000,000 gallons per annum, of which only half a million is of home production. Of these two millions, about 1,600,000 gallons are converted into colouring matters, the remainder is turned into other tar derivatives; so that Germany requires four times the amount of benzene that we do, and she has to depend on ourselves for three-fourths of her supply; but when we consider the

* Ueber die Chemische Synthese. Festsrede bevor der Akademie der Wissenschaften zu München, am 25 Juli, 1878.

quantities of benzene-toluene actually converted into colouring matter, we find that Germany produces more than six times the amount of colours that this country does.

There are carbonised for lighting gas in this country at the present date about 12,000,000 tons of coal, yielding about 144,000,000 gallons of tar, or nearly 3,000,000 gallons of 50 per cent. benzene. The carbonising of coal for producing lighting gas increases per annum at the rate of 5 to 7½ per cent., while the consumption of benzene-toluene has remained about stationary for the last few years. This is partly owing to improvements in the manufacture of coal-tar colours, whereby larger yields of colouring matters were obtained; partly to a decreased demand for aniline and aniline salt by calico printers; partly to the fact that some benzene colours have been replaced by others. It is therefore apparent that there must be at present a larger supply than demand, and this accounts for the extraordinary low price of benzene (90 per cent. benzene being worth to-day only 1s. 8d. per gallon, against 14s. per gallon in 1883: *vide* "The Development and Present State of the Alizarin Industry," *Journ. Soc. Chem. Ind.* 1883).

On the other hand, the price of gas-tar, which was then about 45s. per ton, has come down to such a low price—namely, 7s. per ton—that some gas works have already begun to burn it in preference to selling it to the distillers. If the burning of tar should extend, its effect will be, no doubt, shortly perceptible in the rise of benzene: but we need not be afraid of this article ever reaching anything like the fancy price of 1883, unless new products are discovered in the manufacture of which it may largely enter. The existing carbonising plant for extracting benzene from gas will be the safeguard against any sudden inflation in the price of this article. Most of the carbonising works have now stopped operations, but a rise of 90 per cent. benzene—say, to 3s. 6d. per gallon—would soon see them again in full work.

Besides the benzene-toluene, Germany also imports from England from four to five thousand tons of anthracene, some naphthalene, xylene, etc., and in order to convert these hydrocarbons into colours and other tar derivatives, there are required annually upwards of 70,000 tons of concentrated sulphuric acid, twenty-five to thirty thousand tons of carbonate of soda (100 per cent.), which was nearly one-third of the total quantity of soda produced in Germany in 1883, and 40,000 tons of hydrochloric acid, beside large quantities of acetic acid, ammonia, nitrate of soda, nitrite of soda, salt, etc. The consumption in 1881 of the principal manufactured raw materials by one large German colour works alone was as follows:—

Sulphuric acid.....	20,000 tons
Soda (90 per cent.).....	7,000 "
Hydrochloric acid	13,000 "

These figures will give you some approximate idea of how other industries have been benefited by the expansion of the tar industry, and we need not be surprised at the rapid increase of the production of sulphuric acid in Germany, which has more than trebled within ten years, for while in 1875 only 102,546 tons of sulphuric acid were produced, this quantity increased in 1884 to 345,138 tons, and an increase of a similar nature has taken place in the production of soda in Germany, of which the following information will give us some conception. According to the late Mr. Weldon, Germany produced, in 1883, of Leblanc soda 56,500 tons, and of ammonia soda 44,000 tons, while the production for 1885 is estimated at 30,000 to 40,000 tons Leblanc soda, 90,000 to 100,000 tons ammonia soda.

IMPORTS AND EXPORTS INTO AND FROM GERMANY OF CAUSTIC SODA AND SODA CALCINED AND IN CRYSTALS, FROM JANUARY 1, 1882, TO END OF DECEMBER, 1885.

	IMPORTS.			
	1882	1883	1884	1885
Caustic soda.....	6,577 ..	5,231 ..	3,615 ..	3,261
Soda calcined & in crystals....	19,233 ..	14,802 ..	10,141 ..	8,126
	EXPORTS.			
	1882	1883	1884	1885
Caustic soda.....	413 ..	1,271 ..	1,612 ..	1,316
Soda calcined & in crystals....	6,299 ..	8,049 ..	15,721 ..	17,302

The above quantities are in tons.

From this we not only see that the production of Leblanc soda in Germany has been reduced, while that of ammonia soda has been much increased, but also that the imports of caustic soda and carbonate of soda have been steadily decreasing, notwithstanding an enlarged home consumption, while the exports, especially of carbonate, have considerably increased, and in 1885 amounted to more than twice the quantity of the imports; that is, they had nearly trebled within three years.

We will now inquire into the natural advantages possessed by this country for carrying on the manufacture of coal-tar derivatives, and compare them with those of our great rivals, and in doing so, it must be premised that in making calculations and quotations Manchester has been selected as the British centre and Frankfort-on-the-Maine as the German centre, and in each case the prices are for delivery at the purchaser's works within a radius of about five miles from the respective centres. The following are the principal primary raw materials required in the manufacture of coal-tar colours, whether for the half manufactured or the intermediate products:—

1, The products of gas-tar distillation—viz., benzene, toluene, carbolic acid, xylene, naphthalene, anthracene; 2, ammonia; 3, coal; 4, salt; 5, lime; 6, pyrites; 7, nitrate of soda; 8, iron.

Now all these are natural products, and are obtained at a considerably lower cost (more or less) in England than in Germany. Those numbered 1, 2, 3, 4, and 8 are important articles of export from this country, as everyone knows, while Nos. 6 and 7 can be got here, on account of cheaper freight, at less cost than in Germany. To these advantages must be added our more favourable geographical position, our far larger home consumption of colouring matters, and also greater cheapness of building materials. I shall at once be told that the Germans have a complete set-off against all these advantages, in the shape of cheaper labour, and that their chemists are more skilful than ours. As regards the question of the comparative cost of labour, I concede that there is a difference between the wages paid to the men employed in chemical works in the two countries, but it (again taking Frankfort and Manchester) does not at the present moment exceed 2s. per head weekly. This difference in wages can be compensated, and matters equalised by a larger outlay of capital in the construction of general plant and of comparatively larger buildings, both of which—i.e., steam-engines, boilers, pumps, tanks, etc., and building materials, as well as capital—are cheaper here than there, and therefore would not and do not ultimately increase the general expenses of the manufacturer. But apart from this, it does not require much foresight to predict that ere long—with the fiscal policy of the German Government, which is steadily causing an increase in the cost of living, and must necessarily bring about a corresponding rise in wages, while the opposite is taking place in this country—the question

of the actual cost of labour may change if anything to our advantage.

And as regards the assertion respecting the superior chemical skill of the Germans, this principally applies to the bringing out of new products, but not as much to the manufacture of articles the chemistry of which is well known, and here I must notice some changes which have taken place during the last few years. A number of foreign patents have run out by lapse of time, or from other causes. The chemical constitution of by far the largest number of colouring matters in use is well understood, and the technical difficulties connected with producing them in the most economical manner have been overcome, so that we may safely say, that at least 75 per cent. of our benzene-toluene and 90 per cent. of our anthracene exported might be converted into colours by British manufacturers without the aid from any chemist of special genius. In alluding to the manufacture of these coloured tar-derivatives, in connection with which superior knowledge on the part of the Germans can no longer be argued, it is very far from my intention to harbour the thought that we should be merely imitators of them. I only refer to the fact that for turning the greater portion of our raw material to more profitable account, no special chemical genius is required, and if even for this work our chemists are not yet sufficiently trained, we must secure the services of clever experimental chemists wherever we can find them, and this is no longer so difficult as formerly, as the number of specialists in this department of science who have received a high training in the universities of our competitors is constantly increasing, and at the present rate will, if anything, shortly exceed the demand.

It is true that the production of colouring matters in this country, excluding alizarin, has increased, still the increase, which may be due to the manufacture of some specialities, is not only not nearly what it might and should be, but disappears to some extent when we take into account the greatly increased production of coal-tar derivatives, clearly shown in the following figures:—

EXPORT FROM GERMANY OF COAL-TAR DYES, ANILINE OIL, AND SOME MANUFACTURED INTERMEDIATE PRODUCTS OF THE COAL-TAR INDUSTRY. THE QUANTITIES ARE GIVEN IN TONS.

1882	1883	1884	1885*
3,828	4,181	5,178	6,358

The question then arises—if it is a fact that the natural advantages are all on our side, and if it is also a fact that lower wages and superior chemical knowledge in the manufacture of a large number of coal-tar derivatives can no longer be pleaded—What are the reasons why far greater progress has not been made in this country in the manufacture of these products? or, Do *other obstacles* exist to prevent us from taking full advantage of the lower cost of the primary materials? I, for one, contend that there are no real difficulties in the way of getting hold of the larger share of this business, if only the true position of this industry, its constantly growing extension, its daily increasing importance, and its important bearing on the development of other industries, were fully understood and appreciated by the nation, and especially by its enterprising capitalists. The development of industrial enterprise in this country has for the last thirty years been practically confined to cotton, wool, iron, and coal, to the lamentable neglect of other industries of ap-

parently minor importance, while the chemical industries have been left in the hands of a few, who—often more by good luck than through intelligent and economical management or scientific attainments, but aided by the natural wealth of the country—have carried on the business more or less successfully, whilst outside of these few the general public was in profound ignorance of industrial chemistry. Hence the total want of enterprise in this direction on the part of the nation, owing to an insufficient appreciation of the importance of the chemical industries; the consequent apathy, and the absence of any intimate connection or intercourse between our scientific men and our manufacturers; and, finally, the very great facility with which fortunes had been made in years gone by in what were then considered staple industries. All these combined were the primary and principal causes which fully account for our present position in regard not alone to the coal-tar industry, but to most other branches of chemical industry.

The position of Germany was quite different; in her case none of these adverse circumstances existed. There was no superabundance of accumulated wealth, nor the same easy opportunities of acquiring it, the great natural advantages did not exist, and a knowledge of chemistry was more diffused among the people, consequently new branches of chemical industry were eagerly sought for and energetically taken up by enterprising capitalists, supported by the people and the scientific men.

It is obvious that the unfortunate circumstances which have hitherto influenced and restricted our national industrial enterprise in certain directions must have exercised injurious effects not only on the development of the chemical industries, but also on that of other industries. This country possesses eminent engineers, whose names have a world-wide reputation, but we do not possess what may be termed chemical engineers, or at any rate they are very few indeed in number. For suggesting or discovering new chemical products or combinations we require chemists of talent, but for carrying out their suggestions to a successful issue, highly-trained chemists and chemical engineers capable of devising the necessary apparatus are also needed, and often the practical value of these suggestions depends largely on the skill of the chemical engineer. I apprehend that the expression, chemical engineering, by which I understand the conversion of laboratory processes into industrial ones, is by very few appreciated to the extent which it deserves, and the devising and constructing of plant and appliances in chemical and similar works is as a rule left either to engineers who are not conversant with the chemistry of the processes for which the apparatus is destined, or to the works mechanic, who simply proceeds by rule of thumb, or else it falls to an inexperienced chemist who understands nothing of engineering. The following illustrations may be useful in bringing before the minds of those who are not fully acquainted with this subject, the importance of chemical engineering. Many of you will have heard of the Mather-Thompson bleaching process; now there is nothing new in the chemistry of this process—indeed in 1855 Paul Firmin-Didot patented in this country a process for bleaching textile fabrics, etc., which, as far as the use of carbonic acid to decompose the bleaching lime is concerned, is substantially identical with the Mather-Thompson process. Now I believe neither of the two in their original conception were or ever could have been put into practice: it was owing entirely to the engineering skill of Mr. Mather, M.P., assisted by two technical chemists, that it has entered into a new phase and now promises to revolutionise the bleaching trade as

* This great increase in the export is principally due to the very much extended demand for the naphthalene derivatives.

hitherto conducted; the chemical part was merely subservient. The history of the ammonia-soda process offers quite as forcible an example of the importance of chemical engineering. In this case the merely chemical process was known and understood, nearly fifty years ago, and many years ago it had really been practically tried by some of our largest alkali makers, and abandoned as too costly even when alkali commanded three times the price that it does to-day; it was reserved for the ingenuity of the chemical engineer, Ernest Solvay, in 1866, to turn this process into a practical industrial one.

Now, gentlemen, in consequence of the development of the coal-tar colour industry in Germany, there have sprung up, *pari passu*, not only huge colour works, but also engineering and machine works, the speciality of which is the supply of all the necessary apparatus and plant required by this industry, and also the devising such apparatus for new processes, and they are thoroughly proficient in this class of work. Besides, in the immense workshops of the large German coal-tar colour manufacturing companies, a staff of scientific chemical engineers has been trained, to whom it is as easy to devise plant for practically carrying out the most complicated and novel chemical processes, as it is for any of our engineers to construct a bridge or carry out any other routine work; and it is a fact that there are chemical engineering works on the Continent, which either are the sole source for the supply of certain special plant required in the tar industry, or deliver apparatus of a better and at the same time cheaper construction than we can obtain here. It might be desirable to attach to our chemical laboratories, as a tentative, an engineering laboratory, where all sorts of appliances could be devised and constructed, and the conversion of laboratory processes into practical industrial ones could be effected.

There are some people who are opposed to the teaching of technical chemistry in its present form, and who contend that the only proper school for acquiring the knowledge of technology, or technical chemistry, is to be found in practice. In its present mismanaged form they may be right, when professors are placed at the head of our largest technical colleges who have never in their life done an hour's practical work in any manufactory or works, and whose only qualification appears to be *purely* scientific attainments. Now the occupier of a chair of chemical technology, or any teacher of that department of scientific knowledge, is, in my opinion, entirely out of place and simply useless as far as the teaching of this science is concerned, unless he possesses, in addition to his scientific attainments, practical knowledge acquired in some works, and further, unless he helps himself by constant intercourse with manufacturers, instead of keeping, as most of our professors do, carefully aloof from them. Industry and science must work hand in hand, for each can learn from and benefit the other. Chemists intended for technical work who are wanting in previous training in technology, of which chemical engineering is really a part, find on entering the manufacturer's works, that their time is so much taken up with a mass of mechanical details, with which they would, under other and better arrangements, have been fairly acquainted, that by the time they have mastered these, their previous knowledge of chemistry has suffered. It must also be palpable that a chemist intended for industrial work, who along with a sound training in chemistry has also acquired a fair knowledge of chemical engineering, must be better fitted for his work than the man who is only practically acquainted with the handling of china basins, phials, and a Liebig's condenser.

In the year 1883 I had the honour of delivering

before our Section at this College two lectures on the development and actual position of the alizarin industry, and I then invited our manufacturers to establish or at least extend this industry in this country, and among other things I pointed out the natural advantages which we possessed to make its establishment a commercial success. Since then the English production of alizarin has considerably increased, for whereas at that time we scarcely supplied one-tenth of the home market requirements, to-day one third or nearly so of the alizarin used by our dyers and printers is of English origin. Some of you will perhaps remember that I also stated that 20 per cent. alizarin, which was then worth 2s. 6d. per lb., would shortly come down to 1s. 3d. I well recollect that by many this prediction was received with incredulity, and by others, more interested in this matter, even ridiculed. Well, gentlemen, not many months afterwards the price was reduced to 1s. 3d. per lb., while the average price of this article to-day is 9d. per lb. It is true that some of the materials used in its manufacture are at present lower than formerly, but 9d. per lb. does not just now leave the producer a legitimate profit. It would take too long a time to go fully into the question of how this enormous fall in price was brought about, but I will briefly mention the principal cause, in order that we may all clearly understand the position of this industry at the present moment. It will be in the recollection of some of you, that before the patent had run out in 1883, there existed a combination of the alizarin makers in Germany which had resulted in running the price up to such an extent that between them they cleared in one year about one million sterling. This combination—after issuing the famous circular threatening to stop the supply to British consumers unless they agreed to extend their contracts at this fabulous price for twelve months beyond the time of the expiration of the patent—continued to subsist, and might still, for all we know, have been in existence if the establishment of the alizarin manufacture in this country had not put an end to it. It is the development of the alizarin industry in this country that our printers and dyers have to thank for a cheap and unlimited supply of alizarin. It was the development of this new industry which the combination attempted to crush in the germ, and this fact accounts for the present unremunerative price; and this endeavour on the part of some powerful Continental colour-manufacturing companies to crush British competition by hook or by crook is not the only instance of such action. Now, some may say that with all this reduction in the price of the article, our dyers and printers are not one iota better off to-day than they were when it was much higher. I would just invite such persons to consider what their position would have been if the combination had not been broken up. Turkey red dyers, printers, and merchants, each and all of them would have been at its mercy; and if it had so pleased the German combination, it might even have altogether stopped our export trade in Turkey-red or alizarin dyed goods by exacting prohibitive prices from our consumers, and thus diverted this important branch of the dyeing and printing trade also into the hands of German manufacturers and merchants. Well, gentlemen, this combination has fortunately ceased to exist. There is at present an over-production of the article; its price will therefore continue for a while at a low point, but it will scarcely go lower, for already one of the largest German works has had to admit having suffered heavy losses from its manufacture, and others are not in a more favourable position. We may therefore safely assume that whatever the intention may

be on the Continent in reference to this industry, those manufacturers will not continue for any length of time to produce the article at a loss. Now, I would advise our manufacturers of alizarin, who, in consequence of the manoeuvres of their foreign competitors, are not at the present date realising legitimate profits, to stand firm, to use their best efforts in further improving their plant, thus saving manual labour and economising fuel, and to trust to the exertions of their countrymen to do away with the present anomalous position of the alkali and acid markets, and then they will again realise the profits which are due to them for their pluck and energy, and be enabled to bid defiance to any foreign competition whatever. Great changes have taken place

The export of alkali from Great Britain does not give the true position of the Leblanc soda manufacture. In reviewing the following table, the export has been about stationary for the last three years, but it must not be overlooked that it includes ammonia soda, and that there is annually a largely increasing consumption of soda, which the capacity of the existing ammonia soda works cannot yet supply. On the other hand, it must also be taken into account that the erection of new ammonia soda works and the enlargement of the existing ones, is rapidly proceeding on the Continent, and to this fact is no doubt already due the decreased export of alkali from this country to Russia, Germany, Holland, Belgium, and France.

EXPORT OF ALKALI

	1883.	1884.	1885.	
	Tons.	Tons.	Tons.	Cwts.
To Russia	25,005	24,215	23,036	6
Germany (Austria and Hungary included) ...	36,095	28,230	23,702	11

Total	347,350	328,120	333,080	16

since 1883. We no longer have to record any advantage in the prices of soda or sulphuric acid. That which seemed most improbable has actually happened, and, startling as the assertion may seem to you, the scale has been turned against us. The German manufacturer can now purchase sulphuric acid very much cheaper than we can; caustic soda is no longer of the same importance as formerly, as many of the large German consumers find it to their advantage to causticise for themselves the cheap ammonia soda; and as for ammonia soda, the Germans, not satisfied with their triumph in having made themselves independent of this country, are actually exporting soda to Great Britain. If they cannot as yet show an advantage in price delivered in Manchester, because of the heavy carriage, they are already doing a fair business in this article in the London market and export trade. They are offering ammonia soda (98 per cent.) in London at £5 10s. per ton, while the price f.o.b. at Antwerp is £4 17s. 6d.

What is becoming of the industries of Great Britain? For more than half a century England ruled all the markets of the world for soda, her chief stronghold in the staple chemical industries is threatened, already her home market is invaded by the foreign producer. An important article of export is not alone in danger of being ultimately lost to us, but our strongest competitors in foreign countries can already purchase this all-important article more than 15 per cent. cheaper than we can in this country, and thus materially lessen the cost of production of a number of other articles. But this state of things is not confined to ammonia soda; 96 per cent. caustic soda, made most likely from the ammonia soda, is already competing in the Manchester market with our own make, and is even preferred to ours.

For the information of those who are not chemists, I may say that of the already mentioned primary raw materials, those required principally for the manufacture of soda (by Leblanc's or Solvay's process), and of sulphuric acid, are—salt, pyrites, ammonia, lime, coal, and nitrate of soda. All these primary raw materials, as already mentioned, are cheaper in this country than in Germany. Still the German consumers can purchase ammonia soda (98 per cent.) *delivered at their works* (again taking Manchester and Frankfort as the respective centres) at £4 7s. 6d. per ton, whilst the Manchester consumer has to pay £5 5s.—that is, about 15 per cent. more than his foreign competitor. This is a considerable difference and a great disadvantage to the British consumer, but he is in a still worse position as regards the price of sulphuric acid, for the price of this article d.o.v. 66° B \acute{e} . or about 170° Tw., delivered in carboys free at the consumer's works, at similar distances from the original manufactory, is at Frankfort £3 per ton, but at Manchester £3 17s. 6d. per ton. The prices delivered in tanks free at the manufacturer's works are of course in both instances considerably lower.

I have now disposed of the wages question, and of superior chemical skill, also the cost of building materials, but I anticipate the remark, that is all very well, but the Germans are simply going to ruin with such prices as these. A remark like this would, however, be out of place, as both these quotations—viz., for the soda and the sulphuric acid—are regulated by a convention, and until a few months ago the selling price of sulphuric acid was actually 10 per cent. lower than at present, and it is obvious that if this price did not allow a sufficient margin to the producer, the convention would not have been content with an advance of 10 per cent.

As to the high price of ammonia soda,—which is that form of soda which most especially interests the coal-tar manufacturer,—the explanation is a very simple one, while the causes which led to it, as well as to the extraordinarily high price of sulphuric acid, must be looked for in a similar state of things to that which placed us in such a singular position with regard to the coal-tar industry.

The manufacture of ammonia soda was commenced in this country in 1873, by Messrs. Brunner, Mond & Co., who had a license to use M. Solvay's patents, of which the principal ones expired some time ago. M. Solvay's process soon established its superiority over the only one then in use, known as Leblanc's, with the result that many works in which the latter was carried on had to be closed, and most of those which yet continue to use it are only struggling for existence. The hope was cherished by the Leblanc soda makers that an increased export and an advanced price for bleaching powder, which indirectly is a by-product of this process, would compensate for the falling off in the profits on the principal article of manufacture—viz., soda,—but both these assumptions do not appear to have been realised, as the following table will show:—

EXPORT OF BLEACHING POWDER.

	Quantities in Tons.			Value.		
1883	80,030	£480,278
1884	80,530	661,406
1885	75,407	507,345
				£ s. d.	£ s. d.	
The market value fluctuated in						
1883 from	4	7	6	to	9	10 0
Ditto 1884	9	10	0	„	7	10 0
Ditto 1885	6	10	0	„	6	5 0
The price for bleaching powder						
to-day is	5	12	6			

The dangers which now more than ever menace the existence of the Leblanc soda manufacture are, the possibility of utilising the by-product obtained in the ammonia-soda process in the making of chlorine; the great probability of a further reduction in the price of ammonia soda, which is already comparatively lower than the Leblanc soda; and last, not least, the new competition which has presented itself on the part of Germany. In a word, the Leblanc soda manufacturer seems placed in a dilemma in whatever way he regards his position. In my opinion there is only one way out of it, and that is that the less favourably situated manufacturers reduce the nominal book value of their present works, take advantage of cheap capital, cheap salt, cheap ammonia, and cheap coal, and erect ammonia-soda works on the best and most approved principles. There are a few manufacturers in this country who make ammonia soda, but their output is as yet quite insignificant, and unfortunately, as I think, they have adopted a system differing from that of which the efficiency had been proved. We are certainly yet depending for the supply of bleaching powder on the Leblanc soda process, but then its consumption is limited, and does not stand in any proportion to the productive capacity of our Leblanc soda works, which are now working on a restriction of about 40 per cent. on their output of bleach.

I am, however, not called upon to act the part of adviser to our alkali manufacturers, but it lies in the province of this paper to call attention to the effects of the want of enterprise in the chemical industries, and these are serious enough. An important portion of our staple industry is practically threatened with ruin, other industries are heavily

handicapped, while the development and progress of new industries are seriously impeded.

Only consider the disadvantage at which our bleachers, dyers, scourers, soap makers, woollen manufacturers, paper makers, and coal-tar colour manufacturers are placed with regard to their German competitors, who can purchase these absolute necessities at so much lower prices than we can. That the import and export trade in such an important article as soap must be affected by the higher prices of alkali is certain; and we find that while the export of soap was in 1884, 23,872 tons, it decreased in 1885 to 20,113 tons.

I am fully aware of the fact that many are still preferring Leblanc soda ash to ammonia soda, but this is a prejudice, and at the price at which the Germans can purchase the ammonia soda it will pay them far better to use the latter, and in the purely exceptional cases in which a caustic ash is required, it will be much cheaper to add to the ammonia soda a slight percentage of caustic soda, or to causticise a portion of the former.

We will now pass on to the consideration of the high price of sulphuric acid, and here the explanation is far more puzzling to arrive at. There exists no monopoly; on the contrary, I should think that at this moment plant is standing idle which is capable of producing 100,000 tons annually of sulphuric acid. Our vitriol makers (I am referring to those who only make sulphuric acid *per se*, and not to those who produce it for decomposing salt) contend that if they had to sell concentrated sulphuric acid at anything like the German price, they could not continue to carry on their business, and this in face of cheaper raw materials all round. The logical inference from this would be, inasmuch as the labour question is here also only of secondary importance, that the German maker must either be in possession of a superior process or better plant, or that by more economical management, by better organisation and discipline he obtains a larger yield, or perhaps all these suppositions are correct. It is, at all events, surprising that the northern alkali makers, with thousands of pounds' worth of vitriol plant lying idle, do not send some of their surplus stock into the Manchester market; one would think that the smallest profit would pay better than allowing the plant to deteriorate. The vitriol could be delivered in iron tanks, as is done elsewhere, and I do not doubt that there is a fair market for it at a reasonable price in this city.

It may be of value to some of our vitriol makers to know that the Griesheim Chemical Works, near Frankfurt-on-the-Maine, have turned into an industrial process Marignac's and Lunge's experiments, which were directed towards obtaining, by cooling to a low degree and crystallising, more concentrated sulphuric acid and monohydrate from weaker sulphuric acid. This new process has now been working for some time, and it is said to be very satisfactory both as regards cost and quality.* I was in hopes of being able to give you this evening further details; the necessary information, however, did not reach me in time.

I have so far attempted to bring before you the special advantages which we possess for the development of the coal-tar industry. I have endeavoured to indicate the causes which have led to the present position of this industry in this country, and also the injurious effects which its neglect has inflicted on other industries, and with your indulgence I will now briefly refer to our chances of removing some of the

* English Patent, No. 96, January 8, 1883; German Patent, No. 21,102; and also see Hasenclever (*Chemische Industrie*, No. 3, March, 1884, p. 83).

anomalies to which I have referred. The question of improved chemical engineering is the least important, at any rate for the present, as the extra cost of procuring *special* plant from Germany, disheartening as such a course may be, is fully balanced by the greater cheapness of *general* plant in this country.

The difficulty in the case of the ammonia soda is at present greater; here the only likely chances are either that our enterprising capitalists, or our present Leblanc soda makers, will bestir themselves, or if they cannot be moved, we must trust to the Germans; the fact alone that they have started to compete in ammonia soda may induce practically the only British maker of this article to reduce his present price. But there is still another feature in the case which may favour a reduction in the price of this article. The quantity manufactured in Germany already exceeds the demand, and it may pay the makers there to export it at a still lower price, or even at actual cost, in order to pay expenses, the profit being of course made on the sales in their own country, where they now have the full swing of the market.

The fast-developing ammonia soda manufacture in Belgium must also be taken into account, so that there is at any rate a great probability that the present high price cannot long be maintained.

As to sulphuric acid, if it really is a fact that our makers cannot sell this article with a margin of profit at the same price as their German competitors, they must either remodel their works or alter their process, and if they cannot be induced to do this, then let a few larger consumers of sulphuric acid combine and put up their own vitriol chambers in a convenient locality, adopting all the improvements, whatever they may be, of our rivals.

Now, gentlemen, these suggestions for the immediate removal of some of the obstacles which impede the progress of the coal-tar and other industries must not be understood as implying that, this being accomplished, we shall at once regain our former position in the markets of the world. What is wanted above all is to arouse our dormant enterprise, to wake up to the fact that our natural wealth, by itself, no longer affords us an easy opportunity of acquiring fortunes as in days gone by, and that the ever-increasing activity and energy of our rivals has actually deprived us of industries, for the carrying out of which we possess every natural advantage. Let every Englishman fully appreciate the fact, that the constantly growing importance and extension of the chemical industries, and the bringing out of new products, not only create new collateral industries, but also materially influence the development of those already existing.

After all, if the importance of any industry is once thoroughly understood and appreciated by the nation, and that nation possesses everything that is favourable to its development, there will always be men coming forward of sufficient talent to surmount any other difficulty, and once such an industry is fully established and commences to expand, all the other necessary requirements will present themselves.

DISCUSSION.

The CHAIRMAN, after alluding to the great benefit which papers like that which they had just heard, conferred, not only on Lancashire, but on the community at large, likened the author to one of the prophets of old, standing outside the walls of the city, and calling upon the people to arouse themselves from their lethargy. He had shown that, notwithstanding this country possessed raw materials, men, and money, yet it was losing valuable industries, and that even in its own special department of engineering it lacked adaptability and energy. They must

seek out the causes of this decay, and strive to regain their old supremacy.

Mr. WATSON SMITH called to mind the memorable words of the late Walter Weldon, F.R.S., in his address as retiring president, at Newcastle-on-Tyne, 9th July, 1884:—"It is not willingly that I have announced a new—and much more serious than any previous—menace to an industry already sorely tried. How much I should have preferred to have been able to prophesy smooth things with respect to the Leblanc process, no words can say. Facts, however, must be looked in the face. Nothing can be less wholesome than the atmosphere of a fool's paradise. And the watch-dog at the gate, who gives timely notice of the approach of unwelcome visitors, at least renders such service as is in his power." Two years had fled since these words were uttered, and now the voice of warning was again heard. Mr. Levinstein had, however, sounded an alarm extending not alone to the soda industry, but to other chemical industries; and whilst administering warning in no uncertain tones, he had striven to the utmost to apply wholesome counsel and advice. That Mr. Weldon was a prophet indeed, the clear statistics and logical sentences of Mr. Levinstein did testify, and though upon him the mantle of Mr. Weldon had fallen, his prophesying embraced a wider prospect, and the sound of it went forth in more ominous tones. A panacea for the evils in prospect was to be found in improved education, and naturally, what Mr. Levinstein had said with regard to teaching, was of principal interest to the speaker. He begged to endorse what had been stated as to the importance of teaching the scientific principles involved in the special construction of apparatus and plant for chemical processes on the large scale. It was part of the recognised course for a student of science to learn in those scientific workshops—the chemical and physical laboratories, the construction and use of apparatus. It was a scientific process, and one demanding even more judgment, experience and skill, to pass efficiently from the scientific laboratories to the manufacturing laboratories or workshops, and to convert apparatus for dealing with grains and grammes into that dealing with tons, and further—*dealing in the most economical manner*. Of all subjects connected with the branch of Chemical Technology, the inculcating and teaching of the principles of the economies of manufacturing operations, can least adequately be done by those teachers who have had no living and active experience in the manufacturing workshops. It was also hard to conceive any capacity for setting forth the principles of construction as adapted to apparatus for chemical processes on the large scale, except in cases where practical experience had been gained—and the more painfully, he was going to say, the better. He could well remember the day when, in the majority of cases, the free, unshackled exercise of chemical science by the chemist, was zealously excluded from the alkali and sulphuric acid works of this country, chiefly by those placed in authority as managers, to whom the authority of the chemist was as nothing, who practically trampled on his advice and subverted his doctrines, whose watchword as well as thunderbolt was—"Give me my ounce of practice and you can keep your ton of theory." Thus, and as a natural consequence, he well remembered that a man investing, *e.g.*, in a caustic soda plant, was more frequently than not almost ruined with batches of discoloured caustic ere he sailed into port from the wild ocean of "Rule of Thumb," with the newly-discovered "knack," of making it white. Relying too much on rich natural resources, as Mr. Levinstein had so well pointed out, the English chemical manufacturer had, in most cases, gone too much on the "knack"

principle, or rather—want of principle. There are many large scale chemical processes that must be carried on night and day, and from some considerable experience of the class of men put in charge of certain of these processes—such, *e.g.*, as the vitriol chamber process—the speaker was not at all sure that considerable annual losses were not suffered through inattention in the night and small hours of the morning. Now in a country like Germany, where every man passes under military discipline, where the duty of the sentinel and the watchman must be learnt at the risk of the well-known alternative—the ounce of cold lead, it may be readily conceived that the efficiency of the “night-shifts” will be much superior to those in this country, and so for the most part nocturnal losses *there* will not occur to nearly so great an extent as *here*. He was disposed to think that military discipline was an important factor in the efficient organisation of German works, factories, etc. With regard to Mr. Levinstein's remarks on the importance of the professors of science in our seats of learning keeping in touch with the manufacturers, the speaker pointed to numerous examples showing how this had been, and is generally the case, in Germany; and referring to older times, pointed to the fact that the well-known black-ash vat was the outcome of the consultation of the German alkali maker, Gmelin, then fresh to the difficulties of lixiviating Leblanc black ash, with the great physicist, Buff or Giessen. He surmised that there was benefit derived in the outcome of that consultation on both sides, for Gmelin got an efficient piece of apparatus, and Buff learnt something of the nature of the crude soda and the difficulties of handling it on the large scale. Great things had also sprung from similar consultations in this country, and the taking counsel together of James Young with Dr. Lyon Playfair and Professor Graham, led to the evolution of the important paraffin industry.

Mr. GRIMSHAW, referring to the competition between English and German chemists, said that it was not altogether a fair stand-up fight between them, but was complicated by the question of Free Trade and Protection. No doubt German protection had fostered the coal-tar industry there to such a point that it was on the verge of over-production. If, heretofore, in England they had failed to compete with foreign countries in their own markets, it might fairly be ascribed to a system of hostile tariffs, and not to technological skill. Now was the time for them to make sure at least of the English trade, in which, if they were beaten, they had but themselves to blame. If they strained every nerve now, the tide might turn in their favour, for foreign nations could not go on for ever selling caustic, alkali, sugar, and such like to the English consumer at or below cost price without disaster to their own country, though individuals might profit through a protected home trade. The English chemical manufacturer ought to be able to defy foreign competition at home, while pressing it hard in its own markets wherever the duties were not absolutely prohibitive. This seemed to be the case with the aniline industry, and it remained, therefore, for the Society of Chemical Industry and the colleges of science to point out the proper method of procedure.

Dr. CONEX thought that the author had hit the right nail on the head when he urged the importance of teaching chemical engineering as well as laboratory work; but he also thought that it was cheap education, both elementary and advanced, by reason of schools, universities and polytechnic institutions receiving state aid, which contributed still more largely to the success of German chemical industries.

The author specially ascribed this success to the cultivation of chemical engineering in Germany, but for himself he would divide the honour between the chemical engineer and the scientific chemist. Pure chemistry had become so extended a science that it was necessary nowadays to devote one's whole time to master it thoroughly; hence in this, as in technical chemistry, specialists were required. It was only when these worked side by side that real progress was achieved. Witness the number of important chemical products discovered by men who never were in chemical works at all. He thoroughly agreed with Professor Meldola's views, expressed in a recent paper, in which he urged the importance of the cultivation of pure science. By cheapening education, inducement would be offered to students to remain longer in laboratories, to pass from learners simply to become experimentalists.

Mr. THOMSON said that among the reasons why English manufacturers so often failed to compete in the open market with Germans was that important question of education. In Germany, science formed part of a man's ordinary education, while in England more importance was attached to the study of dead languages than of the laws which governed the world of to-day. This state of things was most unsatisfactory; but, sad to relate, certain so-called learned Englishmen were as proud of their scientific ignorance as they were of their classical knowledge. It was maintained by many that a classical education enabled a man to understand his own tongue better, besides affording a species of gymnastic training to the mind; but surely a study of modern languages would give an equally good mental training, besides being of distinct use to him in the work of the world. But above all, who would be bold enough to deny that a training in mathematics and physical science afforded a better training to the mind than all the classics put together, and such a training as would enable Englishmen to cope with the world in arts and manufactures, and hence in the acquirement of wealth? There was no want of intellect and enterprise in the nation, but it was fashionable to direct this intellect into useless channels, and this was why the Germans excelled us. Masters were selected for boys too often solely for their classical attainments, with the grievous result that their pupils grew up crammed with words, and totally ignorant of the subtle and beautiful laws of nature. Such as the boys were, so would be the men, and thus we had few men in this country capable of turning the forces of nature to account, and utilising them for the benefit of themselves and their country. Would that there were more men like Mr. Levinstein, who would boldly define the causes which were tending to deprive England of her supremacy as a manufacturing and wealthy nation, and point out the remedies essential to the cure of the evil.

Dr. BAILEY said that there was an undoubted feeling that English universities and colleges were not doing all that they might do in this matter, and there were many who looked upon the elevation of the Owens College to university rank with a feeling akin to distrust. This was a mistake, for admitting even that the adoption of a university regime brought conservative tendencies in train, yet it must not be forgotten that Owens College still remained, and was doing for the technical student more than she had ever done in the past. This Society, also, with its powerful organisation, was quite the creation of recent years, and was fully competent to indicate in what direction further extension of teaching was desirable. More science and better teaching were undoubtedly required for middle-class schools, and, moreover, science must be taken up much earlier in the school

career, and until this lack of early instruction in science was remedied no considerable improvement could be expected in our colleges.

Mr. LEVINSTEIN (in reply) thoroughly agreed with Mr. Watson Smith that the three years' compulsory service in the German army, with all its disadvantages, had its salutary effect on the character of the men, as it taught them general discipline, subordination, punctuality, etc., and in no other industry were these qualities more needed by the working men than in the chemical industries. Mr. Grimshaw's remarks in reference to the fiscal policy of England and Germany, did not apply, in his (Mr. Levinstein's) opinion, to the observations in his paper, as the duty on soda did not in any way explain the fact that this article was sold at a lower value in Germany than in this country. As regarded the coal-tar colours, Mr. Grimshaw was labouring under a delusion, as there were no duties on these colours. He would recommend Dr. Cohen to carefully peruse his paper when it appeared in the Journal, and he would find there no such singular statement as that the success of Germany in the coal-tar industry or any other chemical industry was due to chemical engineering. He was fully alive to the fact that for striking out new lines chemical specialists of talent were required, and for the carrying out of known chemical processes, chemists of sound scientific training and chemical engineers were wanted. As pointed out in his paper, our present scarcity of chemical engineers was only the natural consequence of our neglect of the coal-tar industry, and with its development all other requirements would spring up *pari passu*. He quite agreed with Dr. Cohen as to the general excellence of Professor Meldola's last paper on the development of the coal-tar industry, of which he had read a few passages, but he could not endorse the Professor's opinions "that it is now a question of chemical and not of economical science that is pressing for consideration," nor that "the English manufacturers should look after the science and leave the technique to take care of itself."

After his reply, Mr. Levinstein referred to his last paper on Saccharine (*Journal of the Society of Chemical Industry*, 1886, 75-76), in which he pointed out the likelihood of this substance entering the market as a commercial product, and, as he had received a large number of letters on this subject, he thought that it might be of interest to many to hear that a company has now been formed in Germany for the purpose of erecting works for its manufacture. Suitable land has already been chosen near Magdeburg, and it is expected that saccharine will be offered to the trade in the beginning of next year.

The Seventh Meeting of the Session was held in the Rooms, 207, Bath Street, on Tuesday, 4th May 1886.

MR. J. NEILSON CUTHBERTSON IN THE CHAIR.

NOTES ON VISCOSITY AND OTHER TESTS FOR OILS.

BY J. J. COLEMAN, F.I.C., F.C.S.

THE author regretted that he was not able to be present at the last meeting, and to join in the discussion upon the paper of Professor Mills and that of Mr. Ellis, but as he had perused them in print, and also the excellent paper read by Mr. Boverton Redwood at the London Section, perhaps the remarks he had to make now would be more carefully considered than otherwise they would have been. The author used a pipette about seventeen years ago for determining the viscosity of oils whilst making some experiments with spindle oil at the celebrated carpet works of John Crossley & Sons, Limited, Halifax.

At that date none of our great oil merchants or dealers appeared to use any instrument for the determination of viscosities. The author, however, introduced regular viscosity determinations at the works of Young's Oil Company about fifteen years ago, and the instrument used for many years is described in a paper read to the Institute of Engineers and Shipbuilders of Scotland, 24th November, 1872.

At the same meeting a discussion arose upon oil-testing machines, and remarks which coincide very much with those of Mr. Redwood were then made, and which was to the effect that makers of mechanical oil-testing machines generally assume too much. Such machines give an idea of the viscosity of the oil (McNaught's, for instance), but it is a total error to assume that the oil which gives the least friction with a small testing machine will also work with little friction on a piece of heavy machinery, or *vice versa*. As Mr. Redwood concisely puts it, "the lubricant must have such viscosity as to keep the moving surfaces apart at the maximum pressure," to which I will add, any increase of viscosity will augment the friction, and any decrease will also augment friction, the former resulting from friction amongst the particles of the lubricant, the latter from the metallic surfaces approximating too closely. Hence it follows that the suitability of an oil for a particular class of machinery, can only be determined by trying it upon journals or bearings of the same size and subject to the same pressures as that of the machine itself.

Once determine this point by experiment, and it will be found that a particular viscosity is suitable for the work, and such instruments as the pipette, those of Mr. Redwood, or even the old but excellent apparatus of McNaught, can be used to adjust fresh supplies exactly to the viscosity of the sample known to succeed on the machinery.

It occurs to the author that a very simple means of taking viscosities would be the inversion of the pipette method. Instead of making the oil to run out of the pipette, why not allow the oil to run into it, noting the time required for the oil to ascend from a mark on the lower stem to a mark upon the upper one? This method would involve closing the top of the pipette with a temporary stopper (say the finger), and thrusting the empty pipette down to a certain point below the surface of the oil. Moreover, it is a

method that would simplify adjustments of temperature, a troublesome operation in all forms of apparatus.

The oil might be put into a glass tube like a very large test tube, *a-b*, say nine inches by one and a half inches, fitted with a cork through which the stem of a thermometer dipping into the oil is made to project. By dipping this tube into cold water on a warm day, or warming it slightly with a spirit lamp on a cold day, and moving it alternately from a vertical to a horizontal position so as to avoid air bubbles, the contained oil could quickly be brought

to the point *d*. A special form of pipette, with the bottom stem of uniform bore, should be adopted. As the temperature of the oil box of a locomotive engine is generally not less than 120°, and as most lubricants should be compared with melted tallow, this temperature is not too high for general use.

Instruments constructed on the pipette principle, such as those of Mr. Redwood or Mr. Allen, might be called "Oil Transpirometers"—the flow of liquid through tubes being described by Graham as "liquid transpiration." This would distinguish them from such instruments as those designed by our townsman,

SKETCH TO ILLUSTRATE TERM VISCOSITY AS USED BY MR. COLEMAN.

I, is the cylinder containing the oil. B, the chamber filled with steam, and surrounded by the outer cylinder K (both of glass); the steam chamber is closed, top and bottom, by india-rubber plugs, C, C, C, C. The steam being generated in the flask E, passes by the pipe into the chamber B, until the oil reaches 120°; the stopcock is then opened, and the time taken for the oil to run out registered. The apparatus is made of such size as to allow rape-oil to run through in 8 minutes exactly.

to the desired temperature. The cork and the thermometer being then removed, and the pipette substi-

Mr. James Napier. Mr. Napier has been kind enough to send one partly finished from the workshops of White, the optician. It reminds one very much of the contrivances of Dr. Joule for measuring the mechanical equivalent of heat—viz., a horizontal paddle, the vertical shaft of which is connected by a string passing over a pulley to a falling weight—the speed of the fall of the weight measuring the resistance of the medium in which the paddle works. It is obvious that if the specific gravity of the oils being compared be identical, then the true viscosity will be indicated by the falling weight. If, on the other hand, the specific gravity of the oils vary, then the resistance will be partly owing to viscosity and partly to the weights of oil being displaced by the paddles being proportional to the specific gravity. It will be seen, however, from the annexed sketch, that Mr. Napier's improved arrangement is not a paddle which sets up motions in the oil to any very serious extent, so that it becomes a fair measure of viscosity; further, the author can see no force in the objection of Mr. Redwood that the friction of bearings will be a source of error—as if sufficiently accurate for Dr. Joule's

tuted, the viscosity of the oil could be ascertained by the length of time required to ascend from the point

experiments, it is surely so for a commercial oil test.*

In regard to the oil which has to be used as a standard, probably the oil known to apothecaries as oil of sweet almonds, which is almost pure oleme, is of all oils the most constant in quality. Rape oil, however, is certainly the most extensively used and important of vegetable oils, and will perhaps maintain a preference as a standard. It has not, how-

ever, such a constant specific gravity and viscosity as some people imagine. The author has not had any recent experience in the matter, but between the years 1870 and 1880 sampled a large number of fifteen parcels, amounting in all to over 1000 tons. About a third of it came from Stettin, in Germany, one-third from France and Belgium, and one-third

was English crushed. The specific gravity of the German oil was invariably 915 $\frac{1}{2}$, that of the French and Belgian 912, and that of the British 915 to 916 $\frac{1}{2}$, corrected for temperature at 60° F. Possibly the French and Belgian oils would be called colza by some people, but the brokers always quoted it as rape oil, and the price coincided with Stettin rape oil of same date. Mustard and other seeds seem to find their way into the rape seed used by English crushers, which no doubt affects the specific gravity of the oil. Possibly the equal admixture of German, French, and British oils would give a fair standard—otherwise a rape oil standard may vary as seven to eight, or more.

The author is glad to see that Mr. Ellis calls attention to Mauméné's test for oils. In his paper read to the Philosophical Society of Glasgow, 1874, this test was pointed out as one of the few really useful tests suggested by chemists. (See *Chemical News*, vol. xxix. Nos. 748–751.)

NOTE ON MAUMENÉ'S TEST FOR OILS.

BY CHARLES J. ELLIS, F.C.S.

SINCE reading my paper on "Mauméné's Test for Oils" before this Section on 2nd March, I have received the following letter from M. Mauméné:—

M. ELLIS, F.C.S.

MONSIEUR ET CHER CONFRÈRE,—J'ai lu avec un grand plaisir l'article du *Journal of the Society of Chemical Industry* (29 Mars 1886), dans lequel vous exposez les recherches si précises que vous avez faites pour donner à ma méthode d'essai quantitatif et qualitatif des huiles une extension favorable.

Votre bienveillance m'inspire seulement un regret. Vous avez connaissance de mon travail par les *Comptes Rendus* et le *Journal de Pharmacie*. Ces journaux ont donné des extraits peu étendus.

Permettez moi de vous adresser un des exemplaires qui me restent où vous trouverez beaucoup plus de détails et où vous verrez, j'espère, la preuve de mon application à résoudre la question de la manière la plus générale.

- (1) En diluant les huiles siccatives avec l'olive ou une autre huile pour éviter de trop forte dégagement.
- (2) En faisant plusieurs preuves avec des quantités différentes d'huile (ou du mélange huileux) et d'acide.

50grms. de mélange et 1Sec. d'acide.

50	"	"	36	"	
100	"	"	18	"	etc., etc.

Le qui permet de calculer avec une grande approximation la *qualité* et la *quantité* des huiles inconnues existant dans le mélange.

Vous serez mon juge et si vous trouvez bon de porter à la connaissance des chimistes anglais le jugement que vous prononcerez après la lecture de mon mémoire, je vous en serai reconnaissant.

Veuillez agréer, Monsieur et cher confrère, l'assurance de mes sentiments les plus distingués,

E. MAUMENÉ.

Paris, 11 Avril 1886.

As M. Mauméné remarks in his letter, the references which I gave were only short abstracts of his original paper, but as they were the only ones given in the Royal Society's catalogue of scientific papers, and as the original paper (published by the Imperial Academy, Rheims, 1852) is one, a copy of which appears difficult to obtain, I trust I may be excused for not having perused it before reading my paper. I have now, however, read it through carefully, and find in it a very extensive and minute description of details. M. Mauméné draws attention to the necessity for admixture of another oil when testing the drying oils, in order to avoid too violent an action

* Mr. Napier's latest instrument is now being made at White's, in the form of a hollow drum revolving vertically in a brass cylinder, the diameter of which slightly exceeds that of the drum.—June 23.

between the oil and the acid; however, he only records one or two experiments on this subject, and in those he has used olive oil as retarding agent, for which the rise alone is about 40°C ., and gives no hint as to the using of mineral oil. I am still strongly of opinion that the use of mineral oil, on which sulphuric acid has a comparatively slight action, is much to be preferred as a retarding agent to olive or a similar oil, for the following reasons. My experiments led me to the conclusion that in order to obtain the most concordant and reliable results, the maximum temperature attained should not exceed 60°C ., which temperature appears to be a critical one in many chemical reactions. In order to be able to fulfil this condition with the least possible admixture of retarding oil, it is necessary to choose a retarding oil on which sulphuric acid has the least action practicable. By using such an oil as olive, a comparatively small range of temperature is at one's disposal, and therefore only a small proportion of the mixture could consist of the drying or fish oil to be tested if the above condition were to be fulfilled. I may make my meaning more clear by an example. Let the initial temperature in all the experiments be 10°C ., and the rise in temperature due to the mineral oil in a mixture containing two-thirds of it, 10° ; the rise for such an oil as olive, 40° ; for an oil A, 120° ; and for an oil B, 75° .

First, using olive or similar oil as retarding agent—

Mixture.	Maximum Temperature.	Range.
$\frac{1}{3}$ A, $\frac{2}{3}$ Olive	$(10^{\circ} + 35^{\circ} + 15^{\circ}) = 60^{\circ}$) $5^{\circ} 3'$
$\frac{1}{3}$ B, $\frac{2}{3}$ Olive	$(10^{\circ} + 35^{\circ} + 9 \cdot 37^{\circ}) = 54 \cdot 37^{\circ}$	

Second, using mineral oil as retarding agent—

Mixture.	Maximum Temperature.	Range.
$\frac{1}{3}$ A, $\frac{2}{3}$ Mineral.	$(10^{\circ} + 10^{\circ} + 40^{\circ}) = 60^{\circ}$) 15°
$\frac{1}{3}$ B, $\frac{2}{3}$ Mineral.	$(10^{\circ} + 10^{\circ} + 25^{\circ}) = 45^{\circ}$	

Thus supposing a mixture of oils A and B in unknown proportions had to be tested, an error of $\frac{1}{3}$ in the experiment, if olive oil were used, would mean an error of about 9% on the quantities of A and B in the mixture, while by using mineral oil the same error in experiment corresponds to only 3.3%.

On the other hand, it may be objected that it is more troublesome to determine the standard rise for the mineral oil than for olive; but I should think this a very slight objection, especially in laboratories where oils are being frequently tested; for a stock of a special mineral oil can be kept at hand for which the standard value has once and for all been determined, which is easily done for various proportions by means of the formula given in my paper; and I should think the advantage, which appears to be gained by its use, should more than counterbalance any slight extra trouble.

DISCUSSION.

Professor MILLS said that it had been alleged that some connection existed between specific gravity and viscosity. On this point there ought to be no doubt or uncertainty. True they might find a very heavy oil more viscous than a light oil, but that was no evidence of a relationship between the two. Mr. Coleman had suggested almond oil as a standard of viscosity, but did not specify what class of almond oil he would prefer—whether that from sweet or

bitter almonds. All those who used Maumené's test must agree with Mr. Ellis in using mineral oil instead of olive oil, which latter, however, often gave good results. Maumené himself would be the first to admit the use of mineral oil when he read Mr. Ellis's remarks.

Mr. PATTISON said that the great attention which this subject had of late received, was perhaps an evidence of the existing depression in trade and the resulting desire to economise. No doubt in prosperous times great loss arose from the use of unsuitable oils, and any process which would aid in the selection of suitable lubricants was worthy of close attention. From the discussions on papers read in Glasgow and elsewhere they had learnt that neither specific gravity nor viscosity were, either alone or in combination, absolute measures of value. For example, sperm oil—an oil of low gravity and viscosity—was an excellent lubricant. Could they ascertain what became of the oil which was put upon machinery, it might afford some evidence of the changes it underwent. As it was impossible that at the temperature of friction it was volatilised, might it not be decomposed in some way? Hence should they not direct their investigations towards those oils which were most unalterable, and lasted longest in use?

Mr. COLEMAN, in reply, said that there was no reason to suppose that lubricating oils dissipated themselves in vapour or gas, or that, except in the case of vegetable oils, oxidation occurred. There were other qualities besides viscosity desirable, but unquestionably the using of an oil of proper viscosity was the most important, or the consequences might be serious in large cotton and other spinning mills. Sperm oil, which had about half the viscosity of rape or lard oil, was best adapted for spinning machinery; but of late years, owing to the scarcity of sperm oil, almost all spinning machinery was run by rape or lard oil diluted to the viscosity of sperm oil by admixture of mineral oil, hence the importance of measuring the viscosity of mixed oils.

ACTION OF OILS ON METALS.

BY I. J. REDWOOD.

VERY little has yet been published in regard to the action of oils in common use on metals with which they are brought in contact when stored, transported, or employed for the lubrication of machinery; and as the subject is of importance, especially to manufacturers of compound lubricating oils, and to those who use such oils, the following record of the results of experiments extending over twelve months will, it is confidently hoped, be found of practical value.

Mr. C. W. Volney has made a few experiments on the action of oils on brass,* and finds that of olive, cotton-seed, and lard oils, the first has the most action and lard oil the least. Mr. W. H. Watson, in a paper on "The Action of various Fatty Oils upon Copper,"† points out that seal oil has more action than sperm oil.

Dr. Stevenson Macadam has investigated the action of paraffin burning oils on metals,‡ and states that the action varied with different samples of such oils, and that the variation was not traceable to the presence of impurities. Engler, however, contends§ that mineral oils have no action on metals if free from oxygen and air. In this connection it may be

	1.201	1.200	0.33222	Seal		

remarked that the action of hydrocarbons on metals has been generally considered to be due to impurities, such as water and slight traces of phenols and bases, which most commercial paraffin oils contain, on account of the difficulty of entirely removing them.

The experiments were made principally with a view to determine what fixed oils are best adapted for mixing with mineral oils for lubricating purposes.

Metals in ordinary use were employed, and after being thoroughly cleaned, washed with ether and dried, were weighed and placed in cork tubes together with 15cc. of the oil. These tubes were kept for 12 months at an average temperature of about 80° F. in the summer, and at 50° to 55° F. in the winter. It should be mentioned that the tallow oil was solid for four months during the winter of 1884, and one month at the commencement of the winter of 1885.

After the lapse of the twelve months, the oils were all poured off from the metals and set aside for examination, and the metals, after being carefully washed with ether and cotton wool, were dried and weighed. On referring to the tabular statements of the results, it will be seen that in the case of one iron and five zincs the metals gained in weight during the exposure to the action of the oils. This increase in weight is accounted for by the fact that, in the case of iron, the metal contained a flaw which had not been noticed and which became filled with oxide, and therefore could not be thoroughly cleaned; in the case of the zinc, block metal had been inadvertently used; and in all five cases, the rough surface had become covered with a deposit which could not be removed.

Table I. shows the weights of the different metals before and after exposure to the action of the oils, and the percentage loss sustained.

In order to facilitate comparison of the results, a diagram has been prepared. It shows the percentage losses as given in Table I. The results obtained with those metals which gained in weight in the manner described, and those which lost nothing, have been omitted.

On referring to the table and diagram it will be seen that—

Iron is least affected by seal oil, and most by tallow oil.

Brass is not affected by rape oil, least by seal oil, and most by olive oil.

Tin is not affected by rape oil, least by olive oil, and most by cotton-seed oil.

Lead is least affected by olive oil, and most by whale oil; but whale, lard, and sperm oils all act to very nearly the same extent on lead.

Zinc seems, by the four actual weighings that were of any value, to be not acted on by mineral lubricating oil, least by lard oil, and most by sperm oil.

Copper is not affected by mineral lubricating oil, least by sperm oil, and most by tallow oil.

The table and diagram also show that—

Mineral Lubricating Oil has no action on zinc and copper, acts least on brass, and most on lead.

Olive Oil acts least on tin and most on copper.

Rape Oil has no action on brass and tin, acts least on iron, and most on copper.

Tallow Oil acts least on tin and most on copper.

Lard Oil acts least on zinc and most on copper.

Cotton-seed Oil acts least on lead and most on tin.

Sperm Oil acts least on brass and most on zinc.

Whale Oil has no action on tin, acts least on brass, and most on lead.

Seal Oil acts least on brass and most on copper.

From the foregoing results it will be seen that mineral lubricating oil has, on the whole, the least

action on the metals experimented with, and sperm oil the most.

For lubricating the journals of heavy machinery, either rape or sperm oil is the best oil to use in admixture with mineral oil, as they have the least effect on brass and iron, which two metals generally constitute the bearing surfaces of an engine. Tallow oil should be used as little as possible, as it has considerable action on iron.

All the oils were examined for the respective metals with which they had been in contact, by the following methods:—

Iron.—Agitate the oil with a dilute solution of nitric acid, draw off the solution and evaporate to dryness on the water bath in a small porcelain basin. Take up with water, and add ammonia and sulphuretted hydrogen water.

Brass.—See copper.

Tin.—Extract with dilute hydrochloric acid, evaporate solution to dryness, take up with water and a few drops of hydrochloric acid, and to this add a few drops of a mixture of a solution of ferric chloride and ferrieyanide of potassium. If tin be present, a precipitate of "Prussian blue" will be given.

Lead.—Extract with dilute nitric acid and evaporate solution to dryness, dissolve in water and test with sulphuretted hydrogen water.

Zinc.—Extract with dilute hydrochloric acid, evaporate, take up with water and add ammonia and ammonium sulphide.

Copper.—Extract with dilute nitric acid, and evaporate (after the addition of a few drops of pure sulphuric acid) to a small bulk in a porcelain basin in order to remove all nitric acid. Dilute with a little water and place a new clean needle in the solution. The needle will soon become coated with a film of metallic copper if any be present.

The chemical examination of the oils appears to afford the most trustworthy guide in determining what metal is best adapted for the construction of storage tanks for the different oils; as in some cases where the percentage loss of metal arising from the formation of a deposit not taken up by the oil was high, only a trace (and in some cases no trace) of the metal was found in the oil.

Some of the oils have both a dissolving and depositing effect, while others have only one or the other. Slight traces of copper and zinc were found in the mineral lubricating oil, although the weighings showed the metals to have lost nothing; this indicates the importance of examining the oils for the metals.

In conclusion, I beg to thank my employers, Messrs. Young's Company, for allowing me the time and use of the Addiewell laboratory for carrying out these experiments.

DR. RAMSAY IN THE CHAIR.

ESTIMATION OF MANGANESE.

BY R. W. ATKINSON, B.Sc.

SOME little time ago an agitation sprung up for rendering uniform the analytical methods employed by various chemists in analysing the same products, the very laudable and desirable object being to do away with the discrepancies in the results furnished by different chemists as far as might be. I do not propose to enter into this question further than to suggest that the most practicable way of arriving at uniformity is by each one publishing his experience in the work with which he is most familiar, and by the publication of comparative results of different methods. It is with this view that I venture to communicate to the Society the conclusions I have come to in respect of the methods in general use for the estimation of manganese; not that I am able to announce any new process which is perfection, but to point out how the results obtained by different chemists using different methods vary from one another and to show why the variations occur.

Sellers of manganese ore have, with the progress of analytical methods, found the percentages of manganese in their ores steadily diminish, and they have at the same time found prices falling so that they have been unable to make the latter balance the former. In the earlier days, before it was so generally known as at present that the peroxide of manganese when formed in presence of barium, lime or zinc salts, carries down with it important quantities of these metals, no attempt was made to remove them before the precipitation of the peroxide, and thus the latter body was weighted with variable amounts of these elements. As the barium often amounts to four or five per cent., the lime to even more, and the zinc to two or three per cent. of the ore, there can be no wonder if from this cause alone the results rose one and one and a half per cent. above the truth, and the first step, therefore—the removal of the barium by the addition of dilute sulphuric acid before oxidation of the manganese—was in the direction of reducing the apparent percentage of manganese in the ores. The removal of the zinc and calcium is not such a simple operation, and by the majority of chemists who use the gravimetric method no attempt is, I believe, made to remove them, hence the results obtained in this way have the character of being too high, a circumstance which has led to the introduction of the volumetric method, about which more hereafter.

Another very serious source of error in the older methods of manganese analysis consisted in the use of fixed alkalis in the process. It hardly now needs to be insisted upon amongst chemists that once sodium or potassium salts are introduced into the solution, the energy of combination between the manganese peroxide and the alkalis is so strong that it is practically impossible to separate them. The explanation of this fact is doubtless the same as that of the calcium, barium and zinc being carried down with the manganese peroxide—namely, that the latter acts as an acid and combines with bases in preference to a molecule of the protoxide of manganese. Weldon has taken advantage of this in his process for the recovery of manganese from the chlorine-still liquors, by introducing a certain amount of lime, which, by replacing the manganese oxide, allows a larger proportion to be peroxidised to MnO_2 . In analytical operations the only way to avoid an error of this

kind leading to high results is to avoid the use of potassium or sodium salts in any part of the process, and to replace them by ammonium salts, which, even if they are held by the manganese peroxide during the precipitation, are completely removed by the ignition of the precipitate.

The above are the main sources of error which result in the percentages of manganese coming out too high, and it will not, therefore, be a matter of surprise to learn that the same ores ten or more years ago were reported to contain two and three per cent. more manganese than at present. There is, however, an error acting in the opposite direction in the estimation of manganiferous iron ores, but which sellers' chemists early detected and corrected. This lies in the fact that peroxide of iron, when precipitated in the presence of a manganese salt, invariably holds more or less of the latter, and thus leads to a deficiency of manganese. Sellers' chemists were careful to avoid this loss, even at the expense of increased trouble to themselves, by redissolving the first precipitate of ferric oxide and precipitating a second time, whereby only traces of manganese are retained, the remainder going into the filtrate which is added to that first obtained, and practically the whole of the manganese is in this way separated from the iron.

In considering how the various sources of error above mentioned could be eliminated, we have been led to adopt the following procedure, which, in principle, is the old gravimetric method, and depends for its accuracy only on attention to details, combined with a recognition of the fact that the first precipitated peroxide of manganese is impure, retaining both lime and zinc oxide when these are present in the original ore, as they usually are. Starting with the ore finely ground and well dried, we weigh out one to two grams according to its richness in manganese, and having dissolved it in from ten to twenty cc. of pure hydrochloric acid in a small beaker provided with a glass cover, we heat with the cover on until the chlorine liberated is completely expelled. From five to ten cc. of dilute sulphuric acid (strength one to six) are added, and the mixture carefully evaporated to dryness in the beaker upon a warm part of the hot plate, the evaporation being conducted slowly to avoid risk of spitting. When dry the beaker is gradually advanced to the hottest part of the plate, where it is allowed to remain until there is no longer any acid smell to be detected, after which the beaker is cooled and ten to fifteen cc. hydrochloric acid added to the residue. This is then warmed until solution is completely effected, after which the liquid is diluted and filtered through Swedish paper. The filtrate contained in a large narrow-sided beaker is nearly neutralised with ammonia, and finally neutralised entirely with ammonium carbonate solution, until the solution attains a dark reddish-brown colour, upon which twenty-five to thirty cc. of a strong oily solution of ammonium acetate are added, and about 500 cc. of water. The cover being replaced, the beaker is placed upon the hottest part of the plate, and allowed to remain there until the liquid just begins to froth. If allowed to remain longer, the basic ferric acetate, which has in the meantime separated, becomes slimy and will refuse to filter, but if the beaker is removed when boiling first sets in distinctly no difficulty whatever is experienced, filtration goes on rapidly, and the precipitate is easily washed with hot water containing one per cent. of ammonium acetate. The filtrate is collected in a wide, lipped beaker and set upon the hot plate to evaporate, whilst the washings are collected in a smaller beaker and added afterwards to the main portion of the filtrate.

The precipitate is next transferred by means of a platinum spatula, as far as possible, to the original beaker, and what remains on the filter-paper is washed through by solution in hot hydrochloric acid. The solution of ferric chloride thus obtained is again neutralised and precipitated by ammonium acetate as before; the second filtrate contains the remainder of the manganese, and the collected filtrates are then mixed and evaporated to about 100cc. or 150cc. This liquor is filtered, if necessary, into a flask, cooled, and bromine added in small portions, and until, with continued shaking, it fails to dissolve any further quantity. During this oxidation, as much effervescence takes place owing to the decomposition of the ammonium salts by the bromine, it is necessary to keep the neck of the flask constantly closed by means of a watch glass, and to rinse into the beaker anything which collects upon it. When the oxidation is complete, the brominated liquid is washed from the flask into the beaker in which the liquid was evaporated, diluted with water, and an excess of strong ammonia added *at once*. The hydrated peroxide of manganese is thus precipitated in a form in which it can be readily and quickly washed even on Swedish filter-paper. The beaker containing the precipitate is heated on the plate in a good draught until it just begins to boil, after which it is placed on one side to settle and then filtered. The precipitate must be washed with a mixture of dilute ammonia and hot water, which we do by blowing at the mouth pieces of two wash-bottles at the same time; after a little practice it is not difficult to make the two streams tolerably regular and uniform.

The filtrate contains the greater part of the lime and zinc, but sufficient remains in the precipitate to render a second treatment with bromine and ammonia necessary. The precipitated hydrated peroxide of manganese is, therefore, removed from the funnel by the same means as the basic ferric acetate before described, and dissolved in the same beaker in which it was precipitated. The acid solution is to be carefully neutralised, leaving the solution rather acid than ammoniacal, and it is advisable to add about ten cc. of ammonium acetate solution, which helps to render the oxidation more regular. The treatment with bromine and ammonia is carried out exactly as before, and the manganese precipitate, now freed from all but mere traces of zinc and lime salts, is collected upon a Swedish filter, well washed with dilute ammonia and hot water, dried in the steam-oven, ignited over the blow-pipe and weighed as Mn_2O_4 . If the precipitate were washed with hot water alone, the precipitate would after a while show a tendency to pass through the paper, which is avoided by the use of dilute ammonia in conjunction with the hot water.

It would appear unnecessary to give a word of caution against allowing the strongly ammoniacal solution to remain at the boiling temperature in contact with the glass beaker, were it not that some chemists occasionally allow this mixture to remain all night in a warm place. As hot ammonia very strongly attacks glass, possibly this may explain some discrepancies, amounting to one and two per cent., between sellers' and receivers' results. Carried out as above directed, the process is a long and tedious one, but the results obtained are much more concordant than when only a single precipitation is resorted to, and fall below the latter from four to five-tenths of one per cent.

Owing to the length of time occupied in the gravimetric method of estimating manganese, we naturally sought a more rapid one, and if possible a volumetric process. Experiments showed that for practical

purposes, with ores containing numerous impurities, there was only one process which showed indications of being a workable one. I allude to that proposed and worked by our member, Mr. John Pattinson, of Newcastle-upon-Tyne, and I need not therefore occupy the time of the meeting with any account of the methods founded upon the use of potassium permanganate or other oxidising agents.

The process which goes under Mr. Pattinson's name, and which I shall speak of as the *volumetric process*, *par excellence*, is based upon an observation of that gentleman that a soluble salt of manganese in presence of a certain proportion of a ferric salt, is completely oxidised by bromine water or bleaching powder solution to the state of peroxide of manganese. Most volumetric methods have hitherto failed from the difficulty of converting more than a proportion of the manganese into the state of MnO_2 , but Mr. Pattinson asserts that this takes place when ferric chloride is present, and Dr. Kessler also states that zinc chloride is equally effective. In the older methods, where no base was present, the impossibility of completely oxidising the Mn to MnO_2 was due to the combination of some of the MnO_2 first formed with a portion of the MnO present, thus preventing its oxidation. The presence of ferric or zinc salts, it is presumed, allows of the replacement of the MnO, and thus effects complete oxidation to MnO_2 . We carry out the process nearly as described by Mr. Pattinson, adding only a few details which are not mentioned in his paper. We weigh out 0.5gm. or 0.6gm. of an ore containing about 20 per cent. manganese, dissolve in 7 or 8cc. of strong hydrochloric acid, and, when dissolved, wash the whole, without filtering, into a large narrow-sided beaker. When cold it is neutralised with precipitated carbonate of calcium, until the liquid assumes a reddish hue. 40 or 50cc. of saturated bromine-water are added, and the mixture allowed to stand in the cold for half-an-hour. At the expiration of that time the beaker is nearly filled up with boiling water, and precipitated carbonate of calcium added until there is no further effervescence, and part of the carbonate is evidently unacted upon. A small quantity of spirits of wine is then added, the whole well stirred, and the precipitate allowed to settle. The clear liquid is filtered off and fresh boiling water added to the residue in the beaker, a little spirits of wine being used to reduce any permanganate which is formed. The filtration and washing are repeated until the filtrate when cooled no longer turns blue an iodised starch-paper. During the washing about 1.9 to 2.5grms. of pure granular ferrous-ammonium sulphate are weighed out, washed into the beaker in which the precipitation took place, and about 30 to 50cc. of dilute sulphuric acid added. The filter containing the precipitated manganese peroxide is then placed in the beaker, and the latter is quickly dissolved by the oxidation of a portion of the ferrous salt into ferric sulphate. The remaining ferrous iron is then titrated with potassium bichromate in the usual way. The difference in the number of cubic centimetres of bichromate solution used from the number which the original weight of the ferrous-ammonium sulphate would have required if directly titrated is a measure of the quantity of MnO_2 present, and if we assume that the manganese is present entirely in that form we have an accurate and ready means of estimating the percentage of that element in the ore. For rapidity and simplicity the volumetric process leaves nothing to be desired; duplicate experiments agree within very narrow limits, and if we accept the assumption that the presence of ferric chloride enables the complete oxidation of the manganese to the state of peroxide, no other process can compete with it.

We have made, in the course of our work, a large number of manganese estimations by each of the methods above described, and as in a large proportion of the cases Mr. Pattinson has also analysed the same ores, I can say, with the knowledge of his figures, which of course I am precluded from giving, that when using the same process our results have never varied by more than one-tenth of one per cent. So much can certainly not be said for the results of various chemists who have used the gravimetric process; nevertheless I have been confronted with the fact that in my own hands the results obtained by using the two methods described in this paper have never coincided except when the ores contain very small percentages of manganese—less than five per cent. I was unable to persuade myself that the four or five-tenths of one per cent., which the gravimetric method almost invariably yields more than the volumetric, was due to impurities retained by the hydrated peroxide of manganese after the double precipitation. Some results I give below, which show how much the percentage of manganese by the two methods differs, and the fact that in many cases in which the comparison could be made, my results agree with those of Mr. Pattinson, indicate that the discrepancy lies in one of the two methods, and not in the manner of carrying out the experiment. To put this to the test I made use of a sample of well-crystallised manganous sulphate, which had the following composition:—

Manganese oxide (MnO).....	23.61
Sulphuric oxide (SO ₃)	41.04
Water	35.35
	100.00

The manganese was determined by precipitation by sodic carbonate in a platinum dish, using every possible precaution to obtain the precipitate free from alkali, and the sulphuric acid found agrees almost theoretically with the manganous oxide. The composition of the salt having been ascertained, a known weight was made up to half-a-litre, and the manganese contained was determined gravimetrically by means of the bromine and ammonia process, and by the volumetric process. In the latter case a considerable excess of ferric chloride was added, and the experiment carried out in exactly the same manner as described. Calculated upon the manganous sulphate taken, the following percentages were found:—

By precipitation by sodic carbonate	23.61
“ “ bromine-ammonia	23.52
“ volumetric process.....	23.10

We see from this experiment that whilst the two gravimetric processes agree very closely, the volumetric method gives a result which is about four-tenths per cent. below the others, an amount quite comparable with the difference between the results of the two methods when applied to manganiferous iron ores. I regret that pressure of other work has prevented me carrying out these experiments in more detail; it would have been more satisfactory to me if I could have had figures to present to the meeting which would have explained, without doubt, the cause of the deficiency. To my own mind there seems every reason to attribute the difference to the incomplete oxidation of the manganese. I have already referred to the extreme difficulty of obtaining perfectly oxidised manganese peroxide; those who remember Dr. Alder Wright's paper on the oxides of manganese, will know that after trying almost every conceivable mode of preparing the peroxide, he found that the products invariably showed a deficiency of oxygen. In the light of his results, and of the experiments I have myself made, I have come to the conclusion that whilst the presence of a ferric salt does permit of a higher stage of oxidation being attained than when it is absent, there

still remains a portion in a lower state of oxidation, and that this accounts for the lower results found by the volumetric process. Formation of permanganate in presence of Fe₂Cl₆, and reduction by alcohol, also leads to a deficiency in the amount of oxygen present.

If we take what seems to be a general result, that an ore containing 20.4 per cent. of manganese shows by the volumetric process only 20 per cent., the result is that only 98 per cent. of the metal present is completely oxidised to peroxide of manganese, which alone is estimated by that method.

As the manganiferous iron ores also contain more or less zinc, it was suggested to me that the higher results obtained by the gravimetric method might be due to the retention by the peroxide of manganese of some small amount of zinc oxide. To put this to the test, I made a solution of the manganese sulphate, which I had already used, and determined the percentage of manganese by both methods, after the addition of 2 per cent. of zinc in the form of zinc chloride. Calculated as before upon 100 parts of the salt, I found:—

By the bromine and ammonium method.....	23.61 p.c. Mn.
“ “ volumetric method	23.23 “ “

The volumetric method in this case gave a slightly higher result; it may be that zinc chloride is more effective than ferric chloride in promoting the oxidation, and, had time permitted, I would have tried the effect of the addition of a larger proportion of zinc salt. That might lead to a workable modification of the volumetric process, but it would not invalidate my argument that the results given by the volumetric process, as usually carried out, are below the truth, and that however tedious, the gravimetric method, in which the manganese is twice precipitated by bromine and ammonia, is the only practical process.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in Apparatus and Proceedings for Purifying and Filtering of Waters. L. Schröter, Guben. Eng. Pat. 5472, May 4, 1885. 8d.

This invention deals with the purification and circulation of the water in a steam boiler. Exterior to the

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Rander Lück, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

“ 2s. 4d., “ “ “ 2s. 4d.....	2d.

boiler, a vessel of any shape is provided, in the interior of which is a perpendicular pipe, reaching nearly to the top, the lower end being in communication with the water space of the boiler. Communication to the steam space is effected by a regulating valve governed by a float. Water from the boiler enters the vessel owing to inequality of pressure, until the float is raised, admitting steam into the upper part, establishing equality of pressure; a portion of the water then flows off through an outlet in the side of the vessel back into the boiler; that remaining deposits its suspended matter. Condensation of the steam again establishes inequality of pressure, and the operation repeats itself. The mud settling out during the intervals of rest is blown off periodically.

—C. C. H.

Improvements in Apparatus for Separating Solid Impurities from Water or other Liquid. A. Howatson, Lavender Hill, Surrey. Eng. Pat. 6351, May 23, 1885. 8d.

THE object of the apparatus described in this specification is to effect the rapid separation of suspended matter in a liquid without resorting to filtration. The interior of a rectangular tank is provided with a number of "vertical plates with corrugated or angled passages." These are placed near to each other, forming a number of narrow cells. The water containing precipitated matter is admitted at the bottom of the tank, and overflows at the top. During its passage through the angled plates, the cells of which are equivalent to a number of shallow tanks, the precipitate settles out and gradually slides down the surfaces of the plates into a mud pocket forming the bottom of the tank.—C. C. H.

Improvements in Apparatus for Separating Liquids from Solid Matters suspended therein. W. Macnab, London. Eng. Pat. 6587, May 30, 1885. 8d.

THIS specification describes improvements in the apparatus patented by J. Hadden (Eng. Pat. 972, 1883), for separating the suspended matter from a water by subsidence. The shelves upon which the precipitate settles do not run from side to side of the vessel, but are alternately secured to the sides and at the centre; the former do not meet in the centre of the vessel, and the latter do not touch the sides; pockets are thereby formed into which the solid matter slides and may be drawn off. The specification also shows a horizontal form of apparatus similarly constructed.—C. C. H.

Improvements in Filter Presses. S. H. Johnson and C. C. Hutchinson, London. Eng. Pat. 7618, June 28, 1885. 8d.

THE patentees find that the destruction of the cloths used in filter presses, operating upon materials undergoing or liable to putrefaction—e.g., sewage sludge—results from a decomposition of the fibres of the cloth. This change, they find, is best prevented by treating the cloths with enech, or terra japonica. The specification shows apparatus for best carrying this into effect. The cloths are placed in a cylinder from which the air is exhausted, thus compelling the tannin to enter the interstices of the fabric. The claim is for the use of filtering cloths or diaphragms previously treated with a liquor containing tannin.—C. C. H.

Improvements in Forcing Fluids and Semi-fluids by means of Compressed Air, and Apparatus therefor. S. H. Johnson and C. C. Hutchinson, Stratford. Eng. Pat. 8141, July 4, 1885. 8d.

THIS invention relates to improvements in pneumatic apparatus for raising liquids of an acid or semi-fluid nature which cannot satisfactorily be raised by direct pumping. They consist principally of arrangements for the continuous use of the original volume of compressed air first introduced into the apparatus. The inventors make use of three upright vessels of equal capacity, all in communication at their upper ends by means of pipes containing compressed air. Their lower ends have inlet

and outlet pipes for the acid to be raised, and are also connected to water pipes coming from a force pump. There are also floats, valves, etc., for the regulation of the various liquids. The method of working is as follows:—

Assuming the letters A, B, and C to designate the three vessels; the vessel A is first filled with compressed air, under sufficient pressure for overcoming the weight of the column of acid when raised to its full elevation; the vessel B is next filled with acid, and a connection made between A and B by means of their air pipes at the top. On water being then pumped into A, it forces the air contained therein into B, thereby displacing the acid, which is raised to its destination. The air connection between A and B is then closed, and that between B and C opened, C having previously been filled with acid. Water is now pumped into B, displacing the air and forcing the contents of C to their destination, leaving C filled with air and B with water. Meantime, the water which was first pumped into A has been drawn off, and A filled with a new supply of acid, either by gravitation or otherwise. On C being now connected with A by means of the air pipes, and water being pumped into the former, the air is driven over into A, displacing and raising the acid from the latter vessel and leaving it ready for the next operation. Thus the process is continuous, and as the compressed air is never allowed to escape, no power is lost from that cause. The specification and drawing should be consulted.—B.

Improvements in Acid Taps and Valves and Seats for Chemical Works. W. Allen, Manchester. Eng. Pat. 8499, July 14, 1885. 6d.

THE improvement relates to a method of lining cocks and taps with acid-resisting materials.—B.

Improvements in Filtering Apparatus. G. Behrus, Lubeck. Eng. Pat. 2168, February 15, 1886. 8d.

FOR the purpose of filtering dust-laden air, the patentee employs a cylindrical collapsible bag, through which the air is either forced by pressure or drawn by suction. To free the dust from the surface of the bag it is caused to suddenly collapse and expand, thus shaking the dust from the surface of the fabric.—C. C. H.

Improvements in Apparatus for Evaporating and Drying Solutions and other substances. O. Klannig, Munich. Eng. Pat. 4042, March 23, 1886. 6d.

THE inventor constructs drying apparatus by employing a horizontal cylindrical vessel, in which revolve concentrically two sets of blades, one within the other, their driving axles projecting through the ends of the cylinder. The larger set of blades revolves at slow speed, touching the inside of the vessel and acting as scrapers; the smaller blades revolve quickly, dipping into the substance to be dried, with which the vessel is partly filled, and throwing it against the sides by centrifugal action. The cylinder is surrounded by suitable heating flues, and provided with openings for filling and emptying, and for the withdrawal of the vapour developed in the drying process.—B.

Improvements in Filters. W. Oldham, Manchester. Eng. Pat. 5880, May 13, 1885. 8d.

THE patentee describes improvements in a filtering apparatus covered by him in Eng. Pat. 7831, 1884. A is a perforated cylinder covered with flannel or other textile fabric. B and C are similar concentric perforated cylinders. The whole rests on a base plate D, and the interior of A communicates with the outlet pipe G; F is a packing preventing leakage of unfiltered liquid into G. The space between A and B is packed with fine animal charcoal, that between B and C with coarse vegetable charcoal, sawdust, or shavings. The filtering units thus

made up are immersed in tank K, containing the unfil-
tered liquid. When any one unit becomes clogged, the whole replaced. The patentee claims (1) the construc-
tion of such units and their combination in groups or

FIG. 3.

FIG. 1.

centre outlet F is closed by a plug, as shown at L, the
unit withdrawn, the concentric spaces repacked, and the series, (2) the combination of animal and vegetable char-
coal in the apparatus as described.—C. C. H.

II.—FUEL, GAS, AND LIGHT.

The Combustion of Carbonic Oxide and Hydrogen.

Harold Dixon. J. Chem. Soc. (Trans.), 1886, 94—114.

(1.) *Action of Steam on Carbonic Oxide.*—It was shown by the author in 1880 that carefully dried carbonic oxide and oxygen are not exploded by the electric spark, but that a minute trace of water or of a volatile body containing hydrogen determined the explosion; and he brought forward the hypothesis that the steam acts the part of a "carrier of oxygen" by undergoing reductions and successive re-formations; thus: (1) $\text{CO} + \text{H}_2\text{O} = \text{CO}_2 + \text{H}_2$; (2) $2\text{H}_2 + \text{O}_2 = 2\text{H}_2\text{O}$. In the present paper a number of experiments bearing on this point are described. The effect of various substances as regards their power of causing the combination of carbonic oxide and oxygen was first studied. Of the thirteen bodies examined, seven contained hydrogen, and all these were effective; the remainder, which were free from hydrogen, were inactive. The conclusion is drawn that steam acts by virtue of its own peculiar chemical properties, and not as a mere third body.

The author admits that it cannot be directly proved that the steam is chemically changed during the explosion, but shows that the cycle of reactions involved in his hypothesis can occur under the conditions of the experiment, and points out that the hypothesis does not involve the existence of unknown forces. These reactions are (1) the decomposition of steam by carbonic oxide, and (2) the combination of hydrogen and oxygen. The hypothesis has been rejected by Traube on the ground that the first reaction does not take place; Traube assumes that hydrogen peroxide is successively formed and decomposed, thus:—(1) $\text{CO} + \text{H}_2\text{O} + \text{O}_2 = \text{CO}_2 + \text{H}_2\text{O}_2$, and (2) $\text{CO} + \text{H}_2\text{O}_2 = \text{CO}_2 + \text{H}_2\text{O}$. The author then quotes the researches of Groves in 1846 and 1847, in which it was conclusively proved that while carbonic acid is reduced by hydrogen when the gases are heated by a loop of platinum wire, the inverse reaction also takes place, carbonic oxide and steam forming carbon dioxide and hydrogen.

The author has investigated the effect of a coil of platinum wire, heated to various temperatures by a current, on mixtures of carbonic oxide and steam, and of carbonic acid and hydrogen, contained in a eudiometer tube over mercury, and has established the following facts:—The decomposition of steam by carbonic oxide begins at a dull red heat, and the amount of decomposition, which in each case attains a maximum in a few hours, and then becomes constant, increases with rise of temperature up to bright redness, when about 14 per cent. of the carbon monoxide is converted into carbonic acid, an equivalent amount of hydrogen being liberated. The final result is the same when a mixture of equal volumes of hydrogen and carbonic acid is heated by the coil, about 14 per cent. of carbonic acid remaining undecomposed when the coil is heated to bright redness. But if in either case one of the products of the change—the carbon dioxide on the one hand, and the water on the other—is removed, the reaction may be pushed to completion.

The action of induction sparks on a mixture of carbonic oxide and steam is somewhat different, for with moderately powerful sparks not only carbon dioxide but also formic acid is formed, while with very powerful sparks carbon is deposited. With a mixture of carbonic acid and hydrogen, 93·6 per cent. of carbon monoxide was formed, and also a trace of formic acid.

The effect of varying quantities of steam on the combustion of carbonic oxide was studied by saturating the gases at different temperatures, and it was found that the amount of decomposition increased with the quantity of steam present. It has also recently been shown by Nannmann and Pistor (*Ber.* 1885, 2894) that when carbonic oxide and steam are heated in a tube, the reaction takes place at temperatures above about 600°.

The Action of Hydrogen on Oxygen.—It has been observed by Traube that when a jet of burning hydrogen is made to dip into water, hydrogen peroxide is formed, and he concludes that either hydrogen and oxygen unite directly to form hydrogen peroxide, or that the following

reactions occur:—(1) $\text{H}_2 + \text{H}_2\text{O} + \text{O}_2 = \text{H}_2\text{O}_2 + \text{H}_2\text{O}$, and (2) $\text{H}_2 + \text{H}_2\text{O}_2 = 2\text{H}_2\text{O}$. The author confirms Traube's observation, but finds that the same effect is produced by a flame of pure cyanogen, while on the other hand the presence of steam is not necessary for the combustion of this gas. The formation of hydrogen peroxide appears to be due merely to the heating effect of the flame of carbonic oxide or cyanogen, and this conclusion is borne out by the fact that hydrogen peroxide is produced by the rapid evaporation of pure water in the absence of any flame. Again, the most careful experiments show that hydrogen and oxygen, thoroughly dried by phosphorus pentoxide, and perfectly pure, combine at a high temperature, and Berthelot and Vieille (*Compt. Rend.* 95, 151) have shown that the rate of the explosive wave in hydrogen and oxygen is identical with the mean velocity of translation of the steam molecules formed in the reaction, at the maximum temperature of the explosion, and not with the velocity of hydrogen peroxide molecules, or with a velocity intermediate between the two. The author has shown, lastly, that when a mixture of carbonic oxide and hydrogen in any proportion is exploded with a volume of oxygen less than half as great as that of the hydrogen, the pressure being greater than the critical pressure, and the temperature sufficiently high to prevent the condensation of steam, the following relation holds good:—

$$\frac{\text{Vol. of CO} \times \text{vol. of H}_2\text{O}}{\text{Vol. of CO}_2 \times \text{vol. of H}} = 4.$$

But when the quantity of oxygen is greater, this ratio, which he terms the coefficient of affinity, is diminished. The presence of an inert gas such as nitrogen favours the formation of carbonic acid and lowers the coefficient, and the author concludes that the excess of oxygen is inert, the oxidation of carbonic oxide only taking place by means of the steam formed. The presence of inert oxygen is, however, precluded by Traube's hypothesis, and there ought therefore to be no lowering of the coefficient. The same argument tells also against the "contact theory" of the action of steam.

On the other hand, if hydrogen and oxygen combine directly to form hydrogen peroxide, then the lowering of the coefficient should occur when the volume of oxygen is equal to that of the hydrogen.

In conclusion, the author agrees that Prof. Armstrong's views (see next abstract) are not opposed to the observed facts, and points out that his explanation differs only in assuming the simultaneous instead of the successive occurrence of the two reactions.—S. Y.

The Theory of the Interaction of Carbon Monoxide, Water and Oxygen Gases: A Note on Mr. H. E. Dixon's Paper on the Action of Carbonic Oxide on Steam.

Henry E. Armstrong. J. Chem. Soc. (Trans.), 1886, 112—114.

The author suggested in his address to the Chemical Section of the British Association at Aberdeen, that the water may exercise the same kind of action on the oxygen and carbon monoxide as it (or rather the dilute sulphuric acid) does in a Grove's gas battery, and that its hydrogen does not become free in any ordinary sense. In the Grove's gas battery the system before the circuit is closed may be represented thus:—

The state before and after the explosion of a mixture of CO , O_2 and H_2O may be similarly represented, thus:—

The author thinks it conceivable that the influence exerted by the water may be of a mechanical order, that, in fact, it exerts a mere contact action, serving to bring together the carbon monoxide and oxygen which are straining at each other.

The author thinks that Mr. Dixon's "coefficient of affinity" is explicable by either of their hypotheses, but denies that his conclusion that oxygen is inert towards carbon monoxide follows necessarily from the facts.—S.Y.

Petroleum as an Illuminating Agent. W. Thoerner.
Chem. Zeit. 10, 528—530, 553—554, 573—574, 582—583, 601—603.

On distilling crude petroleum, three fractions are usually collected—viz. (1) the distillate boiling up to 150° C.—i.e., "petroleum-spirit;" (2) the distillate boiling between 150° C. and 300° C.—i.e., the petroleum-oil *par excellence*, "kerosene;" and (3) the distillate boiling above 300° C., which contains the lubricating oils and solid hydrocarbons. The fraction between 150° C. and 300° C.

examination of the oil as to its temperature of distillation. The author uses for that purpose the apparatus shown in the drawings. It consists of a copper flask A (Fig. 1) of about 200cc. capacity, with a neck 12cm. long and 1.8cm. wide, which is connected with a distilling tube B 45cm. long and 0.7cm. wide. The latter is bent at one end, which is introduced into the measuring cylinder, which holds 100cc. up to two-thirds of its height, and is divided in 0.5cc. It is surrounded by a cooling vessel C. For each distillation 100cc. at 15° C. are employed, which are distilled in 25 to 30 minutes. If it be desired to collect the different fractions separately, the modification shown in Fig. 2 is used. Table A on following page contains the results of several experiments.*

The rapidity of flow (viscosity) was determined with the apparatus shown in Fig. 3. The pipette holds 100cc.

being the most valuable, manufacturers try to increase that yield as much as possible by overstepping the limits of the fractionating temperature. Such a proceeding is all the more important to the consumer, as it offers a ready means to the manufacturer of complying with the requirements of the law as regards the flashing point and specific gravity, whereas the illuminating power of the petroleum-oil may nevertheless have been greatly deteriorated. Flashing test and specific gravity offer no guarantee whatever against adulteration and fraudulent admixtures, which can indeed only be detected by an

between the marks *a* and *b*, and the bottom outlet is drawn out to a point 0.8mm. wide. It is surrounded by a cooling cylinder in order to keep the temperature during the experiment at 15° C. From the foregoing table it appears that the percentage of petroleum-spirit has steadily decreased since 1881, whereas the percentage of heavy oils has remained constant. It also shows that manufacturers can easily comply with the requirements of the law as regards flashing test. But

* The author published the results of 71 tests, but it was deemed sufficient to abstract a reduced number.

whether an oil fulfils those conditions which can be fairly expected of a good illuminating oil can only be seen by examining its properties while burning. The following points must hereby be kept in view: Firstly, In what manner does the temperature of the oil in the oil-reservoir of the lamp increase during the burning of the lamp? Secondly, Under what conditions and at what temperature is an explosion of petroleum vapours in the oil-reservoir of the lamp possible? Thirdly, Does the chemical composition of the oil

while at the same time the temperature of the oil in the oil reservoir was gradually raised until it could be ignited, when its temperature was observed. Many experiments proved the interesting fact that the flashing test in the Abel apparatus nearly agrees with the temperature at which the same oil ignites in the oil-reservoir of a burning lamp. These ignitions in most cases take place very quietly and without explosions, the flame of the lamp being extinguished with a hissing noise, while the combustion-gases escape through the

change during the burning of the lamp, and if so, in what manner? Fourthly, Does the illuminating power of the oil decrease during the burning, and what is the cause of that decrease? Liebermann (*Chem. Zeit.* 6, 925) published an investigation referring to the first point, in which he shows that the rise of the temperature of the petroleum in the oil-reservoir of lamps of the usual construction never amounts to more 9° C., and he concludes that absolute safety against explosions is only given by an oil the flashing point of which lies 9° C. over the maximum temperature of any locality. According to Thoenner's experiments, the difference of temperature between the heat of a room and that of the oil in the lamp varies from 5° to 8° C., and considering that the maximum temperature of a room is rarely as much as 30° C., an oil with a flashing point of 38° C., which is indeed reached by first-class oils (Kaiser oil, salon oil), should give an absolute guarantee against explosive vapours. With regard to investigating the second point, the author constructed a lamp which could be swung to and fro,

openings of the burner-tube. The quantity of oils present boiling between 100° and 150° C. is, however, of great importance, as they are most probably the cause of dangerous explosions owing to their great vapour-tension. Whenever an ignition occurred, the amount of hydrocarbons in the gas mixture never exceeded 3.2 volume per cent., and this small percentage is not likely to produce dangerous explosions. In order to make them practically impossible, the author suggests some improvements in the construction of lamps. On the third point Thoenner's investigations fully agree with those of Junker (*Chem. Zeit.* 7, 650). Oil was burned in a lamp for three hours, and the determinations were carried out directly before and after the burning. Table B above shows the results.

It will be seen that with those kinds of petroleum which contain no more than ten volumes per cent. of oils boiling below 150° C., the combustion of the more volatile products is not faster than that of the higher boiling oils. The specific gravity and flashing point before

and after burning very little, whereas the illuminating power decreases considerably, as will be shown later on. If the oil contains large quantities of petroleum spirit, the illuminating power remains unaltered, although the spirit burns away faster than the less volatile products, but oils containing more than ten per cent. of spirit were not brought into the market these last few years. It can therefore be stated that the chemical composition of the usual brands of kerosene oil does not change during the burning. As to the fourth point, a large number of photometric tests were made, comparing by means of the same lamp different oils with regard to their illuminating power and consumption of oil. Thus it was clearly proved that a large percentage of petroleum spirit considerably increases the illuminating power of an oil, whereas the presence of considerable quantities of heavy oils has the opposite effect. Generally speaking, the illuminating power of an oil decreases more or less after a few hours' burning in the lamp; the decrease being greater the less the height of the oil in the oil-reservoir, and the higher the percentage of heavy oils in the petroleum. The presence of a large quantity of volatile oils causes not only a high illuminating effect at the beginning, but also a slower decrease of it during the first few hours. The heavy oils are not so easily drawn up by the wick as the lighter ones, and the former consequently char the wick. In order to obtain a regular and uniform illuminating effect it is necessary to construct lamps with an oil-reservoir in which the oil remains at a constant level. The lamp patented by Mr. Witting, of Osnabruck, fulfils this condition.—S. H.

Improvements in Carburetted Apparatus. O. W. Bennet, Washington, Columbia. Eng. Pat. 2258, February 16, 1886. 8d.

A CYLINDRICAL vessel contains a vertical tube centrally situated with regard to the main cylinder, and communicating with the interior of the same by means of a perforated bottom. The upper portion of the main vessel is utilised as a reservoir for the hydrocarbon used. The lower portion is divided into two or more chambers, so connected that when the uppermost is filled to a certain depth the liquor overflows into the next, and finally finds its way into the central tube, where it carries a float regulating the supply of hydrocarbon from the reservoir to the topmost chamber. Air is admitted at the bottom and passes upwards through each of the chambers in turn, playing over the surface of the hydrocarbon therein, and emerging from the topmost chamber impregnated with the hydrocarbon vapours.—A. R. D.

Improved Construction of Carburetted Apparatus for Burning Coal Gas with Hydrocarbons. H. E. A. Wallis, London, and H. T. Ratcliffe, Birmingham. Eng. Pat. 9650, February 27, 1886. 8d.

THE carburetter is a vessel constructed with a kind of hollow lip extending from its main body. Immediately beneath this is the burner. Outside the carburetter, and so disposed as to receive heat from the burner, is a double pipe, arranged to deliver gas either into the body of the carburetter or into the hollow lip whence the outlet pipe issues. Thus the gas entering is heated by its passage through the double pipe, and playing over the surface of the hydrocarbon in the carburetter is impregnated with its vapour. It is then heated still more strongly by passing through the hollow lip to the burner. This second heating secures great steadiness of flame, as well as preventing deposit in the outlet pipe.—A. R. D.

Improvements in Apparatus for Enriching Illuminating Gas. Jas. Parkes, Aston. Eng. Pat. 2950, March 1, 1886. 8d.

THESE improvements mainly refer to the apparatus described in Specification No. 454, 1886. The delivery pipe is carried from the upper portion of the carburetting vessel, and just at the point of exit is considerably widened out so that it may receive the full heating

effect of a gas jet placed immediately below. The supply of gas to this burner is controlled by a separate tap. In this way sufficient heat reaches the carburetter to vapourise its hydrocarbon contents, while the enriched gas, passing away, is made so hot that risk of deposit in the pipes is avoided.—A. R. D.

Improvements in Apparatus for the Production and Utilisation of Vapour Fuel. W. P. Thompson, Liverpool. From A. J. Ambler, Washington, Columbia. Eng. Pat. 4046, March 22, 1886. 11d.

THIS invention is for mixing petroleum with steam, and heating the resulting vapours to form a homogeneous heating gas. It is particularly applicable to locomotive engines. For details the Blue Book and its drawings must be consulted.—A. R. D.

Improvements in Apparatus for Mixing and Heating Materials for the Manufacture of Patent Fuel. S. Butler, Cardiff. Eng. Pat. 7791, March 26, 1886. 6d.

THIS apparatus combines processes employing "steam" and "dry heat." The material leaving the steam "pug" of the ordinary kind is worked by an Archimedean screw into a slowly revolving heated iron cylinder, in which it is caused to travel forward by a mechanical stirrer. Another form of drying apparatus consists of a firebrick cylinder provided with a central shaft and mixing arms. A heating flue runs spirally round the cylinder.

—A. R. D.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

The Action of Heat on Liquid Paraffins. L. M. Norton and C. W. Andrews. Amer. Chem. J. 8, No. 1—9.

THE hydrocarbons employed in this research were obtained from petroleum by careful fractionation, and subsequent treatment with bromine, and with nitric acid, the product being finally again fractionated. The vapours of the hydrocarbons were passed through a glass or porcelain tube heated in a combustion furnace, the products of the decomposition being passed first through a cooled receiver to condense any liquid products and the uncondensed gases through ammoniacal cuprous solution, dilute acetic acid, and finally through a solution of bromine in carbon bisulphide. In no case was there more than a slight precipitate in the ammoniacal cuprous solution. The condensed liquid hydrocarbons were fractionated, the different portions treated with bromine, and the products distilled under very low pressure. The bromides from the absorption flasks, after being freed from excess of bromine and from carbon bisulphide, were also distilled under low pressure, when a non-distillable tarry mass remained, containing, however, a solid bromide, which was extracted with alcohol.

Normal Hexane.—The liquid decomposition products from this contained some undecomposed hexane, amylene, hexylene, and benzene, together with a very little saturated hydrocarbon boiling between 160 and 160°, and some tar. The cuprous solution contained only traces of a precipitate. The products in the absorption flasks contained ethylene and propylene bromides in nearly equal quantities, and a solid bromide $C_{11}H_{16}Br_2$, melting at 112°. Gases were also produced which were not absorbed by bromine. On repeating the experiment at a lower temperature (about 700°) the products were propylene, butylene, amylene, hexylene, butane (*i.e.*, $C_{11}H_{16}$), and gas not absorbed by bromine.

Isoheptane.—The decomposition of this hydrocarbon at a red heat gave ethylene, propylene, butylene, amylene, hexylene, butane (apparently different from the above, as the bromide melted at 107.5°), and gases not absorbed by bromine.

Normal Pentane.—The products of the decomposition of normal pentane at a red heat were ethylene, propylene, butene (the bromide melted at 113°), traces of other unsaturated hydrocarbons and gases not absorbed by bromine.—A. K. M.

The Decomposition and Genesis of Hydrocarbons at High Temperatures. H. E. Armstrong and A. K. Miller. J. Chem. Soc. 1886, 74—93.

IN this paper the authors describe the results of their examination of the various products of the decomposition of petroleum in the manufacture of oil-gas (this Journal, 1884, 462), the products examined being the portion of the compressed gas which combines with bromine, the liquid deposited during compression of the gas to about ten atmospheres, and the portion of the tar which is volatile in steam.

The liquid deposited during compression of the gas contains hydrocarbons of the C_nH_{2n} and C_nH_{2n-2} series, benzenes, and a very small proportion of hydrocarbons not attacked by sulphuric acid; the latter are more abundant in the steam distillate from the tar.

I. Benzenoid Hydrocarbons.—In order to separate these from the unsaturated hydrocarbons, the crude liquid is cautiously agitated, first with moderately dilute sulphuric acid (2 vols. acid and 1 vol. water), and subsequently with a stronger acid (4 vols. acid and 1 vol. water). Much heat is evolved during this treatment, and the unsaturated hydrocarbons are converted into polymerides, which are left behind when the product is distilled in steam. On surrounding the distillate by a freezing mixture, a large quantity of benzene crystallises out, and after fractioning the mother-liquor from the crystals, a further crystallisation may be effected by freezing the fractions, boiling at about 80°. The benzene thus obtained should be purified by treatment with alkaline permanganate, bromine or sulphuric acid, fractionally distilled, and again crystallised. The residual hydrocarbon from which the benzene has been separated is next agitated with hot concentrated sulphuric acid to extract the remaining benzenoid hydrocarbons, and these are then recovered by hydrolysis (*Chem. Soc. Trans.* 1884, 148). The residue undissolved by the sulphuric acid is treated finally with weakly fuming acid, and after distillation in steam forms a brilliant colourless liquid having the characteristic odour of a pure paraffin. This method of separating the benzenoid hydrocarbons and those insoluble in sulphuric acid is of course applicable either to the crude mixture as a whole or to separate fractions. To isolate the toluene fractions of the hydrolysed product boiling below 115° (after separating as much benzene as possible) are fractionally treated with hot concentrated sulphuric acid and the toluene sulphonic acid purified with the help of its potassium salt, from which the hydrocarbon is recovered by hydrolysis. The three xylenes were separated by Jacobsen's method (*Ber.* 10, 1009) from the fraction boiling at 135—145°, and appear to be present in about the same relative proportions in which they ordinarily occur in coal-tar xylene. Mesitylene and pseudocumene were separated by dissolving the fraction 155—175° in sulphuric acid, and submitting the product to fractional hydrolysis; they appear to be also present in about the same relative proportions in oil-gas tar as in coal tar. Fractions 180—190 and 190—200° were separately converted into sulphonic acids, from which barium salts were prepared. The composition of the salt from the lower fraction indicated the presence of a $C_{10}H_{14}$ hydrocarbon, whilst that from the higher fraction corresponded with a $C_{11}H_{16}$ hydrocarbon.

A large quantity of naphthalene separated from the fractions collected above 200°, and after its removal comparatively little hydrocarbon was left. All attempts to detect the presence of diphenyl failed.

II. Hydrocarbons of the C_nH_{2n-2} Series.—The crude liquid obtained during compression of the oil-gas gave off volumes of gas when warmed, and when this was passed through bromine, and the product steam-distilled, a heavy oily distillate was obtained, whilst the residue in the flask solidified on cooling. The latter substance, after purification, was found to have the composition of Caventon's crotonylene tetrabromide $C_4H_6Br_4$; it crys-

tallised in small glistening plates, melting at 116°. The same product was also obtained directly from the oil-gas by passing it through bromine, but in this case it is accompanied by a much larger proportion of oil. When the crotonylene tetrabromide is submitted to the action of the zinc-copper couple, gaseous crotonylene is set free, and when this is oxidised by a 2 per cent. permanganate solution, formic acid, unaccompanied by any higher fatty acid, is produced; from this it is concluded that the crotonylene is dimethylene-ethane or vinyl ethylene

Another hydrocarbon of the C_nH_{2n-2} series was obtained from fractions of the original crude liquid boiling at about 40°; these fractions were brominated and the product steam-distilled as before; and a solid tetrabromide, $C_5H_8Br_4$, was obtained from the residue. It crystallised in long, thin, narrow prisms, melting at 115°. The hydrocarbon, separated by means of the zinc copper couple, boiled at about 45°, and on oxidation with permanganate, yielded formic and acetic acids only. From this and from the fact that the hydrocarbon is not a true acetylene, it is concluded that it must be either isoallylethylene, symmetrical dimethylallene or unsymmetrical dimethylallene; the authors are inclined to select the first of these as being the most probable, from the simple relation which this bears to normal amylene, from which the unsaturated hydrocarbon is probably derived.

III. Hydrocarbons of the Olefine Group.—The method employed for detecting these hydrocarbons depends upon the fact that a normal olefine is converted by oxidation into formic acid and a fatty acid containing one carbon atom less than the hydrocarbon yielding it. Thus the fraction containing normal amylene should yield butyric acid, that containing normal hexylene, valeric acid, etc. The appropriate fractions were oxidised with permanganate, the product acidulated with sulphuric acid, and the volatile acid separated by steam-distillation; the distillate neutralised with sodium carbonate, concentrated and fractionally precipitated with silver nitrate. The silver salts were purified, analysed, and finally converted into calcium salts. In this way normal butyric, normal valeric, and normal caproic acids were obtained, these indicating the presence of amylene, hexylene, and heptylene. No indication of any higher olefine could be found. Lower olefines, if present, should naturally occur in the oil-gas itself, and were, therefore, looked for in the liquid bromide which, as already mentioned, was separated by steam distillation from the solid crotonylene tetrabromide. On fractioning this oil, the greater part was found to be ethylene bromide, but contained also propylene bromide. A relatively small quantity of oil of higher boiling point was present, and in order to test this for butylene, it was oxidised with permanganate, and the product examined by Linnemann's method (*Annalen*, 160, 222) for propionic acid. Nothing but acetic and formic acids were, however, discovered. The presence of butylene in oil-gas is, therefore, very doubtful, and the authors are of opinion that the substance discovered by Faraday amongst the oil-gas products, and thought by him to be butylene, was really crotonylene.

IV. Hydrocarbons insoluble in Sulphuric Acid.—The method of separating these from other hydrocarbons has been mentioned above. They are contained almost exclusively in the higher fractions (boiling above 150°) of the steam distillate from the oil-gas tar. The composition of the different fractions (from 160° to 205°) agrees closely with the general formula C_nH_{2n} , and the density determinations also agree approximately with those given by Markownikoff and Oglobine (*Ann. Chim. Phys.* 1884 [6], 2, 372) for the C_nH_{2n} hydrocarbon found in Russian petroleum. Hence the portion insoluble in sulphuric acid is probably a mixture of these with true paraffins.—A. K. M.

Naphthylhydrazines. E. Fischer. *Annalen*, **232**, 236—243.

α-Naphthylhydrazine.—50grms. of finely-powdered *α*-naphthylamine are mixed with 450grms. of hydrochloric acid (sp. gr. 1.1) and treated with the equivalent

quantity of sodium nitrite. The mixture is filtered and the dark-brown solution added to 250grms. of stannous chloride dissolved in cold hydrochloric acid. The mass is then warmed until the greater part of the precipitate dissolves and a nearly colourless solution is obtained. On cooling, hydrazine hydrochloride is deposited as a crystalline mass, and on adding sodium hydroxide to a hot aqueous solution of the hydrochloride, hydrazine is obtained, which may be purified by recrystallisation from alcohol and ether, and rapid crystallisation from hot water. The base boils at 203°, melts at 116–117°, forms laminar sparingly soluble in ether and alcohol, but readily soluble in benzene and chloroform. Crystallisable salts are formed with mineral acids (the acetate is decomposed by water). Naphthylhydrazine closely resembles phenylhydrazine in its reactions. With pyroacetic acid it yields *α*-naphthylhydrazinepyroacetic acid $C_{10}H_7N_2H \cdot C(CH_3)(CO_2H)$, forming yellow needles melting at 159°; with acetone, *acetone-α*-naphthylhydrazine $C_{10}H_7N_2H \cdot C(CH_3)_2$, crystallising in colourless masses melting at 74°—insoluble in water, readily soluble in alcohol, ether, acetone, and benzene. *Diazonaphthalenimine* appears to be formed when dilute nitrous acid is added to the base. *β*-naphthylhydrazine prepared like the *α*-compound melts at 124–125°, crystallises in laminar, is sparingly soluble in ether, but dissolves freely in hot alcohol, benzene, and chloroform. It oxidises less readily on exposure to the air than the *α*-compound, and forms crystallisable salts exhibiting the same properties as the *α*-derivative.—D. B.

Action of Sulphuric Acid on Durene, and Formation of a New Tetramethylbenzene. O. Jacobsen. Ber. 19, 1209–1217.

In continuing his researches on durene (this Journal, 1886, 25), the author found that by the action of sulphuric acid only a small proportion of the hydrocarbon is converted into duresulphonic acid, hexamethylbenzene and the sulphonic acids of liquid hydrocarbons being formed. After converting the sodium sulphonates into the corresponding sulphonamides the latter were subjected to fractional crystallisation from alcohol, the following compounds being obtained: (1.) An amide melting at 187° and crystallising in prisms with a vitreous lustre, sparingly soluble in alcohol. (2.) An amide melting at 170–172° and crystallising in needles more readily soluble in alcohol. (3.) An amide readily soluble in alcohol melting at 110–116°, and resembling 1:2:3 metaxylenesulphonamide. On heating these compounds with hydrochloric acid at 170–180°, the least soluble amide yielded a liquid hydrocarbon which was found to be a new tetramethylbenzene. The more soluble amides yielded exclusively pseudocumene.

Prehnitene $C_6H_4(CH_3)_4$ [$CH_3 : CH_3 : CH_3 : CH_3 = 1 : 2 : 3 : 4$] is a liquid hydrocarbon boiling at 204°. At a low temperature it solidifies to a crystalline mass which melts at –4°. *Dibromoprehnitene* $C_{10}H_8Br_2$ is sparingly soluble in alcohol, readily soluble in toluene. It crystallises in long colourless prisms melting at 210°. *Dinitroprehnitene* $C_{10}H_6(NO_2)_2$ crystallises from alcohol in yellowish-white prisms having a vitreous lustre, sparingly soluble in cold, readily soluble in hot alcohol. It melts at 178°. *Prehnitene-sulphonic acid* $C_{10}H_7SO_3H$ is obtained by dissolving the hydrocarbon in warm sulphuric acid. The barium and sodium salts are also described. The *sulphonamide* $C_{10}H_7SO_2NH_2$ forms small prisms melting at 187°. *Prehnitylic acid* $C_6H_4(CH_3)_4CO_2H$ is formed by the action of dilute nitric acid on prehnitene. It crystallises from alcohol in long transparent prisms having a vitreous lustre and melting at 167.5°. The *calcium salt* $[C_6H_4(CH_3)_4CO_2]_2Ca (+4H_2O)$ is described. When distilled with an excess of lime it yields a hydrocarbon boiling at 170°, which proved to be hemellithene. Prehnitylic acid is therefore a mono-carboxylic acid of hemellithene of the constitution $C_6H_4(CH_3)_4COOH$.—D. B.

Pseudocumene- and Bromopseudocumene-sulphonic Acids. O. Jacobsen. Ber. 19, 1218–1223.

Monobromopseudocumene-sulphonic acid $C_6H_4(CH_3)_2SO_3H.Br$ [1:3:4:5:6] is formed by sulphonating pure crystallised monobromopseudocumene. The sodium salt is sparingly soluble in cold water, and crystallises in flat needles or scales with a vitreous lustre. The calcium salt forms fine needles sparingly soluble in water. The sulphonamide is almost insoluble in water and crystallises from alcohol in needles melting at 186°. *Pseudocumene-sulphonic acid* $C_6H_4(CH_3)_3SO_3H$ [1:3:4:5] is obtained by reducing the sodium salt of the preceding sulphonic acid with ammonia and zinc dust. The barium and sodium salts are described. The *sulphonamide* $C_6H_4(CH_3)_3(SO_2NH_2)$ [1:3:4:5] is readily soluble in alcohol and crystallises in thin prisms melting at 172°. *Pseudocumenol* $C_6H_4(CH_3)_3OH$ [1:3:4:5] is formed by fusing sodium pseudocumenesulphonate with caustic potash. It crystallises in long prisms, melts at 95°, and boils at 230–231°. *Dibromopseudocumene* crystallises from hot alcohol in beautiful long yellowish-white needles melting at 152°. *Dibromopseudocumene* $C_6H_4(CH_3)_2Br_2$ [1:3:4:5:6] is obtained by further bromination of the mono-derivative. A mixture of mono, di- and tribromopseudocumene is formed, from which the dibromo-compound is separated by fractional distillation and crystallisation from alcohol. It melts at 63–64° and boils at 293–294°. *Dibromopseudocumene-sulphonic acid* $C_6H_4(CH_3)_2Br_2SO_3H$ [1:3:4:5:6:2] is obtained by heating dibromopseudocumene with sulphuryl monochlorhydride. A mixture of tribromopseudocumene and dibromopseudocumenesulphonic acids is formed, which is treated with alcoholic soda lye and boiled with a large quantity of water. Tribromopseudocumene remains in the residue, whilst sodium dibromopseudocumenesulphonate crystallises out, the mother-liquors on evaporation yielding the mono-bromo-compound. The sodium and barium salts were prepared. The sulphonamide crystallises from hot alcohol in slender rhombic laminar. By treating the sodium salt with ammonia and zinc dust, *sodium pseudocumene-sulphonate* $C_6H_4(CH_3)_3SO_3Na$ [1:3:4:2] is obtained. It is readily soluble in water and crystallises in flat needles. Its *sulphonamide* $C_6H_4(CH_3)_3(SO_2NH_2)$ [1:3:4:2] is identical with the second pseudocumenesulphonamide obtained from durene. It forms needles melting at 113°, and yields pure pseudocumene when heated with hydrochloric acid at 170°. The *pseudocumenol* $C_6H_4(CH_3)_3OH$ [1:3:4:2] obtained by fusing the sodium salt with potash, is a solid substance which crystallises in long needles. It gives no colour reaction with ferric chloride, melts at 62° and boils at 232–234°. The *sodium monobromopseudocumenesulphonate* $C_6H_4(CH_3)_2Br.SO_3Na + \frac{1}{2}H_2O$ [1:3:4:5:2] obtained from dibromopseudocumene together with the salt of the dibrominated acid, crystallises in scales of pearly lustre. The sulphonamide is readily soluble in alcohol, and forms long needles melting at 158°. By debrominating the sodium salt the corresponding salt of pseudocumenesulphonic acid is obtained. Its sulphonamide melts at 113°, and yields a liquid monobromopseudocumene when heated with hydrochloric acid at 170°. This compound boils at 236–238°, and does not solidify at –10° to –15°.

—D. B.

Improvements in Coke Ovens and in Methods of and Apparatus for Collecting the Products of Combustion from such Coke Ovens. A. M. Chambers and T. Smith, York. Eng. Pat. 7358, June 16, 1885. 8d.

IMPROVEMENTS in the ovens and apparatus described in a previous patent (No. 4708, March 11, 1884; this Journal, 1885, 49). A fire-clay pipe is arranged round the upper part of the oven close to the fire-brick lining of the same, so that it becomes sufficiently highly heated, and one of the ends of this pipe is brought forward and connected with an air-supply pipe arranged in front of the oven, into which air is forced at a moderate pressure. The inner end of the pipe, after passing round the oven, is directed inwards through the front wall of

the oven and slightly upward, so that the current of heated air forced in is directed upward across the oven without coming into contact with the surface of the coking coal. By this arrangement gas is not admitted into the oven, as the heated air forced through the pipe into its upper part is sufficient to carry on the carbonising process. Novel arrangements relating to the different parts of the apparatus for condensing, washing and separating the products of distillation are described also in the specification.—D. B.

Improvements in Apparatus for Distilling Shale or other Mineral Oil or Petroleum. N. M. Henderson, Broxburn. Eng. Pat. 13,014, October 29, 1885. 8d.

IN treating crude oils obtained by the destructive distillation of shale or similar substances, an apparatus of the kind described in Patent 540, of 1883, is employed (this Journal, 1883, 474) with the following modifications:—The apparatus consists of a primary still which is connected with two secondary stills, one on each side. Each of the secondary stills is again connected by pipes and valves with two or more coking stills, which are used in rotation, one being cleaned whilst the other is in use. In the primary still the oil enters by a vertical feed-pipe dipping just below the surface of the oil, whilst in each secondary still the oil enters by a horizontal pipe situated at a short distance above the top of the concavity of the still bottom, the pipe entering one end of the still and delivering the oil near the other end. As the volatile part of the oil is distilled off, the remaining oil becoming heavier descends to the deep sides of the bottom of the still, the fresh oil continually fed in being lighter and remaining at the top. The deep bottoms communicate through outlet valves with external piping, which has branches leading up to the feed-pipes of the secondary stills. The latter are subjected to a higher heat than the primary stills. From the deep sides of the secondary stills the heavier oil passes off to external piping and to one or other of the coking stills.—D. B.

Improvements in Apparatus and Arrangements for Distilling Mineral Oils. W. M. Fraser, Mid Calder. Eng. Pat. 4094, March 24, 1886. 6d.

THE object of this invention is to simplify and improve the existing processes for distilling oils more especially in their crude state as obtained from the retorts and when fractionation is not required. In the improved apparatus the oil is operated upon continuously, so that increased quantities may be attacked with apparatus of diminished cost and with reduced working expenses. The heat for the distilling apparatus is supplied by a furnace of the form described in a previous patent obtained by the inventor (No. 15,686 of 1885). The main part of the improved distilling apparatus is a horizontal cylindrical vessel supported and enclosed with brickwork constructed with suitable heating flues. The arrangement of these flues cannot be described without reference to the drawings which accompany the specification; they are, however, so constructed that the apparatus is said to be rendered free from the liability which exists in ordinary stills for coke or residuary carbonaceous matter to be deposited on the bottom.—D. B.

IV.—COLOURING MATTERS AND DYES.

Amidodiphenylsulphonic Acid and Azo-dyes from Diphenyl. Thomas Carmelley and James Schleselman. J. Chem. Soc. (Trans.), 1886, 380—383.

Two methods may be adopted in the preparation of dyestuffs from diphenyl. (1) The combination of a hydroxydiphenyl or its sulphonic acid with a diazo-compound, thus:— $C_{12}H_{10}(OH).N:N.X.SO_3H$ or $C_{12}H_9(SO_3H)(OH).N:N.X$, etc.; (2) the sulphonation of amidodiphenyl, diazotisation of the resulting amidodiphenylsulphonic acid, and combination of the diazo-sulphonic acid with a phenol, amido-compound, etc.,

thus:— $C_{12}H_9(SO_3H).N:N.X.OH$. Of the two methods the latter only gave good results. By conversion into the nitro-compound, and subsequent reduction with nascent hydrogen 60grms. of pure diphenyl, melting at 70.5°, gave 16grms. of pure paramidodiphenyl with the melting point 49°. The sulphonic acid $C_{12}H_9(NH_2).SO_3H$ (probably $NH_2.C_6H_4.C_6H_4.SO_3H = 1:4:1:4$) was prepared by heating one part of the amidodiphenyl with 4 parts of strong sulphuric acid to 130° for half-an-hour, and pouring the product into water. It melts above 300° with decomposition. The sodium and barium salts were prepared and analysed. The method of preparation of the dyes is as follows:—The sulphonic acid from 2grms. of amidodiphenyl, after admixture with 2cc. strong hydrochloric acid and 20cc. water, was diazotised by the addition, with frequent stirring, of 1gm. of potassium nitrite dissolved in 3cc. of water. A cold alkaline solution of the phenol was then added gradually with constant stirring.

Sodium phenolparadiazodiphenylsulphonate—

forms an amber-coloured precipitate soluble in warm water; it dyes wool and silk a brilliant yellow, imparts an amber shade to raw jute, but has no affinity for bleached jute yarn. *Sodium resorcinolparadiazodiphenylsulphonate*, $(HO)_2C_6H_3.N:N.C_{12}H_8.SO_3Na$, is a deep brick red precipitate which becomes yellowish brown on drying. It dissolves readily in hot water, and dyes silk, wool, and raw jute a beautiful orange, but has little affinity for bleached jute. *Sodium quinolparadiazodiphenylsulphonate*, $(HO)_2C_6H_3.N:N.C_{12}H_8.SO_3Na$, dissolves easily in cold water and is not precipitated even by salt. It dyes silk and raw jute a golden amber. *Sodium a-naphtholparadiazodiphenylsulphonate—*

is a very deep red precipitate fairly soluble even in cold water. It dyes silk, wool and raw jute a deep reddish brown. *Sodium β-naphtholparadiazodiphenylsulphonate*, $HO.C_{10}H_7.N:N.C_{12}H_8.SO_3Na$, is a bright red precipitate soluble in hot water. It dyes silk, wool and raw jute a very brilliant red, and bleached jute yarn a reddish pink shade. The barium salts of these dyes were prepared and analysed. All the above dyes are fast colours on wool and silk, and are not affected by boiling water, or a boiling half per cent. soap solution, except the yellow dye from phenol, which becomes slightly paler, and the dye from a-naphthol, which becomes a purer brown.—S. Y.

Nitration of Dimethylaniline. E. Nörling. Ber. 19, 545.

THE present paper confirms results obtained by Groll (Ber. 19, 198, and this Journal, 1886, 319)—viz., on nitrifying dimethylaniline, a para- and a meta-nitro-compound are formed. The author in his previous investigation on this subject had omitted to neutralise the mother-liquor from which the para-compound separates, and which contained the whole of the meta-derivative in the form of a nitric acid salt.—J. B. C.

Isomeric a-Naphthylaminesulphonic Acids. O. N. Witt. Ber. 19, 573.

IF a-naphthylamine be treated with sulphuric acid, a sulphonic acid corresponding to that first obtained by Piria results. If, on the other hand, the hydrochloride of a-naphthylamine be added in small portions at a time to fuming sulphuric acid (20—25 per cent. SO_3) and cooled, an acid is obtained, the sodium salt of which is four times as soluble in water as Piria's naphthionic acid. Its several reactions with metallic salts indicate that a new acid is present, to which the author gives the name of naphthalidinesulphonic acid. The azo-derivative with β-naphthol, corresponding to roccelin, is of a less yellow shade, and much less soluble in water. The author has prepared Cleve's naphthylaminesulphonic acid by reducing the nitrosulphonic acid, and finds that

although exceedingly like in properties to his naphthalidenesulphonic acid, identity has not been established. For the acid of Cleve, the author suggests the name of amidonaphthalenesulphonic acid. To determine the constitution of these isomerides, Cleve acted upon naphthionic acid with PCl_5 and obtained β -dichloronaphthalene (melting-point 67.5°), to which the position $\alpha_1 \alpha_2$ has been given. As the same amidonaphthalenesulphonic acid is obtained from a nitro-compound prepared by nitrifying α -naphthalenesulphonic acid, or by sulphoning naphthalene, it is probable that both side chains are in the α position. As the positions $\alpha_1 \alpha_2$ are attached to naphthionic acid, the latter sulphonic acid must contain side chains in two rings as follows:— $(\text{SO}_3\text{H} : \text{NH}_2 = 1 : 4)$ and $(\text{SO}_3\text{H} : \text{NH}_2 = 1' : 4)$ —naphthionic acid and amidonaphthalenesulphonic acid. The constitution of the third isomeride naphthalidinesulphonic acid, is not definitely settled.—J. B. C.

Colouring Matters from Furfuraldehyde. Hugo Schiff. Ber. 19, 847—849.

ON warming β -naphthylamine with furfuraldehyde, the compound β -furfuronaphthylamine $\text{C}_{15}\text{H}_{17}\text{N} : \text{CH}_2\text{C}_4\text{H}_3\text{O}_2$ is formed, which crystallises from alcohol in colourless glittering plates, melting at 85° . The hydrochloride forms golden-yellow needles, soluble in alcohol with a deep red colour. The author has proved that *secondary*, as well as *primary*, aromatic bases are capable of yielding colour-forming bases with furfuraldehyde, giving as an example, the methylaniline compound—

the hydrochloride of which forms fine violet crystals, melting at 94° . *Tertiary* aromatic bases, however, do not directly react with furfuraldehyde. Two different bases can combine at one and the same time with furfuraldehyde, such as primary and secondary bases, or monamines and diamines, the following bodies being thus obtained:—*Monomethylanilinefurfuraniline hydrochloride*—

Toluylenediaminedifurfuraniline hydrochloride—

These and similar bodies dissolve in alcohol with red to bluish-violet colourations, their crystals having a bronzy metallic appearance similar to that possessed by magenta. Compounds resembling these mixed bodies, obtained from different bases with furfuraldehyde in the presence of hydrochloric acid, are also obtained from the aniline salts of aromatic amido-acids, the necessary acid for the reaction being supplied by the amido-acid itself; thus from aniline naphthionate the body

anilinefurfuronaphthionate is formed. Neither pyromucic acid, pyromucamide, anilinepyromucate, furfurine, nor pyromucanilide (melting-point 123.5°) form, with aromatic bases or amido-acids, any colouring matters, but the reverse is the case with thiofurfuraldehyde and hydrofurfuramide. The reaction takes place therefore solely in the aldehyde group, the doubly united oxygen molecule being replaced by two aromatic basic groups.

—T. L. B.

Benzenetrisulphonic Acid. C. Loring Jackson and John F. Wing. Ber. 19, 898—902.

FIVE parts of potassium benzene-meta-disulphonate (or of the monosulphonate) are mixed in a porcelain dish with six parts of ordinary strong sulphuric acid, and gently heated till the salt has dissolved and the water of crystallisation has evaporated; heavy white vapours of sulphuric acid then begin to be evolved, and soon the mass becomes pasty and swells up. The reaction is then

finished, and the dark mass at once is dissolved in water, the sulphuric acid neutralised with barium carbonate, and the potash salt of the trisulphonic acid formed, evaporated down and crystallised. Experiment shows that the formation of the trisulphonic acid is due to the action of the acid potassium sulphate; aluminium sulphate acts in a similar manner, but less satisfactorily. By heating the potash salt with three molecules of potassium cyanide, a nitril was obtained, which, on saponification, produced *trimesic acid*, $\text{C}_6\text{H}_2(\text{COOH})_3$. Fusion with caustic soda gave *phloroglucinol*. This benzenetrisulphonic acid possesses, therefore, symmetrical (1.3.5) constitution.—T. L. B.

On the Action of Sodium on Tribenzylamine. C. Loring Jackson and John F. Wing. Ber. 19, 900—902.

DRY tribenzylamine, mixed with rather more than half its weight of sodium, was heated in a retort on a paraffin bath. The sodium began at 150 — 160° to assume an intense purple colouration, which reached its maximum at 190 — 200° , at which temperature the mixture was heated for two or three hours. During the operation a hydrocarbon distilled over, which was found to consist of *toluene* mixed with about 8 to 10 per cent. of *benzene*. The distillate amounted to 48 to 56 per cent. of the weight of tribenzylamine used. The residue in the retort, besides unattacked sodium and tribenzylamine, consisted of *sodium cyanide* (amounting to 25 per cent. of the total yield), *lephim*, and *blue* and *brown* colouring matters.—T. L. B.

The Eurlhodines. Otto, N. Witt. Ber. 19, 914—918.

BY the action of nitrite of amyl on eurlhodine, a substance was obtained melting at 156° , which possessed the unmistakable character of a quinoxaline (comp. this Journal, 1886, 320), but differed in its properties from that obtained by Hinsberg, which melts at 139 — 142° . On repeating the experiment with ethyl nitrite, a substance was obtained which melted at 175° . This difference in the result led to the idea that the alcohol radical had entered into the molecule of the new compound. The analysis of the substance fully confirmed this, the body being the *ethyl ether* of an eurlhodol, $\text{C}_{17}\text{H}_{11}\text{N}_2\text{O} \cdot \text{C}_2\text{H}_5$. It is a very similar substance to eurlhodine. Crystallised from alcohol and glacial acetic acid, it forms brilliant pale lemon-yellow needles, soluble in sulphuric acid with a carmine-red colour; hydrochloric acid dissolves it, yielding a deep orange colouration, and from the solution the hydrochloride slowly crystallises in reddish-brown plates. It is very difficult to saponify this substance, alcoholic potash even at high temperatures being almost without action on it, and strong acids acting but slowly. When orthotoluylenediamine is oxidised in alkaline solution with α -naphthol, a blue substance belonging to the indophenol group is obtained; but with β -naphthol the reaction is quite different. A dark tarry precipitate is in the latter case obtained, which is extracted with dilute hot hydrochloric acid, leaving a red matter undissolved. On cooling the deep-yellow solution, the hydrochloride of the new base is obtained, liberated by ammonia and recrystallised from alcoholic glacial acetic acid, or toluene. The quinoxaline thus obtained is formed according to the equation—

It forms pale straw-coloured needles, melting at 179.8° , and distilling at a higher temperature. Sulphuric acid dissolves it with a violet colouration; hydrochloric acid forms a yellow hydrochloride, nitric acid converts it into a characteristic nitro-compound. With fuming sulphuric acid a well-crystallised sulphonic acid is formed. There are theoretically possible two isomeric ortho-quinones derived from naphthalene, and consequently two corresponding isomeric naphthylenetoluin-

oxalines. That obtained by Hinsberg corresponds to the formula—

Therefore the new body must correspond to the other possible formula—

and is therefore to be described as β,β -naphthylenetoluquinocoline.—T. L. B.

α -Naphtholdisulphonic Acid and α -Naphthotrisulphonic Acid. A. Claus and P. Mieleke. Ber. 19, 1182—1187.

ACCORDING to Schultze, a mixture of the di- and trisulphonic acids of α -naphthol is formed when the latter is treated with fuming sulphuric acid. These are best separated by conversion into chlorides by treating the dried mixture of potassium salts with phosphorus pentachloride. α -Naphtholdisulphonic chloride is easily soluble in ether, whilst the chloride of the trisulphonic acid is only very slightly soluble, and the greater portion remains as a yellow horny mass.

α -Naphtholdisulphonic chloride forms a bright reddish-brown syrup, which cannot in any way be made to crystallise.

α -Naphthotrisulphonic chloride forms, on recrystallisation from chloroform, small brilliant colourless crystalline plates, which are easily soluble in chloroform, benzene, and glacial acetic acid, sparingly so in ether and quite insoluble in alcohol. It does not melt without decomposition.

The position of the sulphonic-groups in the α -naphthol ring not having been satisfactorily determined, the authors have again investigated their position.

Tetrachloronaphthalene was obtained from the disulphonic chloride by treatment with 3mols. phosphorus pentachloride for some hours at 170–180° C. It forms colourless needles, melts at 82°, and is identical with Faust and Saane's tetrachloronaphthalene, prepared by decomposing α -chloronaphthalenetetrachloride with alcoholic potash.

Tetrachloronaphthalene was prepared from α -naphthotrisulphonic acid, by treatment with phosphorus pentachloride at 210–220° C. in sealed tubes for 1½ hour, and then for 1 hour at 250° C. It forms colourless groups of needles, which melt at 140° C. To determine the constitution of this tetrachloronaphthalene it was oxidised to the quinone. This was obtained in yellow needles, and proved to be α -dichloro- α -naphthoquinone, with the constitution—

Chloroxynaphthoquinone was prepared from the quinone in the usual way. It forms beautiful yellow crystals, melting at 215°.

Dichloronaphthoquinoneanilide forms violet-red crystals, which melt at 203°.

From these derivatives there can be no doubt that the tetrachloronaphthalene has the constitution 1:2:3:4, and that α -naphthotrisulphonic acid is

On oxidising tetrachloronaphthalene, phthalic acid was obtained, and not the chlorinated acid, and the author concludes that the oxidation of naphthalene derivatives does not always take place in the same manner.

On heating α -naphthotrisulphonic acid with large excess of PCl_5 , perchloronaphthalene, C_{10}Cl_4 , is obtained, which crystallises in small colourless needles, melting at 202°.—G. H. M.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Improvements relating to the Preparation of Animal Fibres for Felting. H. H. Lake, London. From John Thomas Waring, New York. Complete Specification. Eng. Pat. 4474, March 30, 1886. 4d.

IN order to increase the felting property of animal fibre, the inventor exposes the fibre to sulphurous acid gas in a suitable chamber. A special feature of the invention is the treatment of felt hat bodies, after being "formed," but prior to felting operations, with sulphurous acid.

—B. H.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

An Improved Method of Purifying and Decolouring the Water in which Silk and other Fibrous Materials have been Boiled, &c. E. Taylor, Rochdale. Eng. Pat. 6331, May 23, 1885. 8d.

THE waste liquor from silk dressing, or other analogous processes, containing soap and fat, is run into a vat and treated with gaseous chlorine, which precipitates the fatty matters.—C. C. H.

Improvements in the Manufacture of Blood Albumen. Thorsten Nordenfjelt, Westminster. Eng. Pat. 7462, June 18, 1885. 6d.

THE blood is first stirred or whisked to remove fibrine, and then carefully filtered. 100 to 1000gms. sugar dissolved in blood, and a similar quantity of a pure volatile oil (e.g., paraffin), are carefully mixed with 100kilo. blood. The sugar acts as a preservative, and the volatile oil makes the serum clear and almost colourless. The blood is slowly poured into a centrifugal machine, such as is now used for separating cream from milk. The serum is then concentrated, preferably *in vacuo*, and the final drying done in flat vessels, care being taken that the temperature never exceeds 45–50° C. By this process 80 per cent. of serum can be obtained yielding albumen of first quality only.—B. H.

VII.—ACIDS, ALKALIS, AND SALTS.

The Manufacture of Sulphuric Acid from Pyrites at New Moldova (South Hungary). Berg. u. Hüttem. Zeit. 45, 97.

THE nitric vapours are mixed with the sulphur gases in the flue leading from the kilns to the chambers. The works have no Glover tower, and therefore denitrate their nitrous vitriol by means of steam in drums lined with acid-proof bricks. The chamber acid is concentrated both in leaden pans and platinum still. Copper sulphate is prepared as follows:—Granulated copper containing from 0.3 to 0.5 per cent. of silver is treated in a large tank with sulphuric acid, of 25° B. at 60° C., and the copper solution thus obtained run into leaden pans. Here the silver settles out, and the warm liquor is allowed to crystallise in narrow wooden vessels. This crude salt is washed and refined by recrystallising. The

argentiferous deposit in the leaden pans, which contains from 3 to 4 per cent. of silver, is sold to silver refining works.—S. H.

Manufacture of Sulphocyanides. R. Gasch. Chem. Zeit. 10, 274.

THE sulphocyanides are daily finding increased application in the dyeing industry. A large source of sulphocyanides are the coke-ovens, from which ammonia and tar are condensed and utilised. It is well known that ammonium cyanide, formed in the gas manufacture, is the basis of the cyanogen compounds produced at the expense of the ammonia. Cyanide of ammonium is a readily volatile salt, and is carried forward along the pipes leading from the retorts of the gas-factory, together with sulphuretted hydrogen, decomposing partly with formation of sulphocyanide of ammonium, partly in presence of soluble ferrous salts into ferrocyanides. A portion remains undecomposed.

Thorough condensation prevents the formation, to any large extent, of sulphocyanides. As might be expected, the quantities of these substances contained in the ammoniacal-liquor vary considerably. The presence of these three compounds adds to the difficulty of producing pure sulphocyanide of ammonium by crystallisation. A further impediment in the manufacture was the working up of the weak liquors (1-3° B.) of the ammonia works, and the precipitation of these weak liquors by copper salt, as well as the difficulty of decomposing the insoluble copper sulphocyanide. The method has been simplified by using liquors of 8-11° B., as raw material, whereby the precipitation of the sulphocyanide with copper has become unnecessary, and by a simple operation a concentrated sulphocyanide liquor is obtained. The production from these sources has reduced the price of the salt to about £7 10s. per 100kiles.—J. B. C.

Danger of Fire through Nitric Acid. G. Lechartier. Compt. Rend. 102, 539-541.

THE author shows that when concentrated nitric acid (sp. gr. 1.5-1.51) acts upon organic substances—as, for instance, straw used for packing carboys—sufficient heat is produced to set them on fire.—D. B.

The Utilisation and Method of using Liquid Hydrocarbons as Carbonising and Neutralising Agents in the Alkali Processes, and for reducing Pyrites. B. H. Thwaite and J. Pedder, Trammere, Cheshire, and Widnes. Eng. Pat. 5514, May 5, 1885. 6d.

THE inventors claim the use of and methods of using mineral hydrocarbon for certain processes as above stated. An abstract is insufficient to make clear the aims of this patent. It will suffice to reproduce one proposition by the patentees:—"We may mix the mineral oil, soda ash (defined as Na_2SO_4), and calcic carbonate or quicklime together, and dissolve them in water at a temperature of say 200° F., and pass a powerful electric current through the solution, in order to displace wholly or partially the sulphur of the Na_2SO_4 by the carbon of the oil. The lime and sulphur combining to form an insoluble precipitate, we run off the supernatant solution and allow it to crystallise."—W. S.

Improvements in the Production of Soluble Phosphates of the Alkalis in the Manufacture of Steel and Iron. T. Twynam, Middlesboro'. Eng. Pat. 6866, June 5, 1885. 6d.

THE inventor aims at the production of soluble alkaline phosphates from phosphatic slags produced in the manufacture of steel or iron, when an alkaline salt has been added in the converter for the purpose of eliminating the phosphorus during the conversion of the phosphatic pig into iron or steel. The phosphoric acid in these slags exists largely in a form insoluble in water, and in order to convert it into a soluble phosphate it is fused with an additional amount of an alkaline salt—the carbonate,

hydrate, or sulphate (the first is preferable)—in a basic lined open hearth furnace or cupola. The soluble alkaline phosphate thus formed can be dissolved out in water and obtained practically pure by evaporation and crystallisation, or the solution may be treated to form precipitated lime phosphate and an alkaline hydrate or carbonate.—S. H.

An Improved Process or Method of Producing Hydrate or Carbonate of Strontium or of Barium. E. F. Trachsel, London. Eng. Pat. 7136, June 11, 1885. 6d.

THE object of this invention is the conversion of strontium or barium sulphate into the hydrate or carbonate of these bases. The result is obtained by means of caustic soda or potash or sodium and potassium carbonate, which are used repeatedly and reconverted throughout the process. Strontium or barium sulphate mixed with coal are calcined in a reducing flame to convert the sulphate into sulphide. The latter is lixiviated with hot water, and the sulphide solution treated with an equivalent quantity of caustic alkali, whereby a deposit of strontium hydrate and a solution of an alkaline sulphide is obtained, as follows:—

Or by using half the amount of caustic alkali, thus—

The strontium hydrate crystallises out partly during the treatment and partly on cooling. The alkaline sulphide or sulphhydrate solution is easily converted into the carbonate by carbonic acid, and the carbonate is causticised by lime, and the hydrate solution thus obtained again applied to the decomposition of strontium sulphide. To obtain strontium carbonate the sulphide solution is treated with sodium carbonate, thus—

and the sodium sulphide solution is converted into carbonate as above described. In the case of barium the treatment and the reactions are analogous.—S. H.

An Improved Process of Producing Chlorine, and Chlorine and Ammonia. B. Mills. London. From Verein für Chem. Industrie, Mainz, Germany. Eng. Pat. 3322, March 9, 1886. 4d.

THE invention relates to the production, on the dry system, of chlorine, or of chlorine and ammonia, by passing vapours containing chlorine in combination over metallic oxides at a high temperature. Ammonium chloride vapours are passed over any oxidation grade of manganese at a temperature not reaching red heat. If protoxide of manganese be used, the reaction is shown by the equation— $\text{MnO} + 2\text{NH}_4\text{Cl} = \text{MnCl}_2 + 2\text{NH}_3 + \text{H}_2\text{O}$. If now air be passed over the resulting manganese chloride, manganese oxide and chlorine are obtained thus— $\text{MnCl}_2 + \text{O} = \text{MnO} + 2\text{Cl}$. In place of ammonium chloride vapours, gases containing hydrochloric acid may be passed over the manganese compounds with equal effect, thus—(1) $\text{MnO} + 2\text{HCl} = \text{MnCl}_2 + \text{H}_2\text{O}$; and (2) $\text{MnCl}_2 + \text{O} = \text{MnO} + \text{Cl}_2$. In the same manner oxygen combinations of other metals possessing several oxidation grades may be employed, as well as other volatile chlorine compounds.—S. H.

Improvements in Apparatus for Distilling Ammoniacal Liquor for the purpose of Producing Sulphate of Ammonia. A. Dempster, Elland, Yorkshire. Eng. Pat. 3220, March 8, 1886. 8d.

THE improvements in such apparatus relate (1) to heating the sulphuric acid in the saturator and the ammoniacal liquor in the feed tank by means of the noxious gases generated in the saturator; (2) to constructing the still with a decomposing chamber under the fire-box for getting off the fixed ammonia, the milk of lime in this chamber being agitated by ammoniacal gases instead of steam as is usual; (3) to providing the still with a

diaphragm in order to concentrate the ammoniacal gases ; (4) to drawing air along with the noxious gases through the purifier ; and (5) to employing a vertical rod

charged through a coiled lead pipe E, the noxious vapours being passed off by means of pipe F. But in order to heat the sulphuric acid they again return

for actuating several valves simultaneously. In the drawing the pipe D carries the ammonia gases given off in the still A to the saturator B, where they are dis-

through pipe C, which is immersed in the sulphuric acid, and ultimately pass out through *d* into F. The ammoniacal liquor is introduced into the liquor feed tank

H, which being narrower than the still A forms an annular space, which is heated by the waste gases from the pipe F. The decomposing chamber is shown at K, in which is placed the milk of lime, the ammoniacal gases passing down the pipe L, and after the fixed ammonia has been liberated the gases return through the pipe N. The still itself is divided by a perforated diaphragm plate W, so that as the gases arise and impinge against it, the steam is partially condensed, and consequently the strength of the ammoniacal vapours increased. The pipe J carries the noxious gases to the purifier C, which is connected with the furnace and flue of the chimney by the pipe R; the draught of the chimney draws the noxious gases along with atmospheric air through the oxide of iron deposited in the purifier, thereby continuously revivifying the oxide. Lastly, a vertical rod S is connected by levers *j* with the valves *m, g, h, n* and the toothed segment T, which is in gear with the worm U. By operating the latter the whole series of valves can be regulated simultaneously.

—S. H.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

An Improved Fire-resisting Cement. W. Montgomery, Newcastle-on-Tyne. Eng. Pat. 6025, May 16, 1885. 6d.

THIS cement is prepared in two parts—one as a powder, the other as a paste. The powder is composed of finely-ground porcelain or pottery waste (about 50 per cent.), finely-ground and long-kept Portland cement (about 40 per cent.), and ground red lead (about 10 per cent.). The paste is formed of very finely-ground porcelain or pottery waste, with about five per cent. of finely-ground plumbago; the water used in making this mixture into a paste contains a flux, such as borax, and a small proportion of silicate of soda. The proportions of the two parts are varied according to circumstances.—E. G. C.

Manufacture of Cement. W. Joy, Northfleet. Eng. Pat. 7189, June 12, 1885. 8d.

THIS invention relates to improvements in the manufacture of cement, consisting in means for ensuring the efficient distribution of the draught through the charge, in a cement kiln, loaded with layers of wet slurry and fuel, pipes or tubes, or bundles of faggots, or of sticks covered with readily-combustible materials, being so arranged as to form air-passages through the whole body of the charge. The cement kilns are built in two rows, back to back, and communicating at their upper parts with a flue between them and leading to a common chimney.—E. G. C.

Improvements in the Treatment of Stone in order to produce a Glazed Surface thereon. J. Matthew, Leeds. Eng. Pat. 8364, July 10, 1885. 6d.

TO produce a glazed surface upon certain classes of stones, rendering them impervious to moisture, the surface is first rubbed down smooth, a coating of any of the vitreous glazes well known to potters and glazed brick makers then applied, and the whole carefully fired in a kiln. The temperature of fusion of the glaze must be so low that the stone remains uninjured in the firing.

—C. C. H.

Improvements in the Manufacture of Artificial Stones and Concretes. A. C. Ponton, Viewfield Parkstone. Eng. Pat. 12,383, October 17, 1885. 6d.

THIS specification describes different methods of preparing artificial stone, the essential features of all of which are the combination of lime, either in solution or in a powdered state, with different varieties of silicates or siliceous materials. The materials are thoroughly incorporated or ground together with the addition of silicate of soda, or "powdered minerals or earthy matter of an inert character;" various salts of lime may be

added. The mixture is moulded into blocks, and dried by heat in ovens and hot sand baths, "to accelerate crystallisation." The prepared stone is stored in tanks containing lime water. Various other vitrifying materials are also described as useful.—C. C. H.

Improved System of Drying the Prepared Mixture of Raw Materials for the Manufacture of Portland Cement. C. Spackman, Leicestershire. Eng. Pat. 2659, February 24, 1886. 8d.

THE heated air, which has passed through the calcined cement, after the process of combustion in an intermittent kiln is completed, is utilised for the desiccation of a charge of raw material stacked in another kiln or kilns, ready for burning.—E. G. C.

X.—METALLURGY, Etc.

Action of Caustic Soda on Metals and Alloys. W. Venator. Chem. Zeit. 10, 319–321.

THE author has carried out the present series of investigations with the object of determining the nature of the action of caustic soda upon different qualities of iron, steel and other metals, and to what extent the action is due to impurities. Commercial caustic soda was used containing, as impurities, Na_2CO_3 1.85 per cent., NaCl 3.05 per cent., Na_2SO_4 .63 per cent., Fe_2O_3 and Al_2O_3 .11 per cent. A silver basin was used in which the metal and alkali were heated. No galvanic action occurred, and no atmospheric oxidation was found to influence the action when the metal was completely submerged in the alkali. The concentration of the alkali varied between 20 and 80 per cent. NaOH . The temperature was maintained just below boiling point of the lye. In other experiments the liquid was allowed to boil with inverted condenser. In other cases anhydrous soda was fused with the metal. The time of heating was generally 72 hours. The quantity of alkali was 2 kilos. The following are the metals tested:—Cast iron, wrought iron (two kinds), steel (two kinds), forged iron, brass, phosphor bronze, alloys of copper, tin, zinc and lead, lead and nickel. There was a strong action in the case of the different qualities of iron, steel and lead, whereas brass, phosphor bronze, nickel and the alloys of copper, tin, zinc and lead, and nickel were less attacked, and in some cases not at all. With copper scarcely any action could be detected. Phosphor bronze and nickel are little attacked. The action upon iron, steel, brass and lead were under similar conditions so different that no rule could be laid down. The action appears to depend upon the shape and surface of the metal; but more especially upon the structure and the kind of surface. Thus, for example, bright and rough-filed surfaces were more strongly attacked than when oxidised. Thin plates of steel were dissolved with evolution of hydrogen. Fine cast-iron borings were completely converted into ferric and ferrous oxide, the latter remaining in solution. The phosphoric acid also partly dissolves in the alkali, manganese is chiefly precipitated as oxide, carbon is to a great extent oxidised. All the qualities of iron evolved more or less hydrogen. With brass the action was almost entirely confined to the zinc and lead, so that a surface of copper remained. The intensity of the action depends on the percentage of the zinc in the alloy. Lead is oxidised, and dissolves in the alkali.—J. B. C.

On the Action of an Aqueous Solution of Carbonic Acid on Thomas-Slag. Chem. Zeit. 10, 531 and 584.

IF Thomas-slag in a very finely-powdered condition be treated with water containing carbonic acid, both phosphoric and silicic acids are readily dissolved. Reis experimented on a phosphatic slag which contained 16 per cent. phosphoric acid, and 8 per cent. silicic acid, and found that 6 litres of water, into which carbonic acid was passed, dissolved 5.8 per cent. phosphoric acid, and 3.5 per cent. silica. Meyer, independently from Reis, inves-

tigated the action of large amounts of carbonic acid water on a phosphatic slag, containing 22.2 per cent. phosphoric acid, and 54.0 per cent. lime. He treated 2 grms. of this slag with 8 litres of carbonic acid water, for 50 hours, and succeeded in dissolving 53.6 per cent. of the total phosphoric acid, and 57.8 per cent. of the total lime present. This result shows that carbonic acid does not act first on the caustic lime and afterwards on the calcium phosphate; but the action takes place simultaneously, and both constituents of the slag are dissolved in nearly equal proportions. This fact is very important in estimating the manurial value of powdered Thomas-slag.—S. H.

Improvements in Crucibles, Muffles, and other Refractory Apparatus. F. Maxwell Lyte, Putney. Eng. Pat. 4889, April 20, 1885. 6d.

MAGNESITE or other magnesium carbonate or oxide is calcined at a strong white heat, in order to ensure sufficient contraction, and thus prevent the subsequent cracking of the manufactured article. This operation should be repeated twice or thrice, the material being re-crushed and sieved after each roasting. The material is then mixed either with water alone, with a solution of a suitable magnesium salt (not sulphate), or with 6 to 10 per cent. of "heavy" magnesium hydroxide, or 10 to 15 per cent. of lightly-burnt magnesia and water, and fashioned into the required article, which may then be fired for use. The addition of sawdust or flour to the mixture increases the porosity; of powdered carbon, the refractoriness of the apparatus, which should be heated by astatki or gaseous fuel rather than by solid combustibles. When the finished apparatus is to be used in contact with fused metallic oxides, it should first be well glazed.—W. G. M.

Improvements in the Manufacture of Puddled Iron and Steel. Job Gilligan, Abertillery, Monmouthshire. Eng. Pat. 5140, April 25, 1885. 4d.

THROUGH holes in the side of a puddling furnace, a blast of air is allowed to act upon the molten metal until the latter begins to sink to the bed of the furnace, when the blast is shut off, and the metal balled in the usual way.—W. G. M.

Improvements in the Treatment of Pig Iron for Eliminating Impurities during the Process of its Conversion into Malleable Iron or Steel, also applicable for Analogous Purposes. Edward Fletcher, South Stockton-on-Tees, Yorkshire. Eng. Pat. 7802, June 26, 1885. 6d.

For a puddling furnace charge of 4½ cwt. of Cleveland pig, containing (say) 1.75 per cent. of phosphorus, a basic mixture of 4 lb. of lime, and 3 lb. each of soda and salt, is either mixed with the fettling of the furnace (which, however, it tends to break up), or preferably, therefore, with the flux of hammer scale, etc., introduced before the charge; or it is mixed with about 14 lb. of mill scale, and added to the melted metal, which then finally yields good merchantable bar.—W. G. M.

A New Bronze. J. P. Reitz, Bockenheim, Germany. Eng. Pat. 7880, June 29, 1885. 4d.

THIS is a bronze, resisting acids and alkalis. It is made by carefully fusing together 2.34 parts of tin, 1.82 parts of lead, and 1 part of antimony, and then adding them to 15 parts of melted copper.—W. G. M.

An Improved Process of Treating certain Descriptions of Auriferous and Argentiferous Material for the purpose of facilitating the Separation of the Metals contained therein. Elizabeth B. Parnell, Sydney, N.S.W. Eng. Pat. 3702, March 16, 1886. 4d.

THE (pyritous) ore is roasted at a temperature of 1100—1300° F., and then crushed and re-roasted at 1200—1600° F., when arsenic, antimony and some sulphur pass off with the gases, iron sulphide becomes peroxide, whilst the sulphides of silver, copper, manganese, nickel and

cobalt are sulphatised. These soluble sulphates are boiled with successive portions of water, until completely removed; the gold may then be extracted from the residue by amalgamation or chlorination, the valuable metals from the solution by precipitation. Additional oxygen, introduced in the roasting, shortens the time required for the operation.—W. G. M.

XI.—FATS OILS, AND SOAP MANUFACTURE.

The Manufacture of Mineral Lubricating Oils from Russian Petroleum Residues. Chem. Zeit. 10, 603—605, 618.

THE residues contain from 1 to 5 per cent. of water, and have a specific gravity of 0.905 to 0.912. To obtain from them light-coloured oils they must be carefully fractionated and refined, and as a high temperature of distillation would inevitably cause decomposition, the distillation must be assisted by means of superheated steam. The stills usually employed are represented in the drawings. They are made of wrought iron, and have a circular or elliptic cross-section. In starting an operation, the residues, which are previously warmed by a steam coil in a separate tank up to nearly 100° C., are run into the still, while the latter is very gradually heated up. The distillation in the beginning proceeds very turbulently owing to the presence of water, which cannot be removed completely by settling. At 130° C. to 140° C., a pretty regular ebullition sets in, and the distillate commences to come over at 150° C. to 160° C. At this stage superheated steam, free from any condensed water, is admitted (figs. 2 and 5 show the arrangement for superheating the steam), whereby the distillation is quickened. The first distillate stands at 0.840—0.860, and is used as an illuminating agent (*Helios oil*) in specially constructed lamps, it being too heavy for lamps of the usual construction. As soon as the distillate has the specific gravity of 0.870—0.880 it is separately collected and worked up for *light spindle oils*. A third fraction stands at 0.895—0.900, and is employed as *heavy spindle oil* and as a lubricating agent for gearing. The fourth fraction, specific gravity 0.908—0.912, is the largest in bulk, and is suitable for steam engines, whereas the last fraction, specific gravity 0.915—0.920, yields an excellent *cylinder oil*. This last fraction distils with great difficulty, and the fire must be carefully regulated to avoid decomposition. The pyrometer of the still shows the following temperatures for the different fractions:—I. 150—170° C.; II. 170—200° C.; III. 200—250° C.; IV. 250—300° C.; V. 300—320° C. The yield of the different oils is about as follows:—

I.	10—12.	Colour, light yellow.
II.	12—15	" yellow.
III.	8—10	" yellow.
IV.	30—33	" reddish-yellow.
V.	10—12	" red.
Residue	12—15	

After separating the distillates from the condensed water in the usual manner, they are completely deprived of the still adhering water by heating them by means of a steam coil. After some time the water collects at the bottom and is drawn off. They are then refined with sulphuric acid of 66° B. in lead-lined conical vessels. The acid is added by degrees, while the mass is continually stirred either by an air current or a mechanical agitator. This treatment is continued for one or two hours. Light oils require from 5 to 7 per cent. of sulphuric acid, whereas up to 12 per cent. is wanted for heavy oils. The mixture of acid and oil is then allowed to rest until all the acid has separated, which is usually the case after the lapse of 20 hours. Then follows the neutralisation of the acid oil, which is indeed the most difficult and delicate operation of the whole process. This is due to the fact that the oils contain a certain amount of slimy matter, which is saponified by the addition of alkalis, thus forming an emulsion, which obstinately prevents the clarification of the oils. Experience has shown that it is best to run at first only a small portion of a very dilute caustic soda solution into

the acid oil, agitating briskly and adding after a while the rest of the alkali in very dilute solution. After some time a sample is taken, and when the emulsion

found necessary to pass a current of warm air through the oil for the complete removal of the water, the presence of which causes a turbidity of the oil. In

and afterwards with water of 65° C., until it has a neutral reaction with phenolphthalein. The water is then allowed to settle and removed. Sometimes it is

Improvements in the Manufacture of Oleaginous Compounds to be employed for Batching Wool and other Fibrous Substances, and for other purposes. M. G. Coltart and J. Menzies. Eng. Pat. 3725, March 23, 1885, 6d.

CRUDE or refined seal, whale, or fish oil is treated successively with strong sulphuric acid, water, and caustic soda solution, and is then mixed with four times its weight of refined mineral lubricating oil. Solutions of magnesium and barium chlorides are then agitated with the mixed oils, and the product is applied in the ordinary batching machines, or sprinkled by hand.—W. L. C.

An Improved Process and Apparatus for Treatment of Greasy Waste preparatory to Bleaching. T. J. Hutchinson. Eng. Pat. 6018, May 16, 1885. 8d.

VOLATILE solvents are used, but the special arrangement of kiers, condensers, retort, and reservoir is unintel-

ligible without the drawing. The waste is subjected to the action of the vapour of the solvent, which is volatilised in a separate vessel, and condenses in the kier. In addition to this general arrangement, the patentee claims two new forms of kier for holding the greasy waste; in the first the coils of steam-pipe for delivering steam to expel the solvent, form its inner walls, and in the second there is an inner perforated shell, lined with wire cloth, which is made to revolve by gearing, thus saving time in the action of the solvent.—W. L. C.

Improved Apparatus for subjecting Neutral Fatty Bodies to the action of Water at High Temperatures, and for the Direct Production thereby of Fatty Acids and Glycerine. C. D. Abel. Eng. Pat. 6562, May 29, 1885. 8d.

The object of the apparatus herein described, and illustrated by drawings, is to effect on an industrial scale the operation termed "aqueous saponification," by effecting an intimate molecular contact between the fatty body and the water. The difficulty of doing this has hitherto been that the agitation of the liquids had to be stopped as soon as the maximum useful pressure had been obtained, since it was necessary then to restrict the application of heat, which alone produced the motion. Two forms of apparatus are described—(1) for direct heating with fire; (2) for indirect heating, operating with steam from independent generators. In the latter there is an arrangement for fractional heating with steam by successive increments, for the purpose of producing this motion and molecular contact between the fatty matters and the water. The claim also includes the use of glycerine liquor as the refrigerating medium, whereby this is simultaneously reduced by evaporation to the required degree of concentration.—W. L. C.

An Improved Manufacture of Saponaceous Materials for Washing purposes. P. Brentini. Eng. Pat. 7454, June 18, 1885. 6d.

QUANTITATIVE directions are given for mixing a vegetable-oil soap with silicate of soda, resin, fucus seaweed or soapberry, and mirbane.—W. L. C.

Improvements in and Apparatus for Extracting or Separating Oil or Grease from Cotton Waste and similar Materials. J. Whittle. Eng. Pat. 1939, February 10, 1886. 8d.

THE patentee claims the use of the vapour of a volatile hydrocarbon, instead of the liquid form, for solvent purposes. The solvent is volatilised in a separate vessel, and its vapor is conducted into pans or chambers containing the cotton waste; these chambers are provided with perforated pipes, a heating coil or its equivalent, and improved clamping doors. Drawings are given.

—W. L. C.

Soap-dipping and Disinfectant Composition. J. G. Swan and R. M. W. Swan. Eng. Pat. 2780, February 26, 1886. 4d.

REDISTILLED crude carbolic acid, heavy tar oil, potassium oleate, glycerine, petroleum, and sulphur are compounded in a given order and proportions.—W. L. C.

XII.—PAINTS, VARNISHES, AND RESINS.

Improvements in Metallic Paints. Ferdinand Bosshardt, Manchester. From H. Graf, Hamburg. Eng. Pat. 6844, June 5, 1885. 6d.

THE inventor employs a powder or dust which is deposited in the condenser pipes or tubes leading from the retorts in which zinc is distilled. This powder is exceedingly fine, and when mixed with white lead, whiting, red ochre, black ochre, etc., yields paints possessing considerable body, and greater preservative qualities than other metallic paints of a similar character.

—E. G. C.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

On Gelatins. Eduard Buchner and Theodor Curtius. Ber. 19, 850—857.

By the action of alcoholic hydrochloric acid on gelatin, a solution is obtained which yields, with nitrite of soda, a uniform diazo-compound. Gelatin, soaked in water, is mixed with absolute alcohol, warmed on the water-bath, and during 20 hours hydrochloric acid gas is passed into the mixture. When entire solution is effected, and the alcohol and excess of acid have been removed, the syrupy mass is transformed by nitrite of soda into the diazo-compound, which is then extracted by ether, and finally purified by distillation with steam. This diazo-body is a lemon-yellow oil of peculiar odour, distilling at 140—142° under 717mm. pressure; it possesses all the characters of a diazo fatty acid, mineral acids eliminate the nitrogen entirely from it; boiling alkali gradually decomposes it, with formation of alcohol and carbonic acid. It reduces nitrate of silver in the cold. Reducing agents form first a hydrazine, but eventually resolve it into ammonia and a base of peculiar odour. It is attacked by cold ammonia solution, with loss of carbonic acid. With an ethereal solution of iodine, a volatile di-iodo-compound is formed, which is converted by strong ammonia into *di-iodoringylamine*, $\text{I}_2\text{C}:\text{CHNH}_2$, a light yellow prismatic crystalline substance, easily soluble in hot water and alcohol, sparingly soluble in cold water and in ether. At 170° it begins to turn yellow, gives off iodine at 175°, and melts at 192°, with complete decomposition. The analysis of the diazo-compound corresponds to the formula of the ether of *diazo-cxyacrylic acid*, $\text{N}_2\text{C}:\text{C}(\text{OH})\cdot\text{COOC}_2\text{H}_5$; and the formation of *di-iodoringylamine* would be expressed by the following equations:—

I.

II.

The product of the reaction of alcoholic hydrochloric acid on gelatin, forms, when treated with alkali, a volatile very unstable base of an intensely nauseous odour. Albumen, when submitted to the same treatment as the gelatin, gave in every respect similar compounds, thus showing the close relationship of the two substances.

—T. L. B.

A Process of Treating Tannic Extracts or Juices. J. C. Mewburn, London. From the firm of J. Marechal and L. Bories, of Paris. Eng. Pat. 10,147, August 27, 1885. 4d.

IN order to decolourise and purify tannic extracts or juices, carbonate of lead, in the proportion of about 2kilos. to 1000 litres of juice, is added. An amount of sulphate of lead, double the weight of the carbonate of lead used, is next added. The precipitate is then to be filtered off in any suitable manner.—B. H.

Improved Means or Process of Preparing Animal Gut for the Manufacture of Strings, Bands, and Belts therefrom. Frank Vornberger, Liverpool. Complete Specification. Eng. Pat. 3441, March 11, 1886. 4d.

THE inventor takes a gut of an "ox or beef animal" and a gut of a sheep, and, after cleansing them in the ordinary way, splits them into as many strands as may be desired. He then plunges them in a bath of pearl-ash water for four to six days, after which a convenient number of strands of each kind of gut are partially twisted together. The strands are then dipped in a bath of "Condy's fluid," and then hung up to dry. When dry they are "sulphured" in a wooden box for 24 hours, after which the twisting is completed. They are next plunged into a bath of isinglass and white-wine vinegar to stiffen them, and then dried. When dry they are smoothed with emery cloth, and finished off with gum arabic and oil.—B. H.

XIV.—AGRICULTURE, MANURES, Etc.

Oxidation of Sulphur in the Germination of Peas.
G. Tammann. Zeit. Physiol. Chem. 9, 416—419.

THE author extracted from yellow peas 0.359 per cent. of sulphuric anhydride, of which 0.075 per cent. was in the form of soluble sulphates, the remainder being present as sulphur. During the progress of germination the sulphuric acid was increased; after 25 days' growth in the dark the sulphuric acid amounted to 0.191 per cent., and in the light to 0.152 per cent. The phosphoric acid was similarly increased from 0.324 per cent. of phosphoric anhydride in the original seed to 0.443 per cent. after 12 days' growth. These results are contrary to the observations of O. Kellner.—D. B.

Occurrence of Allantoin, Asparagin, Hypoxanthin and Guadin in Plants. E. Schulze and E. Bosshard. Zeit. Physiol. Chem. 9, 420—444.

ASPARAGIN was found to be present in the leaf-buds of *Acer pseudoplatanus* and *Acer campestre*, *Betula alba*, *Fagus sileatica*, *Tilia parvifolia*, *Populus nigra* and *Vitis vinifera*. It was found also in the bark of the plane tree stripped from the younger branches in October and November, but was not contained in the bark of the oak, ash, and linden trees. According to Borodin, plants cultivated in water are rich in asparagin. He considers this substance to be a decomposition product of albumen, the products formed by the decomposition not, however, being reconverted into albumen owing to the lack of the necessary non-nitrogenous constituents. The authors incline to this view. They have examined grass, oat, and clover plants in the early stages of growth and found only a minute quantity of asparagin in one plant—viz., the red clover. The quantity was, however, considerably increased by keeping the plants for a week in a dark room with the cut end of the stem immersed in water. In this manner 900 grms. of oat plants gave 3.1 grms. of asparagin, and 800 grms. of red clover 1.7 grms. Allantoin was found in the plane tree and the leaf-buds of *Acer pseudoplatanus* and *Acer campestre*. It was contained also in the bark of *Esculus hippocastanum* and of *Acer pseudoplatanus* but could not be found in the leaf-buds or bark of the other trees referred to in the above. Etiolated lupin plants also contained no allantoin. The method adopted by the author consisted in precipitating the aqueous plant-extract with lead acetate, filtering and treating the solution with mercuric nitrate. This process has rendered possible the identification of hypoxanthin xanthin and guadin in lupins, in young potatoes (tubers), in beetroot, in the leaf-buds of maple and plane, in the bark of the plane tree, and in young grass, red clover, oats and vetches. In the course of their researches the authors isolated a new nitrogenous substance from the mercury precipitates obtained from the extracts of the red clover and vetch plants. It crystallises in silky needles which are sparingly soluble in cold, freely soluble in boiling water, and yields guanin when heated with hydrochloric acid.—D. B.

On the Carbohydrate, resembling Dextrin, from the Seeds of Lupinus Luteus. E. Steiger. Ber. 19, 827.

BAEYER and EICHORN (*Landw. Versuchsstationen*, 9, 168; 14, 164; 9, 275) have shown that a substance similar to dextrin may be extracted from the seeds of *Lupinus* by means of alcohol. The properties of this carbohydrate have now been examined by the author. He finds that it is not changed by yeast, and that boiling with nitric acid converts it into mucic acid. It is of importance to note that when heated with dilute sulphuric or hydrochloric acid, this body does not yield glucose, but a sugar which is identical with galactose (from milk sugar).—A. R.

Composition of the Wheat Germ, and the presence therein of a New Carbohydrate and of Allantoin. (Preliminary Notice.) C. Richardson and C. A. Crampton. Ber. 19, 1180—1.

THE authors have extracted from wheat germs an oil which they state is a very quick-drying one, and will

probably be of practical use. After removing the oil from the germs, a large quantity of sugars may be extracted with hot alcohol, as much as 15—18 per cent. of the germs being obtained. This consists of about 80—90 per cent. cane sugar, the remainder being a carbohydrate with high right-handed rotation, which does not reduce Fehling's solution before inversion, and is not fermentable, but is converted at once into a reducing sugar by the invertase of yeast. So far it has only been obtained in an amorphous form, and its properties do not agree with those of any known sugar. The admixture of this carbohydrate with the cane sugar caused the products of inversion of the mixture with acid to be right-handed, and the authors at first supposed it to be raffinose, but on examination no trace of the latter could be found; a great many experiments with the germs showed the constant presence of this right-handed, unfermentable sugar. The authors have also found allantoin in the germs; it amounts to less than half per cent. It was separated by means of mercury nitrate, it gave the characteristic crystals on recrystallisation, and corresponded in its composition and all its properties with allantoin obtained from animal sources. Until now allantoin has only been once found as a constituent of plants.—G. H. M.

Action of Ferrous Oxide upon Vegetation. O. Kellner, Landw. Vers. Stat. 1886, 32, 365

THE author's results confirm those of Griffiths—viz., ferrous sulphate is not directly injurious to vegetation; on the contrary, it has an action similar to that of gypsum and common salt in producing solution and disintegration of the nutritive constituents of the soil. Although soluble ferrous salts have no injurious action, their presence in the soil is due to a deficiency of oxygen in a soil containing humus, and accompany therefore acid humus. It is from the latter probably, or possibly from the deficiency of oxygen, that the healthy growth of the plant is retarded. The presence of ferrous salts is therefore an indication of the insufficient ventilation of the soil.—J. B. C.

Application of the Thomas-Slag. L. Blum. Chem. Zeit. 10, 339 and 340.

THE present paper is a critical review of Maltzan's process for working up the slag. The process consists in treating the finely-powdered slag with sulphurous acid gas and air. In this way, according to Maltzan's theory, the sulphurous acid in presence of air converts the quicklime into gypsum and oxidises metallic iron and ferrous and manganous compounds, and changes the sulphides into uninjurious oxides. According to the author's theory, based upon experiment, the Thomas-slag contains, in addition to ferrous oxide, several per cent. of ferric oxide. The sulphurous acid reduces the ferric oxide with the formation of H_2SO_4 and FeO . The sulphuric acid then combines with CaO to form $CaSO_4$. Or the reaction may occur in the following way—viz., calcium sulphite reacts upon Fe_2O_3 with the formation of $CaSO_4$ and FeO . When the whole of Fe_2O_3 is reduced, the formation of $CaSO_4$ stops. Sulphur in the slag is usually supposed to be combined with the calcium. By the action of SO_2 in presence of water, calcium hypsulphite is formed, and sulphur deposited. The author is of opinion that it is not possible to convert the whole of the quicklime into calcium sulphate by this method. By further treating the slag in the preparation of superphosphate, the acid liberates SO_2 . The quantity of acid used in neutralising the original amount of quicklime is only partly saved. The author further thinks that the slag prepared in this way for artificial manures must have an injurious effect upon vegetation, because the high percentage of calcium sulphite present has a very strong reducing action taking up the oxygen in the ground, even more than the sulphur and protoxide compounds. He suggests that the quicklime might be transformed into carbonate by the action of moist air on the powdered slag.—J. B. C.

XV.—SUGAR, GUMS, STARCHES, Etc.

Melitose or Raffinose from Molasses, Cotton-seed and Eucalyptus-manna. First Part. *Annalen*, **232**, 169—205.

I. INTRODUCTION, by B. Tollens (p. 169—172). II. Molasses and Cotton-seed, by P. Rischbiet and B. Tollens (p. 172—201). III. Melitose from eucalyptus-manna, by B. Tollens (p. 201—204). The results of the foregoing contributions have already appeared in *Ber.* **18**, 2611 (this *Journal*, 1886, 243). In addition, Tollens has carried out the intended experiments (*Ber.* **18**, 2616, footnote), and has found that eucalyptus-melitose is, like molasses-raffinose, completely fermentable; melitose and raffinose are also identical. IV. Quantitative Determination of the Amount of Raffinose in Mixtures, by R. Creydt and B. Tollens (p. 205; compare *loc. cit.* 2613, footnote).—G. H. M.

Existence of the war Constituents of Milk-sugar in Plants. A. Muntz. *Compt. Rend.* **102**, 624—627.

BOTH the products of the conversion of milk-sugar, galactose and glucose (from which the milk-sugar in animal organisms is probably built up), occur in plants, glucose as such, or as starch, cellulose, etc. The author now shows that the second inversion-product, galactose, is contained in many plants and plant-materials; he obtained it from gum arabic by treatment with dilute sulphuric acid, and also from all other gums, also from Iceland moss and similar substances, and from pectous bodies.—G. H. M.

Constituents of Milk-sugar in Plants. A. Muntz. *Compt. Rend.* **102**, 681—684.

THE author proves, in connection with the paper referred to in the preceding abstract, that the different substances from which galactose can be obtained, as the gums, pectous substances, etc., are very widely distributed in the vegetable kingdom, and are especially found in the edible plants—for instance, in the cereals, leguminous fruits, fruits, edible roots, bulbous plants, vegetables and cattle fodder.—G. H. M.

Analysis of the Products and By-products of the Sugar Industry. L. Harperath. *Chem. Zeit.* **10**, 271—272.

IT was formerly admitted that all sugars, with the exception of cane sugar, were eliminated by means of basic lead acetate. Since then it has been shown by Lippmann and Tollens that raffinose also remains behind. Recent researches have proved that by means of polarisation, before and after inversion, certain and exact determinations of the kind and quantity of these separate sugars may be made. The first object of this process is to aim at a method of sure and exact inversion. Many such methods have been proposed; but the majority are inexact. The methods were only used when the products of separation of the sugar from the molasses, and the molasses themselves, were to be analysed. Raffinose occurs, however, ready formed in the beets, and is separated to a great extent by the treatment of the syrup with lime. It occurs in large quantities in the pressed mash. It appears to diffuse less readily than cane sugar, as it is found in considerably larger quantities in the last cuttings; whereas, in the fresh unlixivated portions the proportion is smaller. Raffinose forms a more insoluble saccharate with lime, so that by thorough saturation and the lime process the larger portion is separated. This saccharate is decomposed by carbonic acid and other acids. When raffinose is present in small quantity, cane sugar crystallises, and the former remains in the syrup. In the analysis, raffinose has to be separated from cane sugar, and also from invert sugar. The inversion method is subject to considerable errors. Frühling and Schulz's method is the one usually adopted. 13.024 grms. (half normal) of the sugar are made up to 50cc., and the rotatory power determined. This gives total polarisation. A further 13.024 grms. are weighed out in

100cc. flask, and 50cc. water added. Then 5cc. of pure strong HCl are poured in, and the liquid warmed for 15 minutes to 67—70°. It is then cooled, neutralised with soda, and acidified with acetic acid. On reaching the temperature of the first solution, it is made up to 100cc., filtered, and the polarisation determined. The calculation is made from Clerget's formula. The author gives the following sources of error which may be introduced by this method:—For inversion a fresh quantity of sugar is weighed out, and the errors of weighing, moisture and mixing, are liable to be doubled. The inversion solution of half normal weight is polarised in 100cc. solution, but instead of 100 dextrorotation it gives only 44° levorotation after inversion. Every reading may produce a quadrupled error; an easy matter, seeing that no clearing with acetate of lead may be employed. Heated above 70°, other results are obtained; below 67°, even for a short period, has the same effect. A more protracted or limited heating than 15 minutes gives a different value. All these are minute but important details of the method. All sugar syrups contain lime, which with HCl forms CaCl_2 . This compound greatly influences the polarisation. Concentrated HCl carbonises sugar, and the dilute acid inverts it. As a matter of fact, the solution often becomes brown. On heating with acid longer than 15 minutes, grape sugar is decomposed with formation of humin substances. Fresh solutions of grape sugar have birotation, which they lose on boiling. By the present method boiling is not admitted, and therefore the birotation is not completely reduced. This reduction is further retarded by the presence of acids. The above is also true of dextrose. The main objection to the method is its want of reliability. There is little doubt, the author thinks, that the inversion does not yield comparable results. The following is the author's method:—52.096 grms. of sugar (twice the normal) are dissolved in a 200cc. flask, and the volume made up, 50cc. cleared with basic lead acetate, and made up to 55cc., then polarised, and the results obtained in percentages by adding a tenth. 100cc. are placed in a shallow porcelain basin of 100—130cc. cap., evaporated on the water-bath at 80—85° to 50cc., and then heated quickly to boiling over the flame with constant stirring, adding just before the solution boils, 5cc. of dilute H_2SO_4 (1 part concentrated H_2SO_4 to 2 parts water). The heating over the flame should not continue longer than 1 minute. The solution is poured back into the flask, and quickly made up to 100cc. with cold water, and cooled to 17½°. It is then filled exactly to the mark, with or without neutralising, filtered with or without charcoal, and the polarisation determined at the same temperature as the first solution. The solution remains limpid and colourless. If for the dextro-polarisation clearing with lead acetate were necessary, charcoal must be used for decolourising, whereby no influence on the left-handed polarisation could be detected. The quantities are calculated by Clerget's or Tuchschnidt's formula. At a temperature of 20° the two formulae are almost identical.

$$\text{Clerget's formula is } R = \frac{100 S}{144 - 0.5 T}.$$

S = total rotation, T = temperature.

$$\text{Tuchschnidt's formula is } R = \frac{100 S}{144.16035 - 0.5078 T}$$

$$\text{At } 20^\circ \text{ this becomes for the former—} \frac{100 S}{134}$$

$$\text{and for the latter } \frac{100 S}{134.01035}$$

—J. B. C.

XVI.—BREWING, WINES, SPIRITS, Etc.

The Influence of Different Processes upon the Composition of Wine. J. Moritz. *Chem. Zeit.* **10**, 322.

THE following modifications were introduced, and their influence upon the composition determined:—(1) The influence of separating the scum of the must before fermentation by heating; (2) the action of the quantity of

sugar in the must on the formation of glycerine: (3) the effect of concentrating the must by evaporation, on the quality and composition of the wine. Three experiments were made with a must of Austrian and Kleinberger grapes. It contained 11.2 per cent. sugar, and 1.36 per cent. tartaric acid. In the first experiment it was allowed to ferment in the usual way, in the second it was previously heated to 65°, and in the third to 95°. The best result was obtained in the case of No. 2. The analysis showed that it contained more glycerine and least tartaric acid. In order to determine the influence of the addition of sugar upon the quantity of glycerine, a series of samples of the same must were taken, and cane sugar added in different proportions. The experiments showed that with the addition of sugar the proportion of glycerine decreases. To what extent the proportions of the other constituents are modified remains undecided. Müller-Thurgau ascribes this result to the decrease in energy of the yeast. Every condition which retards its cultivation produces a corresponding decrease in the amount of glycerine. He considers that for 100 parts of fermentable sugar, the more glycerine is formed in proportion to the amount of albuminous substances at the disposal of the yeast cells. By concentrating the must the proportion of the acid and other constituents are increased. The former, as shown by Müller-Thurgau, retards the action of the yeast, and in consequence, also, the formation of glycerine. It was also shown by the above experiments that the increase in quantity of sugar determined a corresponding decrease in the quantity of alcohol.—J. B. C.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

Albumenoids of Cows' Milk. J. Sebelien. Zeits. f. Physiol. Chem. 9, 445–464.

ENGLING found that after the long-continued passage of carbonic anhydride through diluted whey from the colostrum, flocks separated out, which were soluble in 5 per cent. sodium chloride solution, and which he therefore considered to be *globulin*. Hammarsten stated that milk contained a globulin precipitated by magnesium sulphate. The author found that this *lactoglobulin* showed a great agreement with the *paraglobulin* of blood. For its preparation the milk is first precipitated with sodium chloride (after addition of sodium hydrate if the milk has an acid reaction), warmed at 35° (whereby an albuminous substance and calcium phosphate is precipitated), the filtered liquid saturated with magnesium sulphate; the precipitate thus obtained was dissolved in water and again precipitated with magnesium sulphate. The globulin thus prepared is not precipitated from its solution by dialysis; a cloudiness is caused, which forms a precipitate only after addition of acetic acid. A solution with 5 to 10 per cent. sodium chloride clouds at about 72°, and coagulates at 75–76°. This cannot be casein, since both pure casein and also a mixture of this with blood serum give no permanent precipitate on heating with 5 to 10 per cent. salt. The albumen of milk has not yet been obtained in a pure state; it is stated that it is identical with serum-albumen. The author prepared lact-albumen according to the method used by Hammarsten for serum-albumen. Pure lact-albumen is not precipitated by magnesium sulphate at 40°, but by sodium sulphate at 30°, and by ammonium sulphate at ordinary temperature. A trace of acetic acid does not precipitate a hydrochloric acid solution. A two to three per cent. solution of lact-albumen, free from salts, coagulates at 72°, and at higher temperatures when sodium chloride is present. In this respect it agrees with the serum-albumen prepared by Starke. Lact-albumen has a rotary power $\alpha_D = -36.4$ – -36.9 , whilst serum-albumen is given about -60 – -62° by different observers. A preparation boiled with alcohol and which gave 1.13–2.6 per cent. ash, yielded the following numbers on analysis:

carbon 52.19; hydrogen 7.18; nitrogen 15.77; sulphur 1.73–1.96 per cent. The low carbon and high sulphur percentages distinguish lact-albumen from casein.

—G. H. M.

(B) SANITARY CHEMISTRY.

Improvements in the Treatment of Excreta and House Sewage, and an Improved Manufacture of Material and Apparatus therefor. J. Hewes, Leicester. Eng. Pat. 5153, April 25, 1885. 8d.

THE excreta is submitted to destructive distillation in cast-iron retorts or pipes, closed at each end by valves, set in a furnace. The products of distillation are led by a pipe from the tops of the retorts into the lower part of the furnace and consumed. The resulting product may be used either to prevent incrustation in steam boilers, or as a defecator for sewage, alone, or in conjunction with sulphuric and hydrochloric acids, bichromate of potash, sulphate of soda, picric acid, or an acid extract of end-bear, indigo, or logwood.—C. C. H.

Improvements in the Means and Apparatus for the Separating of Solids and Semi-solids from Sewage and other Liquids. P. Smith, Manchester. Eng. Pat. 7714, June 25, 1885. 8d.

THE apparatus consists of a cast-iron cylinder revolving horizontally in a rectangular closed box; the underside is in contact with an endless band of cloth pressed up thereto by pressure rollers. The endless band is kept in tension by adjustable rollers, one of which is driven by a belt, causing it to travel and rotate the large cylinder first mentioned. The liquid or sewage is admitted between the cloth and the cylinder by a valve at the upper part of the periphery; the liquid portions are expressed by the pressure rollers, the solid adheres to the surface of the cloth, and is removed by a scraper at a point later in the path of the endless band of cloth. The action of the machine is therefore continuous.

—C. C. H.

Improvements in the Treatment of Sewage. J. M. H. Munro, Salisbury, S. H. Johnson and C. C. Hutchinson, London. Eng. Pat. 7759, June 25, 1885. 6d.

SLAG, from the basic process of steel-making, known as "basic cinder," is treated with an excess of sulphuric acid of 1500 sp. gr. This produces a mixture of soluble phosphate of lime, calcium, ferrous, ferric, and magnesium sulphates, etc. An excess of the acid prevents the precipitation of ferric phosphate from a solution of the above "soluble cinder." The sewage is first treated with excess of lime above that required to render it neutral. A solution of the "soluble cinder" is then added, sufficient in quantity to precipitate the colloid matter in solution in the sewage; the excess of lime first added serves to precipitate the phosphoric acid both in the sewage and the "soluble cinder," and this, together with the soluble and insoluble nitrogenous matter also thrown down, produces a rich sludge. The sludge is then treated with about 0.75 per cent. of lime, and afterwards with about 5 per cent. of the "soluble cinder"; this facilitates the subsequent operation of filter-pressing and produces a rich fertiliser. The patentees claim (1) the treatment of sewage with lime and "soluble cinder" as described; (2) the treatment of the sludge as described, or the use of superphosphate of lime in place of the "soluble cinder."—C. C. H.

Improvements in the Treatment of Sewage at or near the Outfall. J. B. Spence, London. Eng. Pat. 8912, July 23, 1885. 4d.

THE sewage is deodorised by the passage of sulphurous anhydride into the sewer at or near the outfall.—C. C. H.

A Disinfectant Tablet for use in Flushing Closets, Stables, Drains, and for other similar Purposes. W. H. Symons, London. Eng. Pat. 8351, July 10, 1885. 4d.

ANY disinfectant or deodorant, preferably permanganate of potassium, is mixed with some binding material—*e.g.*, calcium sulphate, alumina, silica, or lime; the mixture is formed into tablets and suspended in cisterns, drains, etc., where it slowly dissolves.—C. C. H.

Improvements in Filters or Water Purifiers. F. Gresvener, Glasgow. Eng. Pat. 2182, February 15, 1886. 6d.

Two layers of animal charcoal, one fine and the other coarse, separated from each other by a porous diaphragm, are inclosed between two discs of porcelain, the lower of which is fixed, the whole being placed in an earthenware container. The two discs are fitted with compressed carbon plugs. By this combination of parts, the filtering medium can be readily renewed.—C. C. H.

Improvements in Antiseptics and Disinfectants, and in the Manufacture of the same. A. L. Dussek, London. Eng. Pat. 4117, March 24, 1886. 4d.

VEGETABLE TAR is distilled and the acids, spirits, and oils separated. The acids are further separated from the spirits and oils and the latter are mixed with an equal quantity of turpentine; one third of this is distilled off, and to the remainder is added one part of rosin or gum-arabic. The solution when cold is heated with caustic soda. The extract so prepared is called "Sano." This may be mixed with chalk, lime, or baryta, and reduced to a powder, which is a strong disinfectant.—C. C. H.

Improvements in Water Softening Processes. P. A. Maignen, London. Eng. Pat. 7446, June 18, 1886. 6d.

THE precipitate produced in the softening of water, consisting mainly of carbonate of lime, is rendered caustic by ignition and used for softening a further quantity of water either alone or in conjunction with silicate of soda, manganese dioxide saturated with sulphuric acid, or sulphate of manganese.—C. C. H.

(C) DISINFECTANTS.

Apparatus for Disinfecting, Deodorising, or Precipitating Purposes. F. J. Austiu, London. Eng. Pat. 4981, April 22, 1885. 4d.

ANY disinfecting material is placed in the interior of a closed porous vessel, a portion only of the exterior of which is glazed; this is placed in another vessel. Moisture from the outside passes through the porous envelope and liquifies the disinfectant, which, "on the principle of the natural law of Osmosis," passes through the shell of the vessel. The apparatus may be used for disinfecting air or water.—C. C. H.

XVIII.—ELECTRO-CHEMISTRY.

Improvements in Electric Batteries. J. B. Neyraud, Lyons, France. Eng. Pat. 6964, June 8, 1885. 6d.

IN order to prevent water saturated with a salt at the bottom of a porous cell of an electric battery rising to the upper part of it, and the head or screw from becoming oxidised, a battery is constructed with a porous pot having a porcelain or earthenware cover glazed at the upper part. This cover is provided with a nipple having a conical hole also glazed; the hole is stopped by a lead plug, in which is fixed a screw-threaded rod provided with a nut serving as a connection. The lead plug is traversed by a platinum wire, which also passes through a suitable insulating material sealing the plug; the wire is connected to a piece of carbon placed in the interior of the porous pot, and surrounded by small pieces of similar material; the bottom of the porous pot is formed of insulating material.—W. B.

Improvements in Chemical Precipitation, and in the Separation of Matter mechanically suspended in Liquids. J. G. Lorrain, Southampton Row, London. Eng. Pat. 7126, June 11, 1885. 6d.

THIS patent has for its object the facilitating or hastening of chemical precipitation or separation of matter mechanically suspended in liquids, by passing through the liquid in which the formation of a precipitate is taking place, or in which matter is already mechanically suspended, electricity of the kind known as "statical electricity."—W. B.

Improvements in Voltaic Batteries. H. J. Harris, Bristol. Eng. Pat. 8228, July 7, 1885. 8d.

THE author claims the use of porous cells having a flange or foot, by means of which they can be secured to the bottom of the outer cell by pouring in a layer of paraffin so as to cover the flange or foot; also the use of a hollow cover bearing an arrangement of hinged contact plates, by means of which batteries of several cells may be coupled up in a variety of different ways. Outlets through the cover are provided for the escape of the gas from the porous cell only.—W. B.

Improvements in Voltaic Batteries. F. H. W. Higgins, London. Eng. Pat. 8540, July 14, 1885. 8d.

THE negative plates of a voltaic battery are formed with a series of perforations which taper, and are larger on the inner face of the plate than on the outer, the partitions between the perforations being reduced to a knife edge on the inner face of the plate. The perforations are filled with oxide of lead paste. Two plates are fixed with their inner faces together, and on account of the tapering form of the perforations the composition cannot escape from them. The plates are then further prepared by exposing them to the current of a battery or dynamo-electric machine. The liquid made use of is such that the lead does not pass into solution.—W. B.

A New or Improved Method of Metallising Woven Textile Fabrics, especially Flannels, in order to develop Electricity for Hygienic and Medicinal purposes. U. R. Pumariega Aviléz, Spain. Eng. Pat. 2322, February 17, 1886. 4d.

WOVEN materials, especially flannels, are steeped in a bath composed of equal parts by weight of oxides of iron, copper, zinc, and tin mixed in the form of an impalpable powder in a solution of three parts of gum to 100 parts water, and afterwards dried. When woven materials thus prepared are applied to the human body, a weak but constant electric current is generated by means of the perspiration so long as the materials remain in contact with the body.—W. B.

Improvements in Galvanic Batteries. J. Scerson, Boston, U.S.A. Eng. Pat. 3726, March 16, 1886. 8d.

THIS patent relates to the construction of an improved bichromate battery having a porous cell supported on legs and containing an inner chamber perforated at the bottom, whereby the solution surrounding the porous cell is given free access to the lowest portion of the element contained in the inner chamber.—W. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Acetophenone or Hyponone: a New Hypnotic Body. S. Simonsin. Pharm. J. 3, 582.

ACETOPHENONE proves to be an effective hypnotic, according to observations made by Dujardin-Beaumez.—A. R.

Official Quinine Bark. G. Vulpius. Chem. Zeit. 10, 273—274.

THE new German pharmacopoeia demands a minimum of 3.5 per cent. of alkaloids in all quinine barks, from

any source, whereas according to the old regulation a minimum of two per cent. was authorised. This alteration is due to the fact that it had become customary to deliver to the druggist as quinine barks varieties too poor to be extracted for quinine, and that the Indian barks are much richer than those formerly used. The pharmacopœia also adds a method for determining the total alkaloids. This method does not distinguish between the different alkaloids, the result being that the barks poor in quinine are thrown on the hands of the druggist. Thus, for example, quinine bark during one season sold at prices varying from eight shillings to less than three. The latter quality contained 6.6 per cent. total alkaloids, consisting of 1.22 per cent. quinine, 2.80 per cent. cinchonidine, and 2.58 per cent. cinchonine and amorphous bases. The method, in short, given in the pharmacopœia is quite insufficient to protect the interests of the druggist. The author substitutes the following:—The total alkaloids are first estimated by the above-mentioned method, 20grms. powdered bark are macerated with 10grms. of 10 per cent. ammonia, 20grms. of spirits of wine (90 per cent.) and 170grms. of ether for 24 hours, 120grms. of the clear solution acidified with HCl, and freed from spirits of wine by heating. The alkaloids are precipitated in the filtered liquid, made alkaline with caustic potash, dried, and weighed. The total alkaloids thus obtained are shaken with ten times the weight of ether, which is then filtered into a weighed flask, the residue well washed, and the ether expelled. The flask then contains quinine together with inconsiderable quantities of quinidine and amorphous bases. To obtain more exact results, the residue in the flask is dissolved in spirits of wine, the alkaloids in this solution by exact neutralisation converted into sulphates with sulphuric acid and quinine precipitated in the usual way as berapathite, the correction being taken into account. The author recommends as an addition to the present German pharmacopœia the fixing of a minimum of quinine for official barks.—J. B. C.

Manufacture of Chloroform. Chem. Zeit. 10, 338—339.

If fresh bleaching powder be mixed with alcohol and water into a thick mass, a violent reaction occurs, with the formation of chloroform, formic acid, ethylhypochlorous ether, and small quantities of other compounds. In

The Generator.—For this purpose cylinders of boiler-plate, 13–14mm. thick, are used. For a daily production of 125kilos. of chloroform, four generators, 1.4m. high and 2m. diameter, are required. In each generator is an agitator, an inlet tube for steam and one for water, and a manhole for charging with bleaching powder. On the upper edge of the generator is a perforated leaden

FIG. 2.

pipe in connection with the water-main: a tube, 75mm. inside diameter, with the greatest possible dip, combines the generator with the condenser. The latter is placed as near as possible to the generator. On leaving the condenser, the condensing worm ends in a receiver. This is a small cylinder, 75cm. high and 40cm. diameter, of boiler-plate of 15mm. thick.

FIG. 1.

this reaction chloride of calcium is unacted upon. Calcium hydrate only takes part in the action in so far as it saturates a portion of the products formed by an excess of the bleaching powder in its action on the alcohol. In order to prevent the formation of these secondary products, an excess of alcohol must be present. The necessary apparatus for the preparation of chloroform is exceedingly simple. It consists of one or more generators, condensers, small iron receivers, store tanks, washing pans, and a copper rectifying retort.

Washing Pans.—Crude chloroform contains considerable quantities of alcohol in solution, from which it is separated by washing with water. The apparatus consists of a narrow, high cylinder, with a hemispherical bottom, and an agitator in the form of a ship's screw, so that the liquid is worked upwards. At the side of the apparatus taps are attached to let off the wash-water. As this water contains alcohol, it is kept in a store-tank. In order to wash a daily yield of 160–175kilos. of crude chloroform, 800 litres of water are necessary.

Rectification.—The chloroform, separated as far as possible from water, is rectified in a copper retort, as shown in Fig. 2, the construction of which may be readily understood from the drawing. It is desirable, in this case, to connect the retort and the condenser with a tube, as short and as sharply inclined as possible. Experience has shown that with 4 parts of bleaching powder of 103–108°, 3 parts alcohol of 96° Tralles, and 13 parts of water, give the best yield. In order to reach a daily production of 125kilos chloroform, each generator must be charged with 400kilos. bleaching powder, 300kilos. alcohol, and 1300 litres water. The alcohol is first run in, then water, until 1600 litres of liquid are in the vessel, and the agitator is set in motion. The 400kilos. bleaching powder are then added: the vessel is closed and heated with steam. At a certain point of the generator an iron tube dips into the liquid, which tube is filled with oil, and in the oil a thermometer is placed. As soon as the thermometer indicates 40°, steam is turned off; the agitator is kept in motion until the thermometer indicates 45°, and it is then stopped. The temperature now rises slowly to about 60°, usually its highest point. In very warm weather the temperature is apt to rise higher; but this must be as far as possible prevented by running cold water over the apparatus. Between the receiver and the condenser a glass tube is inserted. As soon as the reaction begins a fine rain of chloroform, alcohol, and water is seen to be driven through the tube. The air driven from the apparatus is saturated with chloroform vapour, and this must be allowed to escape into the open air, after previously being washed through water. This violent reaction lasts about a minute and then chloroform begins to run over. As soon as about 3kilos are distilled off, the agitator is again set in motion. When no more chloroform separates out in a sample of the distillate, the iron receivers are changed, and the distillate, consisting of alcohol saturated with chloroform, is collected separately. This is continued till, on shaking with water, no more chloroform separates out. The distillation is continued, and the weak alcohol run into the store-tank until it reaches 3 per cent. Tralles. The lime-mud is then run off. The weak alcohol in the tank is made up to the proper strength and used for a fresh operation.

—J. B. C.

The Action of Papaine. C. Finkler. Chem. Zeit. 10, 357–358.

LIKE many other plants, *carica papaya* contains a ferment which dissolves albumen. From its chemical nature it may be considered as belonging to the group of peptones. Under the name of *Papaine Finkler* two preparations are used in commerce (this Journal, 1885, 571). Experiments have shown that these preparations are ferments which dissolve albumen; that this solvent action occurs under very different conditions; that it is possible with a very small quantity of the ferment to dissolve a large quantity of albumen. The action is not one of simple solution, but the albumen is changed into peptone. Papaine dissolves albumen best in water, almost equally well in a slightly alkaline solution, but less readily in dilute HCl. Experiments were made in these three directions with 30grms. fresh fibrin, 0.32gm. papaine and 100cc. water, 100cc. 0.1 per cent. HCl, or 50cc. 0.1 per cent. KOH. After 72 hours the fibrin in all cases was completely dissolved. This action goes on between wide ranges of temperature. A higher temperature, 40–50°, has an accelerating influence. The author finds from experiment that 1 part of *Papaine Finkler* dissolves 1000 parts of fibrin. It has been repeatedly observed that 8grms. hard boiled albumen were dissolved by 0.01gm., and even by 0.001gm. papaine. Other papaine preparations were tested in the above manner, especially *Papaine Christy* from London, and that of Merck in Darmstadt.—J. B. C.

Remarks on some New Drugs. Chem. Zeit. 10, 618.

Carapa guayanensis Aubl.—The plant is one of the highest trees in Guiana; the fruit has a nearly spherical shape, and contains from 7 to 8 seeds, the skin of which is

spongy, and of a reddish colour. A colourless buttery oil is obtained from the seed, chiefly consisting of palmitin. Experiments are now in progress with a view to using it as an antidote against diseases of the skin. Formerly it was exported to Europe as a raw material in the manufacture of soap. The oil of the West African *Carapa quincensis* Swart. possesses similar properties. The bark of this tree contains an alkaloid, to which the name of touloucoune has been given. Both drugs resemble the azadirachta bark in their action on the human body, and will probably prove effective against intermittent fever and nervous debility.

Anchietia salutaris St. Hil.—The root of this plant is recommended as a remedy for syphilis, and, in form of a syrup, as a cure for quinsy. The syrup is prepared by mixing four parts of a tincture obtained from the root with thirty parts of syrup simplex. The powdered bark of the root is a powerful purgative, probably owing to the alkaloid present—*anchietine*. The plant grows as a bushy shrub in the neighbourhood of Rio de Janeiro.

—S. H.

Some Constituents of the Rind of the Bitter Orange. Tanret. Comp. Rend. 102, 518–520.

THE extract obtained with alcohol of 60° was evaporated, the residue agitated with chloroform, the chloroform layer (A) distilled and the residue therefore treated with cold alcohol, a crystalline powder (a) and a resin (b) being obtained. The aqueous layer (above the chloroform layer A) deposits yellowish crystals (c), and the mother-liquor, on treatment with lead acetate and saturation with sodium sulphate, gives two other constituents, a yellow product (d) soluble in alcohol, and a white powder (e) insoluble in alcohol. The substance (a) is tasteless, and insoluble in water and ether, but dissolves in 100 parts of hot alcohol and 60 parts of chloroform; it is soluble also in alkalis, but not in ammonia, has the composition $C_{25}H_{34}O_7$, and forms a calcium salt of the composition $(C_{25}H_{32}O_7)_2Ca$. Yield = 0.5 per 1000. The product (b) softens at 12°, has a very bitter taste, dissolves freely in hot water, ether, chloroform and alcohol, exhibits a rotatory power $[\alpha]_D = -28^\circ$, closely resembles hesperidin in its reactions, and has the composition $C = 61.14$, $H = 6.57$. Yield 1.0 per 1000. The substance (c) is called *isohesperidin* $C_{27}H_{36}O_{12}$, is distinguished from hesperidin by its solubility and has a rotatory power $[\alpha]_D = -89^\circ$. Yield from 4 to 30 per 1000. The substance (d) is a glucoside, *aurantiamarin*, soluble in water and alcohol, insoluble in ether and chloroform, the bitter taste of the rind being due to this substance. It has a rotatory power $[\alpha]_D = -60^\circ$, contains $C = 53.04$ – 53.48 , $H = 6.36$ – 6.16 , and forms the natural solvent for hesperidin (five parts of this substance suspended in twenty parts of water dissolve one part of hesperidin). Yield 15–25 per 1000. (e) is *hesperidin*. Yield 0.0 to 0.6 per 1000.—I. B.

Crystallised Aconitine. C. F. Bender. Pharm. Centralt. 26, 433.

THE preparation of pure aconitine is as follows: First extract with ninety per cent. alcohol, filter the extract through cloth, distil off the alcohol, separate the alcoholic residue from resin and fats, dilute with water, filter, add pure bicarbonate of soda, agitate with ether, pour into dilute acid, digest the alkaloid solution with animal charcoal, filter, separate the base, extract with ether, and prepare the salt of the hydrobromide. After recrystallising the hydrobromide, the base is precipitated with magnesia and taken up with ether. On distilling off the ether aconitine remains in snow-white crystals.—J. B. C.

Brucine. A. Hanssen. Ber. 19, 520–524.

THE author has prepared *mononitro-brucine* by acting upon the methyl iodide compound in alcoholic solution with nitric acid. The resulting solution, filtered from resinous products, gave yellow crystals. These crystals contained no iodine, and further investigation showed

that the methyl group had been eliminated and that the nitrate of a mononitro derivative had been formed. On addition of sodium carbonate solution, the nitro-base separates in the form of needles. This product was recrystallised from water. When heated on platinum it explodes. The formula given by the author is $C_{23}H_{25}N_2O_4.NO_2$. This nitro-compound was reduced with tin and hydrochloric acid and gave the hydrochloride of an amido-base, which was recrystallised from water and possessed the formula $C_{23}H_{25}N_2O_4.NH_2.3HCl$. The following are the reactions for *amido-brucine*: Fe_2Cl_6 produces first a green and ultimately a brown colouration. A very dilute solution of potassium bichromate produces a blue-violet colouration, which is very fugitive. Amido-brucine dissolves in concentrated nitric acid with a yellow colour, which becomes red with $SnCl_2$. The first two reactions correspond to those of amido-strychnine. The author intends to investigate the action of bromine upon this compound.—J. B. C.

On Morphine. O. Fischer and E. von Gerichten. Ber. 19, 792—795.

IN order to determine the constitution of morphine, various attempts have been made to convert it into bodies free from nitrogen. In connection with Hesse's observations on this subject (*Annalen*, 222, 223), the authors have obtained from morphine methiodide, a substance the formula of which, $C_{14}H_{19}O_2$, is that of a dioxypheanthrene, and its general properties are very similar to, though not identical with, Graebe's pheanthrenehydroquinone. From codeine methiodide a substance of the formula $C_{17}H_{21}O_2$ is obtained.—A. R.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

Filtering Apparatus. Otto. N. Witt. Ber. 19, 918—919.

PERFORATED glass or porcelain plates, about 40mm. in diameter and 4 to 5mm. thick, are made with sloping edges so that they fit closely into a glass funnel; upon the plate two round strong filter papers are placed to form a paper sieve, upon which the substance to be filtered is poured. By connecting the apparatus with an air-pump, the filtration takes place very rapidly, the substances remaining on the filter can be washed thoroughly, and pressed into hard cakes with a spatula. The cakes can then be removed by turning the funnel over and tapping the sides gently or by blowing into it.—T. L. B.

Zinc Dust Reactions. H. Schwarz. Ber. 19, 1140.

THE author describes two simple methods for preparing pure hydrogen gas and carbonic oxide. On heating a mixture of zinc dust and calcium hydrate gradually in a combustion tube, a constant current of pure hydrogen is liberated according to the equation: $Zn + CaH_2O_2 = ZnO + CaO + H_2$. On mixing the zinc dust with calcium carbonate in molecular proportions and heating as before, pure carbonic oxide gas is evolved thus: $Zn + CaCO_3 = ZnO + CaO + CO$. In both cases nearly theoretical quantities of gas are obtained. The author intends to apply this reaction to organic hydroxyl or carboxyl compounds.—D. B.

Determination of the Value of Chloride of Lime by means of Peroxide of Hydrogen. G. Lange. Ber. 19, 868—871.

THE principle of the process lies in the fact that hypochlorites when mixed with peroxide of hydrogen instantly give off all their active oxygen, at the same time liberating the oxygen of the peroxide; therefore the active oxygen of either substance may be easily determined by using an excess of the other substance. The apparatus used is the ordinary nitrometer (compare this Journal, 1885, 495—496). A solution is made of 10grms. bleaching powder in 250cc. water, 5cc. = 0.2grm. are poured into the flask of the apparatus, and an excess, say 2cc.,

of commercial peroxide of hydrogen placed in the inner tube. The flask is then connected to the apparatus, the solutions mixed together by shaking, and the amount of gas evolved measured off in the usual way. The whole operation is complete in 1 to 2 minutes. The oxygen evolved is the direct measure of the active chlorine in the bleaching powder, so that after reduction to 0° and 760mm. pressure, each cc. of gas evolved, as above described, corresponds to 5 Gay-Lussac's degrees, or to 1.632 per cent. of chlorine. It is easier to weigh off 7.917grs. chloride of lime, dissolve in 250cc. of water, and to use for the test 5cc. of this solution, when every cubic centimeter of gas corresponds to 2 per cent. of chlorine. The great advantage of this process, is that it is entirely independent of any normal solution whatever; it also shows at once the amount of active oxygen or chlorine, is more quickly worked than any other, whilst at the same time is perfectly accurate.—T. L. B.

Standardising Iodine Solutions. W. Kalmann. Ber. 19, 728.

THE method at present in use for standardising iodine solutions, exact though it undoubtedly is, labours under the disadvantage of being somewhat complicated. The following simple method, which is based on the well-known fact that sulphuretted hydrogen acts on iodine with production of hydriodic acid and separation of sulphur, according to the equation—

is proposed by the author for determining the amount of iodine in a solution:—A certain volume of that solution is diluted with water and treated with sulphuretted hydrogen until completely decolourised. To the milky fluid thus obtained, methyl-orange is added, which gives no reaction with sulphuretted hydrogen, and the hydriodic acid may then be titrated with one-tenth normal alkali solution. As 1cc. of the latter represents 0.0127grm. I, the amount of the iodine in solution is readily calculated. A few examples of the working of this process are appended, and they fully bear out the statement as to its exactness.—A. R.

New Apparatus for the Estimation of Hydrogen Peroxide. M. de Thierry. Compt. Rend. 102, 611—613.

THE author describes an apparatus in which the hydrogen peroxide to be estimated is mixed with manganese dioxide, and the liberated oxygen is collected and measured under a graduated bell jar.—D. B.

Titration of Phosphoric and Arsenic Acids. A. Joly. Compt. Rend. 1886, 102, 316.

TO the acid solution a few drops of phthalcin are added, and titration with baryta solution follows until a gelatinous precipitate is produced. This is the tribarium salt, which on agitating with the acid liquid changes to the crystalline dibarium salt. On further addition of baryta solution a gelatinous precipitate again forms, which becomes crystalline in the same way. The process is complete when a drop of baryta gives a permanent red colouration. The change from the gelatinous to the crystalline condition is more rapid in the case of arsenic acid.—J. B. C.

Determination of Manganese. C. Reinhardt. Chem. Zeit. 10, 323.

THE author has shown that a double precipitation of manganese by Wolf's method should eliminate oxides of calcium and magnesium. The same method may be adopted for poor manganese ores. For 2—15 per cent. Mn 1grm. ore is taken, for above 15 per cent. Mn ½grm., below 2 per cent. 2grm. The ore is dissolved in HCl of sp. gr. = 1.19 (25cc. to 1grm. ore). The solution evaporated to dryness, moistened with dilute HCl, taken up with hot water, filtered through a double filter into a one-litre flask and washed with dilute HCl. The residue

is SiO_2 , insoluble Al_2O_3 and BaSO_4 . In very exact analysis this residue must be fused and the barium and aluminium separated from the SiO_2 . The filtrate from BaSO_4 containing the alumina is added to the previous filtrate, and the whole boiled with HNO_3 (10cc. HNO_3 of sp. gr. 1.4 for 1 grm. ore), and on cooling neutralised with ammonium carbonate, slightly acid ammonium acetate added and boiled. The mass is filtered into a 12-litre Erlenmeyer flask. The oxide of iron after washing is redissolved in HCl and treated again as above. This treatment is again repeated. Manganese is next precipitated: (1.) According to Wolff's method with a current of bromine-ammonia. To the filtrate contained in the Erlenmeyer flask 60cc. of 20 per cent. ammonia are added, and a current of bromine passed for 15–20 minutes; this is afterwards replaced by gaseous ammonia for 20 minutes. (2.) By means of bromine in HCl , ammonia and a current of gaseous ammonia. If the filtrate contains as much as 0.15 grm. manganese, 25cc. bromine in HCl are added, and then 60cc. of 20 per cent. ammonia, and a current of ammonia passed through for 20 minutes. With small quantities it is desirable to warm the solution. In other cases the solution becomes warm by the reaction. The author gives the preference to the first method, as the bromine is passed until no further precipitation occurs, whereas in the second case an excess of bromine in HCl must be avoided. In method (1) it is essential to pass the bromine through a tube furnished with manganese peroxide hydrate. The manganese precipitate may contain in addition hydroxides of Ni, Co, Fe, Cu, Zn (?), Ba, Ca, Mg and Si. After washing, the filtrate is removed and a 400cc. Erlenmeyer flask substituted into which 10–20cc. strong sulphurous acid are brought. The manganese precipitate is washed into this. The mass is heated when the precipitate is completely dissolved. If solution be not effected, 15cc. HCl of 1.19 are added. Into the solution brominated HCl is introduced until of a reddish tinge. After heating for some time the liquid is evaporated to dryness. In this way by the action of SO_2 upon MnO_2 , MnSO_4 is formed. The addition of Br oxidises the excess of SO_2 and the reduced iron. The sulphuric acid combines with any BaO present to form insoluble BaSO_4 . In case any Sr were present, evaporation brings it into the insoluble form. The mass, should a precipitate form, is filtered. The filtrate is heated to boiling in order to convert MnCl_2 into MnCl_3 , and after cooling 35cc. NH_4Cl (150 grm. in 1 l. H_2O) added, and a strip of litmus paper. Then 10 per cent. NH_4OH is added until just alkaline, and filtered directly into a flask containing 20cc. 50 per cent. acetic acid. The filter must be covered to prevent oxidation. The filtrate is now boiled in order to drive off chlorine in case any oxide of manganese is formed on the filter, and dissolved off with HCl . After cooling 10cc. NH_4Cl solution and 10cc. ammonia are added until alkaline, and filtered through the same filter as before. The precipitate is Fe_2O_3 , Al_2O_3 and possibly SiO_2 . If Mn settles out in the first precipitation with NH_4OH , it is filtered off and treated on the filter with dilute HCl and a few drops of SO_2 . The filtrate is boiled in this case with about 5cc. HNO_3 (1.4), then cooled, 25cc. NH_4Cl solution added and precipitation with 10 per cent. ammonia follows as stated. The acid filtrate is made alkaline with NH_4OH , and acidified with acetic acid until distinctly acid. The solution is heated on the water bath and H_2S passed through. This precipitates the sulphides of Ni, Co, Zn, Cu, etc. The filtrate contains the manganese. The liquid is heated to boiling, 10 per cent. NH_4OH added until alkaline, then colourless $(\text{NH}_4)_2\text{S}$, and the liquid boiled 10 minutes, cooled, a further quantity of $(\text{NH}_4)_2\text{S}$ added and the resultant filtered. The sulphide is dried and heated with sulphur in a Rose crucible in a current of hydrogen. According to Classen, the crucible must cool in a current of hydrogen and should have been heated over the blowpipe. The author adopts the following method: The MnS precipitate is dried, heated in a weighed crucible over the lamp, and finally over the blowpipe. The crucible is then cooled in the desiccator and the manganese weighed as Mn_3O_4 . The Mn_3O_4 is

then treated in the crucible with strong sulphurous acid and a few drops of dilute sulphuric acid, and heated on asbestos. A clear solution is obtained which is evaporated to dryness, and heated gradually to redness over the lamp flame. The manganese is then quickly weighed as sulphate. As a further check, the sulphate may be precipitated with bromine and weighed as Mn_2O_3 .

—J. B. C.

Determination of Phosphoric Acid in the Thomas-Slag.
J. Klein. Chem. Zeit. 10, 341.

AFTER reviewing the various methods at present adopted for the determination of phosphoric acid in slag, the author recommends the following scheme:—2.5 grms. are fused with a mixture of 4 parts of sodium-potassium carbonate and 1 part of potassium chlorate. The half of the latter is placed in a platinum crucible. The substance is brought on to the fusion mixture and the remainder of the latter added, and then the whole is well mixed with a glass rod. The mixture is heated over the Bunsen burner for some minutes, first with a small flame and then for another half-hour with a full flame. By placing the crucible upon a cold plate the contents are quickly cooled and contract to a loose cake, which may be readily withdrawn. This is placed in a beaker and treated with 50cc. HCl . An almost clear solution is obtained, which is diluted to 250cc. 100cc. are used for separating the silica in the usual way. The filtrate is made up to 200cc., in half of which the phosphoric acid is determined by means of ammonium molybdate.—J. B. C.

A Reagent for Detecting the Acidity of Weak Acids. R. Engel. Compt. Rend. 102, 214–217.

THE acid in question is dissolved in water, a few drops of a 1/1000 solution of soluble CLB blue (Poirrier) added and titrated with normal calcium hydrate solution until the colour changes to reddish violet. In this way phenol acts as a monobasic acid (in an alcoholic solution it is neutral), resorcinol acts as a dibasic acid. Morphine dissolved as hydrochloride requires 24 divisions of normal potash for neutralisation of the hydroxyl groups, the calculated quantity being 20 divisions; mono- and poly-basic alcohols and aldehydes cannot be titrated. Chloral acts as a monobasic acid. Hydrocyanic acid may be readily titrated with glyccol, alanine and taurine; the colour changes gradually and is slightly bleached.

—J. B. C.

Indicators for Determining the Basicity of Polybasic Acids. R. Engel. Compt. Rend. 102, 262–264.

IF the indicator soluble CLB blue (Poirrier) be employed, boric acid HBO_3 requires for neutralisation 1KOH; phosphoric acid H_3PO_4 , 3KOH; arsenic acid acts like phosphoric acid. Phosphorus, hypophosphorous, carbonic and *p*-oxybenzoic acids act as dibasic acids.

—J. B. C.

Determination of Rosin in Soaps and Fats. A. Grittner and J. Szilasi. Chem. Zeit. 10, 325.

AFTER reviewing the analytical methods at present employed, the authors propose the following, based upon Gladding's method. If a rosin soap is dissolved in about 80p.c. alcohol, and the solution if acid neutralised with ammonia, and an alcoholic solution of $\text{Ca}(\text{NO}_3)_2$ added, calcium stearate, palmitate and oleate separate out. A portion, however, of the oleate remains in solution. The resin remains also in solution. If silver nitrate be now added and the solution be largely diluted, oleic acid and resin separate out as silver salts. The further separation of rosin and oleic acid may be effected with ether, which leaves oleate of silver undissolved. The analysis is conducted as follows: 1–2 grms. of soap are dissolved in 80p.c. alcohol (5 vol. pure alcohol and 1 vol. water). If acid the solution is neutralised. $\text{Ca}(\text{NO}_3)_2$ in 10p.c. alcoholic solution is added in excess, cooled and filtered. After washing the precipitate with 80p.c. alcohol, AgNO_3 solution is added in excess to the filtrate and this is then diluted with

3 vol. of water. On agitating, the precipitate collects at the surface and may be readily filtered. The precipitate is washed with cold water, dried at 70–80° and digested with ether. After some time, the ethereal solution is filtered into a graduated 100cc. cylinder, and the precipitate washed with ether until it makes up 90cc. To the solution 10cc. of dilute HCl are added and the liquid is agitated. The HCl combines with the silver of the rosin salt and free rosin is formed, which is taken up by the ether. After the precipitate settles, 50cc. of the ethereal solution are drawn off, the ether is distilled off, and the residual rosin, after drying at 100°, weighed. The authors append a series of analyses made by aid of this method with weighed quantities.—J. B. C.

Determination of Fusel Oil. J. Traube. Ber. 19, 892–895.

IN order to test a brandy by means of the capillary-metrical apparatus, described by the author in the *Journal pr. Chim.* N.F. 31, 177 and 514, it is necessary to reduce it to the strength of 20 vol. per cent., before testing. The height to which the column of liquid ascends in the capillary tube, compared with a pure spirit of 20 vol. per cent. on an empirical scale, shows at once the amount of fusel oil the sample contains. Thus, an examination of a brandy can be made in a few minutes, and the fusel oil determined to one-fiftieth per cent with accuracy. The author gives a table of comparative tests made upon a spirit mixed with small quantities (1 to 0.1 per cent.) of various fusel oils, and also with pure amyl alcohol, the numbers for 0.5 per cent. and below this, agreeing very closely. Of twelve different brandies examined, only two or three contained over 0.1 per cent. fusel oil. The apparatus is to be obtained of C. Gerhard, in Bonn.—T. L. B.

Detection and Determination of Fusel Oil. Röse. Pharm. Centralb. 27, 5–9.

ETHYL-ALCOHOL is much less soluble in chloroform than the higher homologues which occur in fusel oil. If 50 per cent. alcohol be shaken with chloroform, the volume of the latter increases in proportion to the quantity of fusel oil present. The method of determination is based upon this principle. The alcohol to be tested is diluted with water to 50 per cent., and 100cc. are shaken with 20cc. chloroform in a graduated vessel at a temperature of 15°. With the aid of a table, the height of the layer of chloroform, and from this the quantity of fusel oil, is determined. If, for example, with pure alcohol the layer measures 37.1, with alcohol containing 1 per cent. amyl-alcohol, it increases to 39.1.—J. B. C.

Detection of Turpentine Oil. H. Hager. Pharm. Centralb. 26, 430–432.

THE reagent is guaiacum, which must have been powdered within two days. The reaction is an ozone reaction. In testing oils by their behaviour with turpentine oil and guaiacum—i.e., according to their absorptive power for ozone—such oils may be divided as follows:—(1) Those which readily form ozone; (2) those which in presence of guaiacum and turpentine oil produce ozone; (3) those which are indifferent in presence of these reagents. To perform the test two test glasses are taken, and into each a small quantity of recently powdered guaiacum, 10 to 20 drops absolute alcohol, and i.e. of the oil to be tested are brought. In the one glass (B) 4 to 5 drops of turpentine oil are added. After adding to each glass 1cc. benzene or other diluent, the mixture is boiled. If the oil belongs to group 2 the liquid in glass B becomes blue or violet, but not in the other glass A, if the oil is pure and unadulterated with turpentine. If neither glass change—i.e., if the oil belongs to group 3—one or more drops of oil of lemons or lavender or any oil of group 2 are added. Glass B shows at once, or on boiling, a blue colour, but not A, if the oil is free from turpentine.—J. B. C.

Reagent for Benzoic Acid sublimed from Gum Benzoin, and that sublimed over Resin. H. Hager. Pharm. Centralb. 26, 392–393.

THIS reagent is a mixture of FeCl_3 and K_3FeCy_6 solutions. The official substance from the resin changes the colour of the reagent in 1–3 seconds from yellow to blue, that prepared by subliming the acid over resin requires 20 seconds to 2 minutes to effect the change. Pure benzoic acid produces no effect with this reagent.—J. B. C.

A Reaction for Albumen. D. Axenfeld. Centralb. Med. Wissensch. 1885, 209–211.

SOLUTIONS of albumen, acidified with formic acid, to which 1 per mil. of AuCl_3 has been added, give, on heating, a rose red colour, on a further addition purple red, then deep blue, and with still more a blue flocculent precipitate, the liquor becoming colourless. This reaction indicates one in a million of albumen. In presence of foreign matter, as in urine, more acid and AuCl_3 must be added. Solutions of caoutchouc also give with these reagents a purple red colouration, but differ from albumen in changing with carbonates of the alkalis to orange yellow. The violet colour, which many other organic compounds produce, vanishes spontaneously, more quickly on addition of metallic mercury, but with albumen the colour remains unchanged.—J. B. C.

New Books.

DIE CHEMIE DES STEINKOHLENTHEERS MIT BESONDERER BERÜCKSICHTIGUNG DER KÜNSTLICHEN ORGANISCHEN FARBSTOFFE. Von Dr. GUSTAV SCHULTZ. Zweite vollständig umgearbeitete Auflage. Braunschweig: Druck und Verlag von Friedrich Vieweg und Sohn. 1886. London: H. Grevel, 33, King Street, Covent Garden.

THE first edition of this now well-known and excellent work was reviewed in this Journal, 1882, 162. A new edition, the second, now appears, and it is issued in parts at a price of 6s. per part. So far, Parts I. and II. are issued, covering 384 pages of subject-matter and dealing with the RAW MATERIALS. This division is further classified as follows:—COAL TAR, under which the composition, constituents, mode of working up, etc., are included. In the second division the INTERMEDIATE PRODUCTS and ASSISTANT PRODUCTS are treated of, and this treatment is also devoted to the Theory of the Aromatic Substances. Part I. ends on page 192, with an account of Diphenyl, and Part II. on page 384, with one of Phenyl- α -naphthylamine.

As above stated the work is entirely remodelled, and will be a complete treatise of the coal-tar colour industry, as well as of the collateral industries based on the coal-tar constituents or their derivatives. The pages of these two parts are embellished with 18 excellent woodcuts. The whole work when complete will form a somewhat thick 8vo volume.

A MANUAL OF THE ALKALI TRADE, INCLUDING THE MANUFACTURE OF SULPHURIC ACID, SULPHATE OF SODA, AND BLEACHING POWDER. By JOHN LOMAS. Second Edition, with Additions. London: Crosby Lockwood & Co., 7, Stationers' Hall Court, Ludgate Hill. 1886.

LARGE 8vo volume, bound in cloth, gilt-lettered, and illustrated with 232 excellent cuts and working drawings. The work contains 340 pages of subject-matter divided into chapters bearing the following

headings:—I. CHOICE OF SITE AND GENERAL ARRANGEMENT OF WORKS; II. SULPHURIC ACID; III. RECOVERY OF THE NITROGEN COMPOUNDS AND TREATMENT OF SMALL PYRITES; IV. THE SALT CAKE PROCESS; V. LEGISLATION UPON THE NOXIOUS VAPOURS QUESTION; VI. THE JONES AND HARGREAVES PROCESSES; VII. THE BALLING PROCESS; VIII. LIXIVIATION AND SALTING DOWN; IX. THE CARBONATING OR FINISHING PROCESS; X. REFINED ALKALI; XI. SODA CRYSTALS; XII. CAUSTIC SODA; XIII. BICARBONATE OF SODA; XIV. BLEACHING POWDER; XV. UTILISATION OF TANK WASTE; XVI. GENERAL NOTES. Next follow several Appendices—A, B, C, D, E. A refers to Mactear's Table of Products, from 100 tons of Pyrites; B, to Elaborate Tables of the Strength of Sulphuric Acid; C, to Fletcher's Anemometer, its construction, mode of employment, and tables of reference; D, to Foreign Legislation upon the Noxious Vapours Question; E, to a Summary of the Alkali Act of 1881. A copious and well-arranged Alphabetical Index closes the work, which, on account of its unique and exceptionally fine drawings and illustrations, must be of the greatest value alike to manufacturers and students of chemical technology.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

- 6086 C. H. Roeckner, F. L. Roeckner, and R. L. Roeckner, Tynemouth. Improvements in separating liquids from solids. May 26
 7289 M. Immisch, London. Apparatus for measuring heat. May 31
 8094 B. J. B. Mills, London—Communicated by C. T. Burcharth, Germany. A method of applying auxiliary heat to steam boilers, and means or apparatus for carrying it into effect. Complete specification. June 18
 8157 O. Imray, London—Communicated by F. Siemens, Germany. Improvements in regenerative gas retort furnaces. June 19
 8201 C. Langer, London. Improvements in apparatus for mixing, stirring, and conveying various substances, and for drying and exposing the same to the chemical action of gases, vapours, etc. June 21
 8212 T. T. Mathieson and J. Hawliczek, Liverpool. Improvements in and in connection with apparatus for distilling volatile liquids and gases. Complete specification. May 21
 6893 G. Sakasser, London. Improvements in an apparatus for filtration and purification of fluids. May 22
 6948 Y. A. Gaston, Viscount de Coetlogon, Liverpool. Improvements in apparatus for carburetting air. May 21
 6958 J. Gamgee, London. A method or methods of agitating liquids in the manufacture of ice, evaporating or other processes, and apparatus employed therefor. May 21
 7022 J. C. Mewburn, London—Communicated by J. Dietze, Germany. Improvements in surface cooling, heating, and condensing apparatus. May 25
 7045 J. B. Alliot and J. M. C. Paton, Manchester. Improvements in filter-presses and in apparatus connected therewith. May 26
 7065 J. F. Brinjes, London. Improvements in apparatus for separating liquids from solids, and for drying the solid residuum. May 26
 7088 G. F. Marshall, London. Improvements in filters. May 26
 7095 E. Sargeant, Birmingham. Improvements in water filters. May 27
 7101 J. C. Thresh, Manchester. Improvements in the manufacture of filtering materials. May 27
 7132 N. Greening, London. Improvements in apparatus for pulverising, brushing, and sieving minerals and chemicals. May 27
 7133 N. Greening, London. Improvements in apparatus for screening and carrying lime and other similar materials. May 27
 7202 A. M. Clark, London—Communicated by M. M. Bair, France. Improvements in reverberatory furnaces. May 28
 7328 J. L. Rigg, Knowle. Improvements in apparatus for the manufacture of transparent ice. June 1
 7106 G. Criner, London. Improvements in furnaces for the combustion of fuel. Complete specification. June 2
 7487 S. H. Adams, York. Improvement in appliances for the intermittent discharge of water or other liquid. Complete specification. June 4

- 7522 W. McCulloch, London. Improvements in filters. June 4
 7526 P. J. Davies, London. Improvements in fastenings for the lead linings of oil bleaching, sulphate of ammonia, evaporating, and other similar lead-lined tanks. June 4
 7768 A. Paget, London. Improvements in and connected with taps for gas and other fluids. June 9
 7988 W. G. Hudson, Manchester. Improvements in carburetting apparatus. June 15

COMPLETE SPECIFICATIONS ACCEPTED.*

1885.

- 7514 G. H. Bolton. Fastening device applicable to lids or covers of caustic soda or other drums, boxes, jars, etc., in which a nearly cylindrical part is required to be quickly fastened and loosed. June 18
 8530 E. Edwards—Communicated by L. Rohrmann and M. Hiller. Apparatus for effecting the absorption of gases or vapours by liquids. June 1
 9108 S. C. C. Currie and J. A. Timmis. An electric air pump. May 28
 9201 D. K. Clark and W. J. E. Feakes. Filter presses. June 8
 9231 H. W. Todd. Metallic drums for containing chemicals, etc. May 25
 9316 W. L. Wise—Communicated by J. G. Hansel and F. L. Krumblegal. Improvements in furnaces. June 22
 9387 W. Thomhison. Stoves for heating the blast for blast furnaces, etc. June 1
 9959 A. Bell. Filters. June 11
 15828 S. M. Lillie, Philadelphia, U.S.A. Process and apparatus for drying bone-black. June 22

1886.

- 2472 C. J. C. Bailey. An improved filter. June 11
 4096 J. Laidlaw and A. J. Liversedge. Construction of centrifugal machines or hydro-extractors. June 1
 5631 J. W. Holland. Apparatus for producing pressure or a varied degree of vacuum. June 18
 5731 J. R. Alsing. Improved triturating mill. June 18
 6310 C. C. Gilman. Improved means for filtering. June 18
 6348 O. Imray—Communicated by J. B. Archer. Boiler furnaces for combustion of gaseous fuel. June 22

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

- 6858 A. J. Boulton, London—Communicated by A. Montenegro, Spain. Improvements in the method of heating apartments. May 21
 6889 A. M. Clark, London—Communicated by C. A. Paquelin, France. Apparatus for automatically generating and burning inflammable vapours. May 21
 6919 E. Edwards, London—Communicated by K. Wehse, Germany. Improvements in heating stoves and furnaces. May 22
 6991 A. Brin, London. Improvements in apparatus for regulating the flow of and uniting and burning oxygen and hydrogen or other gases. May 25
 7112 W. S. Sutherland, Liverpool. Improvements in and applicable to gas producers. May 27
 7228 E. J. Barnfield, Halifax. Improvements in gas retort furnaces. May 31
 7258 R. Good, London. Improvements in hydraulic mains for gas-works. May 31
 7322 J. Bradley, Salford. Improvements in gas-lighting. June 1
 7375 F. Hill, Cheltenham. An improved apparatus for making and burning gas from petroleum and other similar oils. June 2
 7377 F. Radcliffe, Plumstead. Improvements in gas producers. June 2
 7401 J. Hepworth, Glasgow. Improvements in and connected with gas fires. June 2
 7484 G. Parker, Wrexham. An improved apparatus for heating steam boilers, glass furnaces, etc., with gas. June 1
 7578 J. H. W. Stringfellow, London. Improvements in lighting and heating, and apparatus therefor. June 5
 7580 C. F. Claus, London. Improvements in the purification of coal gas. June 5
 7581 C. F. Claus. Improvements in the purification of coal gas. June 5
 7582 C. F. Claus. Improvements in the preparation of ammonia compounds from coal gas. June 5
 7583 C. F. Claus. Improvements in recovering cyanogen compounds obtained in purifying gas. June 5
 7584 C. F. Claus. Improvements in the purification of coal gas. June 5
 7585 C. F. Claus. Improvements in the purification of coal gas. June 5
 7586 C. F. Claus. Improvements in the purification of coal gas. June 5
 7622 N. J. Holmes, Lewisham. Improvements in self-igniting and inextinguishable signal lights for marine and other purposes. Complete specification. June 7
 7705 J. Bartle, London. Improved appliance or means of adjusting and locking the handles of gas retort covers or lids. June 8

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Specifications thus advertised are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

7706 H. Cockey and F. C. Cockey, London. Improvements in gas purifier centre valves. June 8
 7733 T. Drake, Huddersfield. An improved method of manufacturing gas from benzoline or other similar suitable oil, and in apparatus employed therein. June 9
 7755 J. Holden, London. An improved injector for feeding furnaces with liquid fuel. June 9
 7770 J. Dredge, London. Improvements in apparatus for producing intense heat by gas. June 9
 7868 G. A. Biddell, London. Improvements in apparatus used in the production of gas from coal or other suitable substances. June 11
 8163 R. Stone, London. Improvements in the manufacture of fuel, and in machinery or apparatus used in connection therewith. June 19
 8207 G. Anderson, London. Improvements in apparatus to be used in the purification of coal gas. June 21

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

6938 T. S. Lindsay, London. Generating fixed gases for illuminating, heating, and metallurgical purposes. May 25
 8880 J. Hanson. Construction and arrangement of hydraulic mains and ascension pipes for the manufacture of coal gas. June 18
 9116 R. de Soldenhoff. A continuous arrangement of regenerating apparatus for coke ovens. May 25
 9298 A. H. W. Brown. Means for economising fuel and consuming smoke in steam boilers. June 18
 9477 H. H. Lake—Communicated by M. Ritter von Pichler. Apparatus for utilising the heat from lamps or candles for heating food, etc. May 28
 9591 J. McCulloch and W. Black, Glasgow. Machinery for preparing and compressing materials for use as fuel or for smelting purposes. June 22
 9731 W. B. Westlake. Apparatus for manufacture of artificial fuel, etc., and preparing materials for same. June 8
 10139 J. K. Field. Treating hydrocarbon bodies or substances. June 15
 12059 M. B. Parrington. Improvements in coke ovens, and in doors for the same. June 8

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

6853 J. G. Johnson, London—Communicated by The Farbenfabriken vormals F. Bayer & Co., Germany. Improvements in the manufacture of choline derivatives. May 21
 6965 C. D. Abel, London—Communicated by The Farbwerke vormals Meister, Lucius & Brüning, Germany. Improvements in the production of compounds of laevulinic acid, with the aromatic hydrazines. May 21
 7137 C. D. Abel, London—Communicated by The Farbwerke vormals Meister, Lucius & Brüning, Germany. Improvements in the production of indol-derivatives from the compounds of the aromatic hydrazines with the ketones and aldehydes. May 27
 7283 C. A. Martius, London. A process for the production of mixed azo colours from the diamido combinations of the ethers of diphenole. May 31
 7284 C. A. Martius, London. A process for the production of azo colours from the para-diamines of stilbene and florenone. May 31
 7910 W. E. Gedge, London—Communicated by Messrs. Ewer and Pick, Germany. Improvements in the manufacture of azo dyeing stuffs. June 12

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

9858 J. H. Johnson—Communicated by The Badische Anilin und Soda Fabrik. Manufacture of yellow and orange colouring matters suitable for dyeing and printing from dioxystartaric (carboxytartaric) acid. June 1
 10377 W. Clark—Communicated by The Farbfabrik vormals Branner. Production of colouring matters. June 15

1886.

6190 L. Landsberg. Preparation of *m*-methoxy-*p*-nitrobenzaldehyde for use in the manufacture of vanillin. June 11

V.—TEXTILES: COTTON, WOOL, SILK, ETC.

APPLICATIONS.

6908 W. B. Ritchie, London. Improvements in the manufacture of bituminous and other felts. Complete specification. May 22
 6916 J. Priestley, Wakefield. Chemically treating rags and the waste materials of silk, or combinations of silk with other animal or vegetable fibres. May 21
 7278 F. Mollet-Fontaine, London. Improvements in the treatment of vegetable textile materials, and of threads and fabrics made therefrom. May 31
 7634 L. A. Groth, London—Communicated by Holzer & Co., Germany. A new or improved method of cleansing wool and woollen fabrics. June 7

7735 W. M. Archer and J. Archer, Sandal, Yorks. Process for treating silk and silky rags for manufacturing purposes. June 9

COMPLETE SPECIFICATION ACCEPTED.

1885.

8795 C. D. Abel—Communicated by La Société Dubus, Coget et Cie. Removal of vegetable impurities from wool by chemical means, in combination with steam. May 28

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

6988 J. Smith, Manchester. Improvements in dyeing cotton, silk, wool, and other textile materials, either in the raw state or in the form of yarn, or as cloth in the manufactured state; and in apparatus therefor. May 25
 7083 T. R. Shillito, London—Communicated by The Zittauer Maschinenfabrik und Eisengiesserei, Germany. An apparatus for oxidising aniline black on woven fabrics. May 26
 7841 T. Holliday, London. Improvements in dyeing textile fibres. June 11
 8065 C. Lohmann, London. Improvements in dyeing blue, especially adapted for wool. June 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

7152 H. Willey, J. W. Robbs and J. S. Wallace. Method of and appliances for marking patterns on textile fabrics. June 11

1886.

6070 H. H. Lake—Communicated by C. N. Waite. Mordants for use in dyeing or printing calico and other fabrics. June 8

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

6824 D. G. McLellan, Glasgow—Communicated by P. K. Oushkoff and J. Y. McLellan, Russia. Improvements in the manufacture of sulphate of alumina. May 21
 6917 W. L. Wise, London—Communicated by Oesterreichische Anilin-fabrik Strakosch & Co., and C. O. Weber, Austria. Improvements in the manufacture of fluoride of aluminium, and compounds containing the same. May 22
 6999 W. C. Wren, London. A process of and apparatus for distilling ammonia. Complete specification. May 25
 7129 J. Y. Johnson, London—Communicated by C. Dubois, France. Improvements in apparatus for extracting and subliming sulphur. May 27
 7157 A. M. Clark, London—Communicated by M. Honigmann, Germany. An improved method of protecting copper vessels used for soda, steam boilers, and for evaporating the potash and soda lyes. May 27
 7192 A. Fritsch, London. Improvements in the manufacture of carbonic oxide gas. May 28
 7199 J. Brock and T. Minton, Widnes. Improvements in the manufacture of bleaching powder, and in apparatus for effecting the same. May 28
 7299 F. Maxwell Lyte, London. Improvements in the manufacture of lead sulphate and certain bye-products. May 31
 7355 H. H. Lake, London—Communicated by U. Cummings, United States. Improvements in the manufacture of sulphuric acid. Complete specification. June 1
 7395 P. M. Justice, London—Communicated by H. Y. Castner, United States. Improvements in the manufacture of sodium and potassium. June 2
 7603 C. Toppan, London. Improvements in bleaching compounds. Complete specification. June 8
 7801 J. Y. Johnson, London—Communicated by F. von Heyden, Germany. Improvements in the manufacture of salicylic acid, and of the substitution compounds and homologues thereof. Complete specification. June 10
 7859 B. Dawson, London. New or improved means or apparatus for evaporating waste lyes, and recovering soda from black liquor. June 11
 7861 M. Schwab, London. Improved method of treating and rendering innocuous liquid residuals of the manufacture of sulphate of ammonia and the like. June 11
 8018 M. von Nencki, London. Improvements in the manufacture of salicylic acid "esters." June 16
 8155 J. Y. Johnson, London—Communicated by C. Kolbe and C. Rentsch, Germany. An improvement in the manufacture of alpha- or beta-carbonaphthol acid alkaline salts. Complete specification. June 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

7867 A. Brin, London. Manufacture of bioxide of barium, and use of same in oxygenating water for bleaching, etc. May 25
 8182 F. W. Holloway. Improvement of sea salt or other salts for baths in lieu of sea-bathing, etc. June 11

8623 S. H. Johnson and C. C. Hutchinson. Preparing milk of lime, and apparatus therefor. May 25
 8692 F. Foster. Generating carbonic acid gas automatically. May 28
 9125 F. J. P. Cheesbrough—Communicated by J. Hawliczek. Manufacturing soda crystals and caustic soda direct from the bicarbonate resulting from the ammonia soda process, and recovery of ammonia and carbonic acid; and apparatus therefor. June 1.

1886.

5170 J. Maclear. Manufacture of hydrates of strontia and of baryta. May 25

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

6691 J. French and J. Craig, London. Process of manufacturing rolled plate-glass, and machinery employed therefor. June 22
 6873 F. H. It. Manchester. An improvement in earthenware pipes used for sewage and other purposes. May 22
 7123 G. Goodyear, Birmingham. Improvements in the decoration of glass vases and other objects. May 27
 7214 F. Gibbons, Brockmoor. Improvements in the manufacture of ceramic tesserae, mosaic, tiles, eggars, and other fictile goods, and in the machinery connected therewith. May 31
 7233 R. E. Donovan, F. Hazlett and A. Ross, Dublin. A new or improved method of blowing glass or other plastic substances. May 31
 7338 E. Picard, London. Improvements in or relating to the manufacture of glass. June 1
 8022 M. Schreiber, Manchester. Improvements in the method of annealing glass tubes, cylinders, hollow-ware, and analogous articles. Complete specification. June 16
 8023 F. S. Shirley, London. Improvements in the manufacture of glass, and articles therefrom. Complete specification. June 16
 8071 E. A. Cowper, London. An improvement in the moulding of ceramic vessels. June 17

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

7285 J. B. F. Frédeureau, London. Treatment of slate, schist, and waste thereof, for the production of material applicable for structures, vessels, and other uses. May 31
 7326 E. Brething, London. Improvements in the manufacture of roofing tiles, and in apparatus employed in this manufacture. June 1
 7361 H. H. Lake, London—Communicated by U. Cummings, United States. An improvement in the manufacture of cement. Complete specification. June 1
 7438 E. Kerry and E. C. Kerry, Highgate. The improved formation of building bricks. June 3
 7492 W. Brierley, Halifax—Communicated by F. Wallbrecht and H. Russe, Germany. Improvements in the manufacture of artificial elaterite or elastic bitumen, to be employed in road-making, roof-surfacing, and other like purposes and uses. June 4
 7617 H. Diedrich, Liverpool. Improvements in tiles. Complete specification. June 7
 7671 H. Mathey, London. Improvement in the manufacture of cement. Complete specification. June 8
 7675 H. Mathey. Improvement in the manufacture of cement. Complete specification. June 8
 7676 H. Mathey, London. Method of colouring cement. Complete specification. June 8
 7745 H. Poole, London. Improvements in compositions for artificial stone, cement, and analogous uses. June 9
 7762 H. R. Snelgrove, Clapham. The more perfect calcination of Portland cement, the better preservation of its qualities during transport in bulk by sea, and for other advantages associated with its manufacture. June 9
 7888 F. W. S. Stokes, Kensington. Improvements in the processes and manufacture of cement in a powdered state, and the apparatus relating thereto. June 12
 8067 P. J. Milligan, Glasgow. Improvements in and connected with the manufacture of bricks. June 17
 8120 S. Lowden, London. Improvements in the manufacture of Portland cement. June 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

9017 J. H. Wood. Ovens for drying slurry and similar substances. May 28
 9789 W. P. Thompson—Communicated by G. Lilienthal. Improvements in manufacture of artificial stone. June 1

1886.

5994 G. Marcion. Process for preserving timber. June 4
 6061 L. A. Groth—Communicated by F. L. Perriere. Roofing tiles. June 22

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

6974 E. Hunt, Glasgow—Communicated by G. Thomson, United States. Improvements in obtaining copper from solutions of its salts. May 25
 6977 C. J. Sandahl, G. Bargate, and C. B. Phillips, Chester. The manufacture of ferro-manganese, silico-spiegel, spiegelisen, and chrome-iron. May 25
 6992 L. L. Sagendorph, London. Improvements in machines for corrugating sheet metal. Complete specification. May 25
 7008 W. Evans, London. Improvements in apparatus for manufacturing steel sleepers and other metallic articles. May 25
 7191 A. Fritschl, London. Improvements in smelting iron and other metallic ores, and apparatus therefor. May 28
 7371 D. Caddick, Middlesbro'. Furnaces for heating and melting iron or steel, with improved brick for building furnaces, etc., manufactured from old material with a certain admixture of fire clay. June 2
 7462 W. C. Tweney, London. Improvements in machinery or apparatus for blowing, refining, preparing, and purifying molten metals. June 3
 7637 G. D. Fitzgerald, London. Improvements in separating and obtaining gold and silver from their alloys with each other and with other metals. June 7
 7777 W. Briggs, Arbroath. Improvements in the process for preserving iron and steel structures from oxidation. June 10
 7796 P. Jensen, London—Communicated by The Deoxidised Metal Co., United States. A process for deoxidising metals. June 10
 8130 J. Noad, London. Improvements relating to the extraction of gold, silver and copper from ores and other substances or products containing such metals. Complete specification. June 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

6633 F. Siemens. Construction of open hearth or tank furnaces for melting iron and steel, etc. June 1
 8235 P. J. Davies. Apparatus for lead burning. May 25
 8906 H. W. Hollis. Improvements in rolling and forging metals. June 8
 9009 W. H. Walton. Process of preparing copper for casting. June 4
 9883 G. Leyshon. Method of and apparatus for manufacturing tin andterne plates or sheets, and for galvanising sheets of iron. June 15
 10237 O. M. Thowless. Soldering aluminium, and preparing aluminium for such soldering. June 4
 12485 F. W. Koffler and E. Zwierzina. Process of and means for coating sheet metal with zinc. June 11

1886.

1872 A. J. Boulton—Communicated by L. W. Sinsabaugh. Reducing steel railroad rails to plate metal. June 18
 3448 F. Brain. Shot firing and blasting in mines by the agency of electricity. June 18
 6128 G. Craig. Treatment of blast furnace or other slags for obtaining useful products therefrom. June 8
 6367 P. A. Newton. Communicated by C. A. Paillard. Metallic alloys. June 18
 6372 H. H. Lake—Communicated by E. E. Wood. Rolling and welding iron and steel, and fluxes therefor. June 18
 6404 A. Gutensohn. Process for coating the surface of iron or other metals with tin, lead, or terne. June 15

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

6981 R. Jaques, Newcastle-on-Tyne. Improvements in toilet soap tablets. May 25
 6989 A. Watt, Manchester. An improvement in the manufacture of a compound for washing and cleansing purposes, and apparatus to be used in its manufacture. May 25

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

9352 M. Bauer—Communicated by J. Merz. Extracting fat, etc., from dissolvable materials, and apparatus therefor. May 25
 12305 R. Livesey, London—Communicated by Dr. Duncan. Liquid soap. June 22
 13361 A. T. Hall, London. Refining vegetable oils. June 22

1886.

6172 F. P. Warren. Improvements in lubricants. June 15

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

6815 W. Corbould, Peckham. Improvements in manufactured whitening, to be called Corbould's sanitary whitening. May 21

- 7374 J. Blain, Manchester. Improvements in the manufacture of shoe blacking. June 2
 7197 J. Cameron, Glasgow. Improvements in anti-fouling compositions for ships. June 4
 7917 H. F. A. Prinzhorst, London. Improvements in the manufacture of hard rosin. June 12
 7955 A. Buck, London. Improvements in the method of and in apparatus for drying pigments and other comminuted pasty substances. Complete specification. June 15

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 10109 H. Gardner—Communicated by D. Lublinski. Compound for application to wood, metal, or other substance as a paint or varnish to prevent decay, rust, or other injury by atmospheric action. June 22

1886.

- 4736 H. E. Newton—Communicated by H. M. Hanmore, R. Van Selous Mattison, and H. G. Keasbey. Non-conducting composition and covering for pipes, vessels, and receptacles. June 4
 5270 J. B. Melvin. Manufacture of resinous compounds. June 1

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

- 7145 A. H. Mangin, London. A new product for depilating and preserving hides. May 27
 7274 T. Brain, Peckham. The continuity system of tanning. May 31
 7692 W. P. Thompson, Liverpool—Communicated by J. W. Fries, United States. Improvements in tanning. Complete specification. June 8
 7743 E. P. Nesbit, London. An improvement in tanning light hides or skins. June 9
 7744 E. P. Nesbit. An improvement in tanning. June 9

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 12302 H. E. Howe. Method of rendering leather more durable, pliable, and proof against damp. May 25

1886.

- 5491 N. A. Alexanderson and L. Hvass. Method of tawing hides and skins. May 28
 6668 A. J. Boulton—Communicated by G. E. Kasemodel. Treatment of leather, and an improved mixture therefor. June 18

XIV.—AGRICULTURE, MANURES, Etc.

APPLICATION.

- 7510 W. G. Gard, London. A manurial insecticide. June 1

COMPLETE SPECIFICATION ACCEPTED.

1886.

- 5686 H. J. Allison—Communicated by W. S. Pierce. Fertilising compounds, and process of manufacturing the same. May 28

XV.—SUGAR, GUMS, STARCHES, Etc.

APPLICATIONS.

- 7186 F. Bauder, London. An improved process for manufacturing perforated or figured sugar tablets or blocks. Complete specification. May 28
 7524 R. Dick, Glasgow. Improvements in gutta-percha compounds, and in the manufacture thereof. June 1
 7950 M. Blake and J. Barclay, Glasgow. Improvements in and connected with sugar mills. June 15

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 8857 C. Lyle and J. Lyle. Apparatus for cleansing sugar in centrifugal machines. May 25
 10110 A. C. Henderson—Communicated by G. Durozad. Manufacturing sugar from amylaceous and cellulose matters. June 1

XVI.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

- 7325 P. M. Justice, London—Communicated by J. D. Hazlett and W. R. Bennett, United States. Improvements in apparatus for automatically supplying gas to beer or like beverages. Complete specification. June 1

- 7591 A. J. Boulton, London—Communicated by H. A. O. P. Lissagaray, France. Improvements in the treatment of alcoholic liquors or other stimulants or liquors. June 5
 7619 J. Death, London. Improvements in preserving beer. June 7
 8082 W. S. Squire, London. Improvements in the manufacture of yeast. June 17
 8161 Sir F. Bolton, London. A process for cleaning or fining beer. Complete specification. June 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 8921 A. Ralu, fils, J. Grathvold and H. A. Browne. Preparing and treating syrups and molasses by mixing them with substances adapted for distillation, and manufacturing spirit therefrom. May 28
 9950 H. H. Lake—Communicated by A. E. Ferve. Manufacture of syrup and beer from maize and malt. June 22

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

APPLICATIONS.

A.—CHEMISTRY OF FOODS.

- 7303 C. Hoorn, London. Improvements relating to the preservation of milk. May 31
 7644 H. H. Lake, London—Communicated by N. Muller, Russia. Improvements relating to the preservation of alimentary substances. June 7
 7815 G. Porter, London. A preparation of food for dogs and other animals, game, and poultry. Complete specification. June 10
 7842 H. W. Hart, London. A new food compound. June 11
 7862 G. Grout, Hornsey. An improved preparation of cocoa and chocolate. June 11

B.—SANITARY CHEMISTRY.

- 6819 W. Thomson, Manchester. The employment of certain substances for antiseptic purposes. May 21
 7174 H. Fewson, London. Improvements in the treatment of sewer and other similar noxious gases. Complete specification. May 28
 7333 J. Fenton, Leeds. An improved means of purifying, precipitating, and filtering sewage, drainage, and the like matters. June 1
 7536 J. W. Fereday, London. Improvements in the construction and arrangement of tanks for treating sewage. June 1
 7730 G. V. Alsing, Sheffield. Improvements in the treatment of sewage and other polluted waters and their deposits, and in apparatus employed therein. June 9
 8087 J. C. W. Stanley, London. Improvements in the method or process for recovering combustible matters from town and similar refuse, and an improved manufacture of fuel therefrom. June 17
 8088 J. C. W. Stanley. Improvements in the treatment of road sweepings, and in apparatus therefor. June 17
 8144 H. R. Newton, Weybridge. Improvements in drainage and drainage works applicable to towns or to country districts; and also for improvements in dealing with sewage and waste waters. June 19

C.—DISINFECTANTS.

- 6966 H. M. Caldwell, London. An improved deodorant and disinfectant. May 24
 7324 W. H. Bibby, Preston. An improved disinfecting, deodorising, and fumigating powder. June 1
 7386 E. Foster, Preston. Fumigating, disinfecting, and deodorising purposes. June 2

COMPLETE SPECIFICATIONS ACCEPTED.

A.—CHEMISTRY OF FOODS.

1885.

- 9437 W. W. Nightingale. Means for forming and maintaining ice surfaces, and treating the atmosphere of glaciers or cooling chambers. June 22

B.—SANITARY CHEMISTRY.

1885.

- 13761 G. W. Bremner. Treatment of chemical agents, and employment of the resultant for the precipitation, clarification, and defecation of sewage. June 8

1886.

- 6520 G. R. Redgrave. Treatment of sewage-water by the lime process for the production of cement. June 15

C.—DISINFECTANTS.

1885.

- 9353 W. R. Lake—Communicated by M. R. Garcia. An improved disinfectant. May 25
 10130 H. H. Lake—Communicated by C. Collin et Cie. Manufacture of an improved antiseptic. June 11

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

- 6845 P. Bailly, London. Improvements in primary and secondary batteries. Complete specification. Nov. 6, 1885.
- 6869 C. Clamond, London. Improvements in the transformation of heat into electricity, and in apparatus for that purpose. May 21.
- 6921 J. T. Armstrong, London. Improvements in or relating to the construction and working of electrical batteries. May 22.
- 6957 M. Kotyra, London. Improvements in galvanic batteries. May 21.
- 6969 G. V. Lagarde, London. Improvements in and relating to electric batteries. May 21.
- 7002 A. H. Reed, London—Communicated by J. T. Williams, United States. A new or improved electro-magnetic transmitter. Complete specification. May 25.
- 7004 R. E. R. Crompton, London. Improvements in apparatus for generating currents of electricity and in electro-motors. May 25.
- 7028 G. F. Rose, London. Improvements in primary electric batteries. May 25.
- 7117 E. Tuteur, London. An improvement in or connected with galvanic batteries. May 27.
- 7189 J. E. Pearce, London. An improvement in primary voltaic batteries. May 28.
- 7270 P. W. Williams, London. Improvements in combined dynamo-electric machines and motors. May 31.
- 7277 A. Le Neve Foster and F. V. Andersen, London. Improvements in dynamo-electric machines and electric motors. May 31.
- 7279 A. H. Byng, London. A regulator for high-tension electric currents. May 31.
- 7312 R. H. Courtenay, London. Improvements in the method of, and an amalgam for amalgamating zinc or other metal plates, such amalgam being alone applicable for voltaic electric elements. June 1.
- 7353 P. R. de Fumcheux d'Ifumy, London. Improvements in galvanic batteries. June 1.
- 7376 V. Nowak, Vienna. Improvements in automatic regulators for electric currents. June 2.
- 7426 C. Petri, London. Process for the production of the ferri-cyanides of potassium, sodium, and ammonium by electrolysis. Complete specification. June 2.
- 7440 T. Parker, Wolverhampton. Improvements in the winding and connection of dynamo machines with accumulators. June 3.
- 7474 W. T. Whiteman, London—Communicated by R. J. Gulcher, Germany. Improvements in secondary batteries. June 3.
- 7544 H. J. Smith, London. Improvements in dynamo-electric machines. Complete specification. June 4.
- 7561 J. Gibson and F. M. Gibson, Glasgow. An improved electrode. June 5.
- 7576 J. A. Kingdon, London. Improvements in dynamo-electric machinery. June 5.
- 7596 J. Pitkin, London. An improvement in the construction of elements for secondary batteries or accumulators. June 5.
- 7636 D. G. Fitzgerald, London. Improvements in the preparation or manufacture of negative elements for voltaic batteries. June 7.
- 7704 E. J. Houghton, Peckham. Fuse for dynamo-electric machines. June 8.
- 7818 C. Smith, London. Improvements in secondary batteries. June 11.
- 7860 S. P. Thompson, London. Improvements in dynamo-electric machines. Complete specification. June 11.
- 7953 W. Geipel, Edinburgh. Improved method of regulating currents generated by dynamo-electric generators. June 15.
- 7966 E. Commelin, G. Bailbacko, C. Desmazures, A. Lebrun de Virloy, and L. de Bousignac, London. Certain new and useful improvements in secondary batteries acting as accumulators of electricity. June 15.
- 7983 A. Serrailier, London. An improvement in the construction and automatic regulation of primary batteries. June 15.
- 7997 J. E. Chaume and P. Perrier, London. Improvements in accumulators of electricity. June 15.
- 8003 L. B. Atkinson, W. T. Gooden, and A. P. Trotter, Halifax. Improvements in dynamo-electric generators and motors. June 16.
- 8040 C. Ziperowski, M. Deri, and O. T. Blathy, London. Improvements in regulating alternating electric currents. June 16.
- 8081 A. M. Clark, London—Communicated by C. R. Goodwin, France. Improvements in voltaic batteries. June 17.
- 8151 J. G. Tongue, London—Communicated by J. Kirby, Belgium. Improvements in the manufacture of carbons for electrical purposes. Complete specification. June 19.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 8717 A. I. Gravier, London. Machines for generating electro-motive power. June 8.
- 9522 C. P. Elieson. Electrical accumulators. May 25.
- 9526 T. J. Handford—Communicated by F. J. Sprague. Electro-dynamic motors. June 15.
- 9580 A. Muirhead and C. R. Alder Wright. Preparation of insulating compounds for electrical purposes. June 1.

- 9896 H. J. Haddon—Communicated by K. Pollak and G. Wehr. Improved galvanic element or battery. May 25.
- 10041 S. H. Emmens. Compound galvanic batteries, and method of working the same. June 8.

1886.

- 1937 W. R. Lake—Communicated by W. E. Case. Conversion of heat energy into electrical energy, and apparatus therefor. May 25.
- 5611 H. H. Lake—Communicated by The Helios Electric Light and Telegraph Construction Company. Machinery or apparatus for the generation of electric currents. June 4.

XIX.—PAPER, PASTEBOARD, ETC.

APPLICATIONS.

- 7305 F. L. Teed and H. W. Teed, London. Improvements in the manufacture of sensitised paper, cloth, or the like, for copying drawings, and for similar purposes. May 31.
- 7453 J. Morley, London. Waterproofing millboard, paper, and cardboard for advertising tablets, posters, and signs. June 3.
- 7530 E. de Pass, London—Communicated by La Société de Lafarge, Lebré et Cie., France. A process and apparatus for rendering all kinds of paper impermeable and transparent; the said apparatus being likewise applicable for rendering cotton or other fabrics impermeable. June 4.
- 7562 J. Gibson and F. M. Gibson, Glasgow. Improvements in the manufacture of paper and analogous materials. June 5.
- 7633 L. A. Groth, London—Communicated by H. Schnurman and G. Closs, Germany. A new or improved process and apparatus for manufacturing sulphite cellulose in beton boilers. June 7.
- 7901 C. Weygang, London. Improvements in waterproofing and sizing paper and such like material. June 12.
- 8039 E. Thiebaud and C. Thiebaud, London. An improvement in the manufacture of coloured paper, plain or ornamented. June 16.
- 8148 C. Morfit, London. Improvements in the manufacture or treatment of paper. June 19.

COMPLETE SPECIFICATION ACCEPTED.

1885.

- 9575 W. B. Woodbury and F. Vergard. Method of making paper transparent to render it suitable as a substitute for glass for photography, etc. June 22.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

- 6899 S. Waters, London. Improvements in tonic bitters. Complete specification. May 22.
- 7903 W. L. Wise, London—Communicated by E. Mourlot, fils, France. Obtaining certain products or substances from essence of birch-bark, and utilising the same in the manufacture or production of certain compounds or substances. June 12.

XXI.—EXPLOSIVES, MATCHES, ETC.

APPLICATIONS.

- 7323 D. F. Downing, Woolwich. Improvements in the manufacture of certain explosives. June 1.
- 7407 A. M. Clark, London—Communicated by H. J. Smith, United States. Improvements in electric fuses for pyrotechnical and other purposes. Complete specification. June 2.
- 7911 J. Rigby, London. Improvements in ammunition. June 12.
- 8032 A. V. Newton, London—Communicated by A. Nobel, France. Improvements in explosive compounds. June 16.
- 8033 A. V. Newton, London—Communicated by A. Nobel. Improvements in detonators. June 16.
- 8127 T. Nordenfellt, London. Improvements in fuses. June 21.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 10110 W. F. Ruston. Detonating fog signals for railways. May 28.
- 11112 C. D. Abel—Communicated by F. Guens. Explosive compound for firearms and blasting purposes. June 11.

1886.

- 6310 E. L. Zalinski. Fuses for explosive shells and torpedoes. June 15.
- 6661 H. Schöneweg. Explosive compounds. June 18.

THE JOURNAL

OF THE

Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 7.—VOL. V.

JULY 29, 1886.

Non-Members 30/- per annum; Members
21/- per Set; Single Copies 2 6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.

COUNCIL FOR YEAR ENDING JULY, 1887.

President: David Howard.

Vice-Presidents:

Sir I. Lowthian Bell, Bart., F.R.S.	Sir H. E. Roscoe, M.P., F.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
Dr. Peter Griess, F.R.S.	E. C. C. Stanford.
Dr. Ferdinand Hurter.	J. C. Stevenson, M.P.
E. K. Muspratt.	John Williams.
Dr. W. H. Perkin, F.R.S.	Philip J. Worsley.

Ordinary Members of Council:

John Calderwood, F.R.S.E.	John Pattinson.
Eustace Carey.	S. A. Sadler.
R. Forbes Carpenter.	Sir Bernhard Samuelson,
Henry Boulton.	Bart., M.P.
Dr. John Evans, F.R.S.	Sir Chas. Tennant, Bart.
S. H. Johnson.	Lewis T. Wright.
Ivan Levinstein.	

With Sixteen Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

THE JOURNAL.

Publication Committee:

The President.

Sir F. A. Abel, F.R.S.	Prof. A. K. Huntington.
Joseph Bernays, M.I.C.E.	F. Hurter, Ph.D.
H. Brunner.	Ivan Levinstein.
W. Lant Carpenter.	Prof. R. Meldola, F.R.S.
Prof. Frank Clowes, D.Sc.	Ludwig Mond.
George E. Davis.	E. K. Muspratt.
W. Y. Dent.	C. O'Sullivan, F.R.S.
Prof. Dewar, F.R.S.	John Pattinson.
Prof. Chas. Graham, D.Sc.	Dr. W. H. Perkin, F.R.S.
Peter Griess, Ph.D., F.R.S.	Sir H. E. Roscoe, M.P., F.R.S.
D. B. Hewitt, M.D.	John Spiller.
David Howard.	A. Norman Tate.
J. J. Hummell.	Thomas Tyrer.

Editor: Watson Smith, The Owens College, Manchester.

ASSISTED BY THE FOLLOWING STAFF OF

Abstractors:

G. H. Beckett.	C. F. Cross.
D. Bendix.	A. R. Davis.
E. E. Berry.	A. G. Green.
E. J. Bevan.	S. Hamburger, Ph.D.
W. Dalrymple Borland.	James Hulme.
T. L. Briggs.	Bertram Hunt.
E. G. Clayton.	C. C. Hutchinson.
Julius B. Cohen, Ph.D.	D. E. Jones.

Abstractors:

W. E. Kay.	H. A. Rademacher.
A. J. King, B.Sc.	A. Rec. Ph.D.
D. A. Louis.	F. W. Renaut.
F. Machenhauer.	James Taylor, B.Sc.
Wm. Macnab, Jun.	V. H. Veley, M.A.
W. G. McMillan.	Alex. Watt.
G. Harris Morris, Ph.D.	Sydney Young, D.Sc.
J. M. H. Munro, D.Sc.	

NOTICES.

The attention of members is requested to the copy of the new Bye-Laws accompanying this issue of the Journal, as it supersedes all previous copies and renders them useless.

The supply of copies of the Journal for January, 1882, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of that number, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the number will be reprinted.

CHANGES OF ADDRESS.

E. E. Berry, 1/o Upper Bedford Place; 76, George Street, Gower Street, London, N.W.
T. T. Best, 1/o Owens College; "Slicma," Victoria Park, Wavertree, Liverpool.
E. Bramwell, Charlwood, Hutton, near Liverpool (not "Hutton," as given in April No.)
G. Donald, 1/o Campsie; Arnold Printworks, North Adams Mass., U.S.A.
U. K. Dutt, 1/o Leicester; 70, Portsdown Road, Maida Vale London, N.W.
A. E. Fasnacht, 1/o St. Mary's Gate; Sandy Lane Chemical Works, Clayton, Manchester.
H. S. L. Gurney, 1/o Warrington; 19, Aughton Road, Southport.
R. Valentine Jackson, 1/o Northwich; "Ashurst," West Hill, Sydenham, S.E.
E. T. James, 1/o Cannon Street; British Alizarin Co., Ltd., Silvertown, Victoria Docks, E.
T. E. Mackenzie, 1/o Glasgow; Tharsis Mines, Huelva, Spain.
Wm. Marshall, 1/o Blue Bell Hill; 7, Walter Street, Nottingham.
T. G. McDonald, 1/o Silvertown; "Kirtoun," Seabank Road, Liscard, Cheshire.
H. Meadows, 1/o Charles Street; Spa Place, Humberstone Road, Leicester.
T. Moffatt, 1/o Tyneside Chemical Works; 5, Brandling Terrace, Felling-on-Tyne.
Dr. H. Schaeppi, 1/o Manchester; Badische Anilin und Soda Fabrik, Ludwigshafen-am-Rhein.
F. T. Schreiber, 1/o Lower Norwood; Halliwell Bleach Works, near Bolton.
Jas. Taylor, 1/o Tasmania; Waikaura, Oamarn, New Zealand.
A. Twivey, 1/o Coventry Road; Five Ways, Edgbaston, Birmingham.
S. G. Webb, 1/o Peckham; c/o F. J. Webb, 13, Portland Villas, Plymouth.

CHANGES OF ADDRESS REQUIRED.

T. McCall, 1/o Beckton, E.
John Miller, 1/o 154, Glenpark Street, Glasgow.

LIST OF CANDIDATES FOR ELECTION—JULY 30, 1886.

J. B. Aitken, Gerard's Fold Chemical Works, Widnes, chemical manufacturer.
 Andrew Campbell, 14, E. Thirlestane Road, Edinburgh, analyst.
 John Campbell, 25, New Chambers Street, New York, U.S.A., aniline dye manufacturer.
 Malcolm E. Chisholm, S. Kennington Park Road, London, S.E., technical chemist.
 Eardley Bailey Denton, Palace Chambers, Westminster, S.W., civil engineer.
 J. Doughty, Union Oil Mills, 251, Rotherhithe Street, S.E., superintendent.
 Wm. Crake, Corral Quemado, Andacollo, Coquimbo, Chili, analyst.
 Arthur Fielding, 22, Dantzic Street, Manchester, drysalter.
 F. A. Gatty, Elmfield Hall, Accrington, dyer and calico printer.
 P. Eugen Heer, 311, Oldham Road, Newton Heath, Manchester, dyer.
 Edw. Mallinckrodt, chemical works, St. Louis, Missouri, U.S.A., manufacturing chemist.
 John Metcalf, Henry Street, Church, Accrington, manager, tar distillery.
 Chas. Moseley, Grangeorpe, Rusholme, Manchester, india-rubber manufacturer.
 Henry Peaty, Longport, near Stoke-on-Trent, gas engineer and manager.
 Wm. Ross, 12, King Street, Manchester, chemical and mineral merchant.
 Alphonse Steiger, 16, Mincing Lane, London, E.C., consulting engineer.
 Cuthbert Vaux, The Brewery, Sunderland, Brewer.
 E. Robinson Walker, 18, St. Ann's Street, Manchester, patent agent.
 Chas. Williams, 1, Leadenhall Street, London, E.C., chemical engineer.

PROCEEDINGS OF THE FIFTH ANNUAL MEETING.

The Annual Meeting was held on Wednesday morning, July 14, at eleven o'clock, in the new Chemical Theatre of the University College, Liverpool. The chair was taken by the President, Mr. E. K. MUSEPRATT, who, after the reading of the minutes of the last annual meeting and their confirmation, called upon the General Secretary to read the

REPORT OF THE COUNCIL.

The Society of Chemical Industry now contains 2271 members, residing in and about the following districts:—London, 642 members; Liverpool, 184; Manchester, 312; Newcastle, 120; Birmingham, 112; Glasgow, 251; Bristol, 73; Nottingham, 75; Yorkshire, 121; Ireland, 30; parts of England and Wales not included in any of the above, 115; United States and Canada, 96; and other Countries, 140. Since the last Annual Meeting 266 members have been elected, and 86 have been lost by death and other causes, making a net gain of 180 members.

Among the names of those who have died, that of our late President, Mr. Walter Weldon, F.R.S., who passed away somewhat suddenly on the 20th of last September, stands foremost. His services to the Society were so important, and must be so fresh in the minds of all its members, as to render an extended reference to them here superfluous. In him Chemical Industry has lost a most devoted servant, and one whose place it will be difficult to fill. During his year of office he had expressed an intention of leaving to the Society his collection of scientific, technical, and chemical works. Death came upon him too suddenly to enable him to effect this disposition in writing; but his son, Mr. Raphael Weldon, has, nevertheless, agreed to fulfil his father's known intention. The Society thus becomes possessed of a thousand or more valuable works, which will form the nucleus of a reference library.

Other noteworthy losses are Mr. H. S. Evans, Chief Analyst of the Dominion of Canada, and formerly President of the Pharmaceutical Society; and Mr. Alfred Tribe, Professor of Chemistry at Dulwich College,

who was well known for his researches on the zinc copper couple.

The Council has received no applications for its consent to the formation of new sections during the year; at the same time the increasing number of members in Yorkshire encourages the belief that at no distant period of time a section will be in operation in that district. Members residing in and near Edinburgh have now resolved to form a joint section with those at Glasgow; and in future the united body is to be known as the "Glasgow and Scottish" section, due provision being made for the representation of the East of Scotland on the Committee.

Original papers read before the various sections show an increase upon the seventy-one recorded last year. Manchester heads the list with 18, Glasgow 17, London 16, Birmingham 7, Liverpool and Newcastle 6 each, and Nottingham and Bristol 5 each; making, with the two read before the last Annual Meeting, a total of 82. To their authors, as well as to those officers of sections whose zeal has elicited so much valuable information, the best thanks of the Society are due.

The Journal continues to maintain its position, and affords evidence of progress. For the guidance of the Publication Committee, Editor, and Abstractors, an amended set of rules has been drawn up by the President, Editor, and others; and after careful revision by the Publication Committee, has received the sanction of the Council. The "List of Patents Published" having been found of little use, has been replaced by a list of "Complete Specifications Accepted." Members will find this list to afford not only earlier information, but if they wish it an opportunity to lodge objections within the prescribed time. In 1882 each number of the Journal averaged 43 pages of matter; in 1883, 47; in 1884, 56; in 1885, 65 pages. The increase of cost has been more than proportional to the increase of matter, owing to the abundance of woodcuts, tables, and diagrams, which illustrate the papers. If this is to be maintained, the Society must receive still more support from the Chemical Industries.

In accordance with the expressed wish of the Liverpool and Manchester Sections, arrangements are being made to hold the meetings of the Publication Committee during the next six months in Manchester, in order to permit Northern members to attend more frequently. The Editorial Committee has been abolished, and in future each section will appoint an Editorial Committee to examine its own papers before sending them to be printed, and for the revision of discussions. It is hoped that these arrangements will conduce to economy in the production of the Journal.

The Council has to ask the approval of the members for certain alterations in the Bye-laws, one or two of which are of importance to the welfare of the Society, and are worthy of careful consideration. The most important of all deals with the subscription. Three alternative propositions have been before the Council—viz., the imposition of an entrance fee, the raising of the subscription to 30s., and the raising of the subscription to 25s. It has been resolved to recommend the last of these alternatives. The reasons which have induced the Council to ask for increased support are the following:—For several years the balance between receipts and expenditure has shown either a deficit or so narrow a surplus as to leave no margin for contingencies. This is due mainly to the cost above referred to of producing the Journal, but also in some degree to the subventions granted to sections, the levy of a special local subscription having been found impracticable. The amount paid for sectional expenses during the past

session has been £223 1s. 2d., or about 2s. 6d. per sectional member.

The Journal, when we consider the amount of valuable information contained therein, is alone well worth the proposed addition to the subscription, without taking into account the other advantages which the Society affords. Another proposed alteration will give the Council power to withhold the Journal from any member until his subscription for the current year has been paid. This plan is adopted by other societies with good results.

In conclusion, the Council expresses a hope that the existing depression among the Chemical Industries may soon pass away; and that the work which this Society has been formed to achieve may bear fruit in the shape of increased prosperity to existing industries and the establishment of new manufactures.

Sir HENRY ROSCOE, M.P., moved that the report be adopted.

This motion, seconded by Mr. A. NORMAN TATE, was carried unanimously.

The Report of the Treasurer was then read.

SOCIETY OF CHEMICAL INDUSTRY.—TREASURER'S STATEMENT FOR THE YEAR 1885.

Tate, Dr. Ad. Liebmann, and Mr. Alexander Watt, Whilst the scrutiny of the votes was proceeding, the President delivered his Address.

PRESIDENT'S ADDRESS.

On behalf of the Local Section, I have to welcome the members of the Society to Liverpool, the principal commercial centre of the large Chemical Industries of this country, and, in conjunction with Manchester, the birthplace of the Society itself.

More than 50 years ago Liverpool contained several soap and glass works, and here the manufacture of alkali was first carried out on a large scale, but the town itself has long ceased to be the principal seat of these manufactures, which have migrated to the neighbouring towns of St. Helens, Widnes, Runcorn, and Flint, and together with large works for the extraction and smelting of copper, form the staple industry of this portion of the County of Lancaster.

Having these industries principally in view, when the formation of the Society was first discussed, it

We have examined this Account of Receipts and Expenditure, and certify it as correct.

19th February, 1886.

THEABALD BROS. & MIALL,
Chartered Accountants.

ELECTION OF OFFICERS AND COUNCIL FOR THE ENSUING YEAR.

The scrutineers appointed to examine the balloting papers were—Mr. A. E. Fletcher, Mr. A. Norman

was proposed to call it the Society of Chemical Engineers, since of late years the greatest improvements had taken the direction of improvement of plant, and were clearly more due to the progress of the science of engineering than to that of chemistry.

But, on second and better thoughts, it became clear that the progress of chemical manufactures must be permanently based on chemistry, and aided by the advice of Sir H. Roscoe and other scientific chemists, we decided to found a society which should embrace all the Chemical Industries of this kingdom.

From time to time we continued to attract new adherents, and the Society was firmly constituted. On its council were placed men eminent in the scientific world as well as practical manufacturers, and the Society thus became a striking example of that union of science with practice which is the cause of the enormous progress of industry during the latter part of this century.

At our first general meeting the object of the Society and the lines upon which it might act were admirably laid down by our first President in his address, and by members of the Society in the various papers which were read.

It was pointed out that legislation on the control of the emission of noxious vapours or the pollution of rivers, or the amendment of the patents law, could be more wisely considered and guided by a Society such as ours, containing both scientific and practical chemists, than by any individual, however eminent, or by the individual action of each industry affected. The advantage of scientific and technical education, as illustrated by the progress of Germany in certain branches of chemical manufacture, was enforced by Sir H. Roscoe, and the importance of engineering devices and improved plant to the progress of the alkali manufacturer was shown by Mr. Maclear. It became apparent, however, that the annual meeting would not suffice for the discussion of these questions, and local sections were formed in the various centres of chemical industry, where papers are read and discussions take place during the year.

When any question of common interest comes to the front, it is discussed in each section, and by this means it is hoped that a common action may be elicited. The advantage of this was clearly shown in the discussion on the Pollution of Rivers. The subject was discussed in each section of the Society, and the principles upon which such legislation should be based, and how far purification of waste liquors was practicable, was clearly brought out in these discussions. As a consequence, when the River Purification Bill came before Parliament this year, Sir H. Roscoe was able to convince the President of the Local Government Board and the country of the impracticable character of that measure, and whenever legislation does take place, the opinion of this Society is certain to have considerable influence. The proposed adoption of uniform methods for estimating the commercial value of certain products, was discussed in several sections, but in this and in the special case of the assaying of copper ores, which we discussed in our Liverpool Section, the difference of opinion manifested, prevented any united action being taken. These discussions, however, will, I am persuaded, lead to more uniform methods being adopted, even if the time is not ripe for an international system.

I have briefly alluded to these subjects to show in how many ways the Society is of use, but the greatest work of the Society is the publication of the *Journal*, a publication which, in its way, is without a rival. When we consider how deficient we have been in publications of this character as compared with Germany, the Society has already conferred a great boon on the country, and will in future have a great and increasing influence on the progress and development of the chemical manufactures of the kingdom.

It has been the custom of my predecessors in the office of President to devote the greater portion

of their address to the history and progress of one special industry connected with the district in which the annual meeting is held. I am, however, in this unfortunate position, that the principal chemical industry with which I am specially identified, formed the subject of the eloquent address at Newcastle, of the late Mr. W. Weldon, whose loss this Society and the chemical world continue to deplore. I cannot emulate the eloquence of one who, in addition to his connection with the soda industry, was also a literary artist; nor can I pretend to the same intimate acquaintance with the various new processes, and the recent development of the manufacture of alkali.

I have thought, however, that it will not be uninteresting to the members of the Society, if in this city of Liverpool I endeavour to trace the history and development of the manufacture of alkali, including that of sulphuric acid, hydrochloric acid, and the production of copper, which are essentially connected the one with the other, and have been enormously increased, and improved by the introduction of the Leblanc process for making alkali from common salt by my father in 1823, within two miles of this building.

The economical success of the manufacture of artificial soda depends on the cheapness of the raw materials, and the perfection of the chemical and mechanical operations by means of which the final result is obtained.

The neighbourhood of Liverpool, in close proximity to extensive coal fields and salt deposits, and with a port in direct communication with the countries whence are derived the raw materials—sulphur, pyrites, and nitrate of soda—was well fitted to be the cradle of the manufacture, and notwithstanding the rivalry of Newcastle and Glasgow, still retains its pre-eminence. When we consider that, with the exception of sulphur, the prices of the several raw materials are not materially different from what they were 50 years ago, great improvements must have been made in the chemical operations to enable the manufacturer to sell soda ash at present prices, even taking into consideration the aid afforded by the increased consumption of the chlorine products.

The first chemical operation in an alkali works is the production of sulphuric acid. In or about the year 1823 the cost of producing this acid was, as far as I have been able to ascertain, about £3 10s. per ton of acid 140° Tw.; at the present time the cost is about 25 or 20 shillings per ton.

I shall now review briefly the means by which this economy of production has been obtained.

Attempts have often been made to supersede the costly leaden chambers by more economical structures, without success, but improvements have been made in the mode of construction of the plant, and a cheaper source of sulphur has been found in the cupreous pyrites of Spain and Portugal. The actual process followed is essentially the same as that first applied by Dr. Roebuck, in 1746, converting the sulphur into sulphurous acid at the expense of the oxygen of the air, and by the intervention of a nitrous compound for a further oxidation to sulphuric acid. The most important improvements have been the substitution of pyrites for sulphur, and the economy of nitrate of soda and fuel by means of the Gay Lussac absorbing column and the Glover Tower. Mons. Scheurer Kestner in a recent publication asserts that the first successful use of pyrites to Mons. Perrel, in 1833, but long before this date pyrites, obtained from his mines in Anglesea, was used in Liverpool by Mr. Hill. It was, however, the suicidal policy of the King of Naples in granting a monopoly of

the trade in Sicilian sulphur to a French firm, which raised the price of sulphur from £5 or £6 per ton to £12 and £14 per ton, that roused the English manufacturers to seek a substitute, which they found in the Wicklow and Welsh pyrites, and it was in this neighbourhood it was first used on a large scale, for in the years 1839 and 1840 large quantities were burnt by my father at his works at Liverpool and Newton.

As some of the pyrites contained copper, the residue, after burning, was delivered to the Sutton Copper Co., at St. Helens, so the utilisation of the copper in the pyrites was attempted at its first introduction.

The use of Irish pyrites in place of sulphur was soon generally adopted by alkali makers in the Lancashire district, but sulphur still continued to be used on the Tyne and so late as in the year 1852 we find 7580 tons of sulphur consumed in that district, when none was used in Lancashire.

Many difficulties were met with in the use of pyrites, and when the price of sulphur fell to £5 per ton, it was a disputed point among alkali makers whether at that price it was not more economical than Irish pyrites at about 25s. per ton.

Sulphur could be readily burnt on an iron plate, and although the admission of the necessary quantity of air to support combustion without admitting at the same time an excess, presented some difficulties, this was comparatively easily regulated. With Irish pyrites, however, containing only about 32 per cent. of sulphur combined with iron, sufficient air had to be admitted not only to burn the sulphur, but also to oxidise the iron; and as a consequence, the constitution of the gases entering the chamber was very irregular, and much larger chamber space was required than was necessary when using sulphur.

Pyrites smalls presented another difficulty—shelf burners were not invented—and to facilitate their burning in an ordinary kiln, the smalls were mixed with clay and shaped into balls, and dried, but the combustion was usually imperfect, and from 5 to 10 per cent. of sulphur was left in the residue. I have already mentioned that some of the ore, and particularly the smalls, contained copper, and large quantities were burnt and afterwards treated for copper in the ordinary smelting furnace, so long as the copper contents were sufficient to render the operation remunerative. It was found, however, that the percentage of copper decreased, and much of the ore contained less than 1 per cent. of copper, which was not profitable to smelt, and the residues were thrown away and accumulated in large heaps, until in the year 1850 Mr. Gossage purchased for a nominal sum large quantities of these residues, and smelted them to a regulus both at Widnes and Newcastle. This regulus was sold to Messrs. Vivian & Sons, of Swansea, who at that time were able to pay a higher price than the copper contents alone would have warranted, on account of the silver therein contained, and which they extracted, I believe by the Augustin or Zierooegel process.

In the year 1859 pyrites from Spain and Portugal was first introduced into this country and burnt by alkali makers on a large scale. This pyrites, containing about 2½ to 3 per cent. of copper, was very suitable as a flux for smelting when mixed with other ore, and large quantities of the burnt ore were delivered to the copper works at St. Helens and Widnes, but the price obtained was not sufficient to materially reduce the price of the sulphur to the alkali manufacturer, as the quantity required as a flux with ores was limited, and the smelting of the residue by itself was unprofitable. The assay of copper ores by the Cornish assayers also militated very much against the general use of these ores, for

the production of sulphuric acid and non-cupreous ores of very fine quality testing about 40 to 45 per cent. were also introduced from Norway and Belgium, and these for a time competed successfully with the cupreous ores. I have not been able to obtain full statistics of the imports of foreign pyrites into the United Kingdom for the first ten years of their introduction, but the imports into the Mersey rose from 26,641 tons in 1859 to 133,864 in 1869. From that year the statistics are fuller, and Tables A and B will show the course of the trade.

In the year 1871 about 100,000 tons of the non-cupreous ore also was imported and consumed, but this gradually fell off as the extraction of copper increased. The great aim of the alkali manufacturer was to obtain the sulphur at the lowest possible price; but as I have before explained, the intricacies of the copper assay left him very much in the hands of the copper smelter, and the increased consumption of the ore gradually raised the price directly or indirectly until a combination of alkali makers acquired the Tharsis mines, together with Mr. Henderson's patent rights for the extraction of copper by calcination of the ore with common salt, and subsequent lixiviation of the calcined mass and precipitation of the copper by iron. The calcination was conducted in a close furnace, the HCl evolved, and the copper volatilised being condensed in the usual manner, and used for the lixiviation of the roasted ores. The process itself does not differ materially from Mr. Longmaid's, to which I shall refer later, but to Mr. Henderson is due the credit of discovering the suitability of this method for the treatment of the burnt Spanish ores in the market.

The process when first applied to the burnt Irish ores was not very remunerative, but with the burnt ore from Spanish and Portuguese ores the oxide of iron or purple ore left after lixiviation found a ready sale, and practically paid for the cost of extraction, leaving the difference between the quantity of copper yielded by the wet and dry assay as profit on the operation. By the introduction of this wet extraction process, the sulphuric acid manufacturer was freed from depending on the copper smelter, and the price of sulphur was reduced owing to the competition of the various pyrites companies.

This lasted till 1879, when the three large companies combined to fix the price of pyrites, and since that time until the combination was broken up by the Tharsis Company in 1885, with a view to enable the alkali manufacturers to compete with the ammonia soda process, the price of sulphur has always been a source of great anxiety. The course of the price of sulphur to the alkali manufacturer may be seen from Tables C and D.

The effect of these improvements in copper extraction has been to bind more closely together the manufacturer of alkali with the production of copper, sometimes by the same firm, or, as in the case of the Tharsis Co., by the shares in the copper company being largely held by alkali makers. I shall, later on, trace the progress and improvement in the copper extraction, and now return to the use of pyrites in the production of sulphuric acid. The chemical process in the sulphuric acid chambers was by no means as regular as could be desired, even when burning sulphur; but with pyrites, for the reasons already given, the irregularity was still greater, and as a consequence the production of sulphuric acid showed a result considerably below what was theoretically possible, and the quantity of pyrites and nitre used to produce a ton of sulphuric acid differed in various works from 10 to 20 per cent. In his letters on Chemistry which appeared in 1851, if not in his earlier letters, Liebig says, speaking of the

process of making sulphuric acid:—"As regards the process and the apparatus, this manufacture has reached its acmé, scarcely is either susceptible of improvement," but to those practically acquainted with the manufacture and with the immense improvement since that date, this statement must appear extravagant. Liebig was, no doubt, misled by reports of very careful working with sulphur and enormous chamber space.

The introduction of Gay-Lussac's system for the absorption of the nitrous fumes escaping from the chambers was the first great improvement in the conduct of the chemical operation. In this system the exit gases of the chambers pass up a tower filled with coke, down which percolates a stream of concentrated sulphuric acid, by means of which the nitrous gases are absorbed. By diluting this nitrous vitriol and heating with steam, the nitrous gas is returned to the chambers. This system was first adopted at the St. Gobain Works in France in the year 1842, with a saving of fifty per cent. of the nitrate of soda used; but notwithstanding this saving, after it had been introduced into several works in this neighbourhood, it was subsequently abandoned, partly on account of the great wear and tear on the apparatus employed, and partly because when working with Irish pyrites the exit gases were so diluted by air as to render the absorption comparatively difficult. The use of the richer Spanish ores since 1859, which rendered the composition of the gases leaving the chambers more regular, and Mr. Glover's improvements in the concentration and denitration of the sulphuric acid, brought about the general adoption of the Gay-Lussac absorbing column. It is clear that Gay-Lussac's invention was incomplete, and at an early date (about the year 1843) experiments were made at our works in Liverpool to concentrate the sulphuric acid by means of the sulphurous gas from the pyrites kilns; but the tower through which the gas passed, and which was filled with coke, took fire owing to the carelessness on the part of the workmen, and the attempt was abandoned. To Mr. Glover is due the merit of having successfully constructed an apparatus, by means of which the nitrous vitriol is denitrated and the sulphuric acid sufficiently concentrated for use in absorbing the nitrous gas in the Gay-Lussac column. With this invention the apparatus for producing sulphuric acid in leaden chambers is complete, but the present perfection of working has only been attained by the application of trained chemists to the study of the process, and the introduction of apparatus for the accurate but rapid estimation of the constituents of the gases entering and leaving the chambers. Much of this work has been done in Germany, and by the investigations of Winkler, Weber, Schwarzenberg and others, we have a much clearer idea of the reactions which take place in the chambers and absorbing columns than formerly. Dr. Hurter's paper on the dynamic theory of the manufacture of sulphuric acid, read before the Liverpool Section of this Society in 1882, seems finally to have placed the operation on a thoroughly scientific footing. Orsat's apparatus for gas analysis, and the nitrometer, enable the manufacturer to control the working of his chambers in a very different way to that in use in the best works thirty years ago, where the colour of escaping gas on coming in contact with the air, or the use of the nose, served as an indication of how the reaction was proceeding. For the past ten years no important improvement in the manufacture has taken place, nor can we expect any, since with good apparatus the loss of sulphur escaping is reduced below one per cent., with a consumption of nitre of less than two per cent. on the sulphur burnt. In order to treat the large quantities

of burnt pyrites furnished by the alkali manufacturers, large extracting works were erected in this neighbourhood and on the Tyne, and the quantity of copper extracted greatly exceeds the aggregate production from the copper mines of the United Kingdom, as is apparent from the annexed table, extracted from the mineral statistics:—

Aggregate Productions from the Copper Mines of the United Kingdom.		Copper Pyrites imported and treated here, and Precipitate obtained.	
	ORE.		
	Tons.	Tons.	Tons.

1884	42,149	3,350	416,412

It had long been known that the copper precipitate produced from the Spanish and Portuguese ores contained both silver and gold, but as the amount of silver present in the burnt ore was exceedingly small (and even the whole of this small quantity is not obtained in solution), a simple and expeditious method was necessary, if its extraction could be made remunerative. In the year 1870, Mr. Claudet introduced his beautiful process at the works of the Widnes Metal Co., and since then about 2½ millions of ounces of silver, and 11,965 ounces of gold have been extracted from the burnt pyrites, as is shown by the following table, for which I am indebted to Mr. Claudet:—

	Silver.	Gold.
	Ounces.	Ounces.
1870 to 1879	492,727	1,925'6
1880	206,981	1,017'6
1881	258,463	1,489'8
1882	377,189	1,518'9
1883	356,349	1,983'2
To January 31st, 1884	1,691,709	7,965'1
Estimated 1884 and 1885	800,000	4,000
	2,491,709	11,965

This process is based on the precipitation of the silver from the copper liquors by means of a soluble iodide, the precipitate consists of silver iodide together with lead sulphate and chloride and sub-salts of copper. These last are removed by washing with diluted HCl, and the precipitate is then decomposed by metallic zinc, which completely reduces the silver iodide, and the resulting zinc iodide is used over again to precipitate further quantities of silver.

Where the pyrites residues are thus treated, it will be seen that all the constituents of the pyrites are practically made available: the sulphur for the production of sulphuric acid, and the iron, copper, silver, and gold, in the extracting works.

Unfortunately all the salt used in the calcination process, amounting to over 20,000 tons per annum, is at present lost, and is run away as sodium sulphate in the waste liquors.

This drainage from the extracting works, coming in contact with the chloride of calcium, the waste liquor from the Weldon process in alkali works, deposits large quantities of gypsum obstructing the drainage, which gave rise to a long and expensive lawsuit in the Widnes district.

To avoid this nuisance, the liquors were for a time evaporated and calcined, and the sulphate of soda, together with a small quantity of ferric oxide, were obtained in a marketable form, but the high price of fuel rendered all these processes unremunerative.

Sulphate of Sodium.

The second operation in the manufacture of soda by the Leblanc process is the decomposition of common salt by means of sulphuric acid, and the consequent production of sulphate of sodium and hydrochloric acid. As the chemical reaction is a very simple one, and had been carried out for the production of hydrochloric acid long before the introduction of the Leblanc process, the improvements that have been made have necessarily taken the form of improved apparatus. Where the primary object was the production of hydrochloric acid, the apparatus employed was either glass retorts or iron pots; but when the sulphate of sodium became the main object of the operation, furnaces were employed, either with or without a lead lining.

The operation is now conducted in two stages. The first, decomposition with the formation of bisulphate of sodium, takes place at a low temperature in an iron or lead pan, yielding strong hydrochloric acid, which can be easily condensed, and when the hydrochloric acid was of little value, the decomposition was completed, forming neutral sulphate of sodium, in an open reverberatory furnace, the liberated hydrochloric acid passing off together with the products of combustion. Where more hydrochloric acid was required, either for sale or for use, than was yielded by the pan, a close or muffle furnace was substituted for the second stage, or the roasting of the sulphate.

By the use of these improved sulphate furnaces, together with condensers or towers filled with coke, through which the gas passes, meeting a stream of water (a plan for which Mr. Gossage obtained a patent so early as 1836), the sulphate can be manufactured of excellent quality, and without causing injury to the neighbourhood. The substitution of machinery for hand labour, first attempted by Mr. W. W. Pattinson in 1848, has been carried to perfection by Messrs. Jones & Walsh, Mr. Maclaur, and the Bede Co. Owing to the difficulty of obtaining strong hydrochloric acid, in the case of Messrs. Jones & Walsh and Maclaur's furnaces, most manufacturers find it convenient to use improved muffle furnaces worked by hand.

Mr. Gossage introduced his plan of condensing the hydrochloric acid in 1836, but a long time elapsed before it was generally adopted. The construction of plant for chemical purposes was then very imperfect and costly, and only those manufacturers who were possessed of sufficient capital were able to apply the improved system, notwithstanding the complaints of nuisance and the frequent litigation that ensued. The present generation can hardly form an idea of the intensity of feeling and prejudice aroused against

chemical and alkali works during the first forty years of their existence—*i.e.*, up to the passing of the Alkali Act in 1863.

Hardly an assizes passed without an action for nuisance or damage, and, as this litigation continued without absolute ruin to the manufacturer, the public believed the profits to be fabulous, and many people without chemical knowledge commenced to decompose salt, sometimes selling the salt-cake to soap-makers to be converted by them into black ash, or, as the demand for alkali continued to increase, converting the salt-cake themselves into soda ash. The effect was, that long after Mr. Gossage had solved the difficulty of condensing the large quantities of hydrochloric acid evolved, many works continued to manufacture without condensation, and those who expended money on condensing apparatus were only induced to use it in proportion as they found an outlet for the liquid hydrochloric acid.

How, at last, in the year 1863, the Alkali Act was passed, and good condensation was made compulsory, I have already described in my paper on Noxious Gases Legislation, read before the first meeting of the Society. In Lancashire, and more particularly in Liverpool and St. Helens, there was a considerable local demand for hydrochloric acid: but, as this acid was required in a comparatively concentrated form, a different mode of making the salt-cake was adopted to that which was found suitable on the Tyne, where the greater portion of the acid, after condensation, was run to waste. It was in Lancashire, therefore, that the pot was first separated from the furnace, and the close roaster introduced by Mr. J. C. Gamble.

With an increasing demand for alkali, much more acid was produced than could be easily disposed of, and the alkali manufacturer was gradually led to manufacture bleaching powder for the purpose of utilising his hydrochloric acid. When bleaching powder or dry chloride of lime was first made by Mr. C. Tennant, of St. Rollox, the chlorine was produced from a mixture of salt manganese and sulphuric acid; but when, by the manufacture of sulphate of sodium, a large quantity of liquid acid was obtained of little value, it was used to produce the chlorine by the direct action of the hydrochloric acid on peroxide of manganese.

Much difficulty was encountered in constructing suitable apparatus for such a pungent and corrosive gas as chlorine, and many improvements were gradually introduced into the manufacture in the form of improved apparatus.

At an early date attention was called to the possibility of recovering the manganese which ran to waste in the still liquor; but Mr. Dunlop was the first to effect this regeneration in a practical manner, by a very ingenious process, which he introduced in Messrs. Tennant's works at Glasgow. In this process the waste manganese liquors were neutralised by lime, and the neutralised liquor converted into carbonate of manganese by treatment with carbonate of calcium under pressure of $2\frac{1}{2}$ atmospheres. The resulting carbonate of manganese was then converted into the peroxide by heating in a current of air. The plant required was very costly in proportion to the quantity regenerated, and this, together with the cost of the fuel employed, prevented the extension of the process to other works.

With this exception none of the various processes suggested to recover the manganese were successful, and the preparation of chlorine continued without any great change, till Mr. Weldon carried to perfection his well-known method of recovery, in Mr. Gamble's Works at St. Helens. This process has been so often described that it is unnecessary to further particularise it here. It was early adopted in

the Widnes and St. Helens district, and, as the demand for bleaching powder increased, spread rapidly. The economic effect of the process was very great, since the alkali manufacturer was enabled to produce chlorine and its products at a marvellously small cost, so long as the price of the soda left a small profit.

With a decrease in the price of bleaching powder came a rapid increase of consumption, since the paper manufacturers, freed from the Excise Duty on paper in 1861, turned their attention to other fibres, requiring large quantities of bleach, such as straw, esparto, wood, etc., as a substitute for rags, which were daily becoming scarcer. There was, simultaneously, a large increase of the exports of bleaching powder from this country to the Continent, as it was manufactured so much cheaper by the new process before it had been generally adopted in France and Germany.

The increase in the trade was greater in Lancashire than elsewhere, and for the next ten years there was a marvellous increase in the population of Widnes and St. Helens, owing to the erection of new works.

Another use for hydrochloric acid was found in the production of potassium chlorate, first manufactured on a comparatively large scale by Mr. Balmain and Mr. E. A. Parnell, at St. Helens in 1847, and by Mr. Gamble in 1848.

The process employed was the saturation of milk of lime by an excess of chlorine, which produces a pinkish solution of chlorate of calcium and chloride of calcium, in the proportion of about 1:5.5, and the subsequent decomposition of the chlorate of calcium by heating with chloride of potassium. The chlorate of potassium is then separated from the calcium chloride by crystallisation. This process was first proposed by Liebig, but it is not certain whether he was aware of the necessity of perfectly saturating the lime with chlorine before applying heat. This fact seems to have been known to Mr. Parnell, who proved by experiment that when even a small quantity of lime was present, oxygen is disengaged largely on heating, with a proportionate loss of chlorate in the liquors.

The demand for chlorate of potash being comparatively restricted, the manufacture could not be largely increased without an undue fall in the price, and for many years the quantity made was exceedingly small. The price at first was 2s. 4d. per lb., but with an increased production the price fell quickly, and in 1852 was 10d. per lb., at which it left little or no profit, until by the introduction of the Weldon manganese recovery process the cost of production was materially lessened. Of late years, with a largely-increased consumption for match-making, the manufacture has increased considerably, particularly in Widnes and St. Helens, but as the consumption in the colour manufacture fell off, a large stock accumulated, and it was almost unsaleable even at 5d. per lb.

I must not leave this portion of the subject without alluding to the beautiful process for the production of chlorine invented by Mr. Deacon, another Widnes manufacturer, but which, for reasons which it would take me too long to explain fully, has not been generally adopted. I shall have to recur again to the effects of these improvements in the utilisation of the chlorine of the salt, when I come to speak of the ammonia soda process.

Before proceeding to the third operation in the Leblanc alkali process, I must call attention to some interesting attempts that have been made in this district to supersede sulphuric acid chambers, and the manufacture of sulphuric acid, as a preliminary to the conversion of common salt into sulphate of sodium.

The first in point of time is that of Mr. Longmand, which consisted in roasting iron pyrites, containing small quantities of copper, with salt, in a reverberatory furnace. The result was the production of sulphate of sodium and ferric oxide, with the evolution of hydrochloric acid chlorine and some chloride of iron and copper. From the calcined mass the sulphate of sodium was extracted by lixiviation, and the residue worked for copper and silver. The chlorine evolved was used to make bleaching powder, but the difficulties which had to be overcome in utilising the chlorine on account of its dilution, and the loss of sulphur in the calcination, rendered the process less remunerative than might have been expected. It was worked at the Patent Alkali Company's Works at St. Helens, from 1846 to about 1856, when it was abandoned. The process, however, in another form—viz., treating the burnt instead of the unburnt ore—has, as I have already shown, been more successful, and the sulphate of sodium, which now runs to waste, may be utilised, if the expense of evaporating the liquors is not too great.

Another process, perfected by Mr. Hargreaves, and first carried out by him at Widnes, has been adopted by some manufacturers, and would have been more generally used if it had not been for the simultaneous improvement of the sulphuric acid manufacture by the introduction of the nitrate-saving apparatus, and the low price of nitrate of soda.

The process consists in the direct action of sulphurous acid and steam upon common salt, at a temperature of 800° to 900° F., yielding a very pure sulphate of sodium and hydrochloric acid, which is condensed in the usual manner. The process is in operation at three works in Widnes, decomposing about 25,000 tons of salt annually.

The next step in the conversion of sulphate of sodium into carbonate, is the making of black ash by fluxing the sulphate of sodium with carbonate of calcium and coal. This is the true Leblanc process, and so far as the chemical operation is concerned remains essentially the same as that practised by Leblanc himself. The theory of the operation is, however, not absolutely decided, even at the present day, and its obscurity led to numerous analyses of and investigations into the nature of black ash, and of the waste after lixiviation, that fill volumes of chemical literature. It is not necessary for me to refer more in detail to these investigations of Gossage, Meyer, Brown, Kynaston, Scheurer Kestner, Kolb, and Mactear, which are well known to all interested in the alkali manufacture, as the practical result has been confined to some slight alterations in the quantities of the materials used in the mixing, before the introduction of the charge to the furnace. The almost universal adoption of mechanical furnaces has brought about a general uniformity in the production, which with hand furnaces varied considerably in different works. When my father first commenced making black ash on the large scale, in 1823, the principal improvement he effected was in the quality of the black ash produced, since the small quantity then made in England and France contained only about 10 or 12 per cent. of alkali. From the first he produced black-ash testing by the then alkalimetric test, 24 per cent. of alkali, and in this form it was delivered to the soap makers, of which there were seven or eight in Liverpool itself, to be used in place of kelp. It was found, however, when this black ash was exported, it lost strength from exposure to the air, and to meet this difficulty the carbonate of soda was extracted by lixiviation, and the liquors calcined in a reverberatory furnace, producing the so-called white ash or soda ash. It is not necessary for me, nor would time allow, to refer at length to the numerous small improvements gradually introduced

into the manufacture since its commencement, but many were first introduced in this neighbourhood, such as the utilisation of the waste heat for evaporation, the systematic lixiviation of the black ash, the use of boat and fishing pans, the separation of the salts of monocarbonate of sodium from the caustic alkali or red liquor, and finally the manufacture of caustic soda itself.

These, and many other improvements, are due to Lancashire manufacturers, among whom I may mention Gossage, Gamble, Deacon, etc. In addition to these, the greatest improvement of all, the use of revolvers or mechanical furnaces, was also first introduced in this neighbourhood, in 1853, by G. Elliott and W. Russell, at the Patent Alkali Company's Works at St. Helens. This first revolver did not work satisfactorily, and it took a long time and numerous experiments on the part of Messrs. Stevenson & Williamson at Jarrow to overcome the difficulties encountered in the lixiviation of the metals, which were not porous enough; but now all these have been overcome, and the metals produced by the revolver are superior in every way to the best worked by hand.*

At an early period a difference in the mode of working on the Tyne, and in Lancashire, developed itself. On the Tyne the greater portion of the alkali produced took the form of carbonated ash and crystals of soda, but in Lancashire, where so much of the ash was used for bleaching and soap making, a caustic ash was produced, and as the sulphide and ferrocyanide of sodium it contained was found to be injurious for many purposes, much ingenuity and skill were employed to eliminate these from the liquors. In 1853 Mr. Gossage obtained a patent for purifying the black ash liquors by the oxidation of the sulphide of sodium, by passing them through a tower filled with coke, meeting a current of air, or if a carbonated ash was required by passing carbonic acid through the tower. This patent also included a process for the production of caustic soda, and at a later period (1857) he suggested removing the sulphide by means of hydrated ferric oxide, zinc, manganese, or other suitable metal. These suggestions all culminated in the separation of the carbonate of soda from the caustic soda in the liquors by the use of so-called fishing pans, where the salts, as they are deposited on evaporation, are withdrawn by perforated ladles, and the salts carried to a drainer.

The concentrated liquor is further evaporated with addition of nitrate of sodium, and is then run into settlers, where it deposits a further quantity of salts, and the red liquor is further concentrated in a cast-iron pot, and when strong enough to solidify is packed as cream or red liquor caustic soda. The nitrate of sodium reacts both on the sulphide and cyanides of sodium, but it was observed first, I believe, by Dr. Pauli, that by a further concentration when the heat approached redness, the destruction of the cyanides is complete, and graphite is formed proceeding from the carbon of the cyanide. When this, together with the aluminium silicate, is allowed to settle out, the caustic soda becomes colourless, and, when packed, perfectly white. The first red liquor caustic soda made on a large scale, was made by Mr. Gamble at St. Helens, under Mr. Gossage's patent, but much difficulty was experienced in the manufacture, and it was confined to a few firms in the Widnes and St. Helens district. As a market was found at good prices for this caustic soda, it occurred to some manufacturers to causticise the liquors with lime before evaporation, and Messrs. Roberts, Dale & Co., of Manchester, and

Messrs. Hutchinson & Co., of Widnes, erected a large plant for the manufacture of this so-called artificial caustic soda, to distinguish it from the red liquor caustic then in the market. Most of this good coloured or white caustic soda was made in this manner, but the cost was considerably greater than that of the red liquor caustic, and until the consumption increased very considerably it did not pay the manufacturer to incur this expense. In the exhibition of 1862, there were exhibited samples of this article by several manufacturers, and in 1866, as is seen by the statistics of that year, a large quantity (11,213 tons) was manufactured in Lancashire, and 3720 tons on the Tyne. With the extended consumption of caustic soda for use in the refining of petroleum, the manufacture of soap and paper making, and in the manufacture of aniline colours, this industry has taken an enormous development, and in 1885, 140,795 tons were manufactured in Lancashire, and 4159 tons on the Tyne.

After the black ash has been lixiviated, and the soda converted into either soda ash or crystals or caustic soda for sale, there remains the alkali waste, containing nearly all the sulphur consumed in the manufacture, and this waste, when not removed out to sea, as on the Tyne, accumulates in large heaps round the works, and unless properly treated, infects the air with the unpleasant odour of sulphuretted hydrogen. Since the passing of the Alkali Act of 1863, it may safely be asserted that nearly all the complaints of nuisance from alkali works are due, not to hydrochloric acid, but to the sulphuretted hydrogen given off by the drainage from the waste heaps. It has not been for the want of either enterprise or science on the part of the manufacturers that this source of nuisance continues to exist. Means are well known which will render the waste comparatively innocuous, and it is satisfactory to know that the method now recommended by the Alkali Inspector for the prevention of the nuisance from waste heaps, emanated from the manufacturers themselves. It is, however, to be regretted that hitherto no process for recovering all the sulphur in the waste has been successful from a pecuniary point of view.

A small quantity is extracted by Mr. Mond's process, but Mr. Gossage's original scheme for decomposing the sulphide of calcium by carbonic acid, and Messrs. Schaffner and Helbig's plan for decomposing the waste by magnesium chloride, promised sufficiently well to induce my father, in 1839, and Messrs. Chance Bros. in 1882, to spend large sums of money in attempting to work them practically.

The fall in the price of sulphur, and the increasing value of hydrochloric acid, owing to the ammonia soda process, have entirely changed the commercial conditions, so that unless Messrs. Parnell and Simpson's process for uniting the Leblanc with the ammonia soda process (to which I shall allude later on) succeeds, I see little prospect of the recovery of the sulphur in future.

I have now traced very rapidly the rise and progress of the Leblanc alkali industry in this district, from 1823 to 1878, a period slightly exceeding half a century, and it is desirable at this stage to review the position of the trade, and to mark the change which the process has wrought in the prices of alkali and bleaching powder, the two forms in which the chlorine and sodium of the salt is made available for industrial purposes. I have selected the year 1878 for comparison, as from that date forward the competing ammonia soda process began to influence the price of alkali, and the whole position of the trade changed. I have also added the prices of this year, showing the influence exercised by the competition of the ammonia soda. (See Table E.)

* The extent of this improvement may be gauged if we consider that in a modern revolver of large dimensions, as much salt cake can be decomposed in a given time as in ten hand furnaces requiring 40 men, and the decomposition itself is from 10 to 15 per cent. more efficient.

The prices of the raw material have not varied nearly so much as those of the manufactured products, as will be seen from Tables E and F. The cost of the sulphur used has been reduced by the substitution of pyrites, but to-day the price of sulphur itself is the same as in 1830—viz., £5 per ton. For the prices of manufactured goods and of the raw

demand, to 1d. per degree. Before the introduction of revolvers and the more modern improvements a price of 1½d. per degree, or £7 per ton, for 48 per cent., barely covered the cost of production.

In 1852 we have the first estimate of the production of alkali for the United Kingdom, prepared by Mr. Allhusen; and, in 1861, according to Messrs. Schunck,

TABLE E.

COMPARATIVE PRICES OF MANUFACTURED ARTICLES AT VARIOUS DATES.

	Liverpool, 1827—1830.	Liverpool, 1839—1840.	Liverpool, 1878.	Liverpool, 1886, After Ammonia Process.

TABLE F.

COMPARATIVE PRICES OF RAW MATERIALS.

	Liverpool, 1827—1830.	1839—1840.	Widnes, 1878.	Widnes, 1886.
Sulphur	£5 10s.	£11 10s. (monopoly).	£6 15s.	£5.
Salt	6s. to 8s.	9s.	8s. 9d.	8s.
Limestone	—	1s. 6d.	5s. 6d.	4s. 6d.
Lime	13s. 1d.	7s. 6d.	11s.	11s. 6d.
Nitrate of Soda	—	£16 10s.	£14.	£9 10s.
Nitrate of Potash	£30.	—	—	—
Slack	(1831) 6s. and 6s. 9d.	At Liverpool, 1839, 5s. ; 2s. 6d. per ton at Newton in 1840.	5s.	1s. 6d.

materials at the earlier period, I have taken the prices according to my father's books during the years 1827—1830, when the consumption of black ash had superseded that of kelp, in Liverpool. On referring to the table, it will be seen that black ash was sold in 1827 at 10s. for 20 per cent., or 6d. per degree. In 1828 the price had been reduced to 7s. for 20 per cent. In 1830 the first large sales of white ash were made at about £16 10s. per ton, but this ash seems to have been only about 35 per cent., and may have been made partly from the mother-liquor of crystals. In 1835 the same price seems to have been paid, but the strength now was 48 to 50 per cent., and from that date forward the strength 48 per cent. was taken as the standard, and the ash sold according to degree at prices varying from 3d. to 4d., and this price has been gradually reduced, with fluctuations according to the

Smith & Roscoe, the production in Lancashire was as mentioned below :—

	1852. Manufactured in the United Kingdom.	1852. In Lancashire.	1861. In Lancashire.
Alkali	71,193 tons.	26,313 tons.	93,630 tons.
Soda Crystals	61,011 „	3,500 „	8,810 „
Bicarbonate of Soda	5,726 „	1,200 „	11,700 „
Bleaching Powder	13,100 „	1,250 „	8,060 „

But all these estimates were very imperfect, and it is not until 1866 that we have a trustworthy record

of the trade, which is shown in the following table :—

	Lancashire Branch.	Tyne Branch.	Total.
Soda Crystals	24,978	86,000	110,978
Soda Ash and Refined Alkali....	87,314	74,000	161,314
Caustic Soda	11,213	3,720	14,933
Bicarbonate of Soda	6,457	11,000	17,457
Sulphate of Soda	32,137	2,400	34,537
Bleaching Powder	20,006	27,000	47,006
Bleach Liquor	5,871	—	5,871
Oil of Vitriol (for sale)	18,592	9,000	27,592
Muriatic Acid (for sale)	13,819	700	14,519
Salt decomposed ..	194,000	157,000	351,000

In 1877 the Alkali Association commenced their annual statistics, and in the report of 1878 the most notable feature is the large increase in the production of caustic soda, and bleaching powder, more especially in Lancashire as compared with the Tyne. In 1861 the manufacture of caustic soda in Lancashire is estimated at 4680 tons, in 1878 the total for the United Kingdom was over 96,000 tons, of which 94,000 tons were made in Lancashire, and this is important in connection with the competition from alkali produced by the ammonia process.

STATISTICS OF ALKALI TRADE, 1878, AS ISSUED BY THE ALKALI MANUFACTURERS' ASSOCIATION.

	West District. Lancashire, Scotland, etc.	East District. Tyne.	Total Tons.
Salt decomposed ..	384,958*	183,584	568,542
Alkali equal to 48°	120,939	87,053	207,992
Soda Crystals	47,697	123,175	170,872
Caustic equal to 60°	82,585†	2,027	84,612
Bleaching Powder..	77,100	27,944	105,044
Bicarbonate of Soda	4,703	7,053	11,756
	717,982	430,836	1,148,818

Although I have been able to give the prices of the raw materials before 1860, it is impossible at the present day to estimate the cost of producing alkali before that date with any approach to accuracy; and as the wages paid and wear and tear and general charges vary in different works, it is useless making comparisons, even at the present time. In 1860, for the purpose of fixing the duties under the French Treaty, Mr. Allhusen and I endeavoured to arrive at the cost of production in the two countries, and found a great difference between the cost on the Tyne and in Lancashire; but in order to show the effect of the improvement in the manufacture, and the use of Spanish instead of Irish pyrites

has had on the cost of soda-ash, the following comparison of the cost of the raw materials to produce a ton of 48 per cent. ash in Lancashire in 1861 and to-day, after a lapse of twenty-five years, is interesting. For 1861 I have taken Mr. Gossage's figures :—

	1861.		1886.
1½ tons Pyrites (Irish)	£1 15 0	13½ cwt. Spanish Pyrites, 14° (Sulphur value)	£0 9 3
1 cwt. Nitrate of Soda	0 12 0	23 lb. at 10°	0 2 0
1½ tons Salt	0 10 0	25 cwt. at 8°	0 10 0
1½ .. Limestone ..	0 10 0	26 .. at 5°	0 6 6
3½ .. Fuel	1 1 0	2½ tons at 46°	0 12 6
	£4 8 0		£2 0 3

It is thus seen that, principally by the improvements in the sulphuric acid process, the cost of the raw materials has been reduced over 50 per cent. To this saving must be added the saving in labour by the use of machinery, and the reduction of wear and tear by improved apparatus; but, notwithstanding these improvements, as the cost of production by the ammonia process is very considerably less, the Leblanc alkali maker cannot continue to work at a profit, unless he is able to utilise the chlorine of the salt to a greater extent and more economically than the ammonia-soda maker. As the consumption of alkali in the form of soda-ash is limited, if ammonia-soda works continue to increase, part of the alkali produced by them must be converted into other forms, such as bicarbonate, crystals, and caustic soda; but as the Leblanc alkali maker can causticise his liquors cheaper than the ammonia-soda maker, the tendency will be for the Leblanc maker to manufacture caustic soda in the place of soda-ash. This has already taken place to a considerable extent, as the manufacture of caustic soda has increased from 96,000 tons in 1878 to 145,000 tons in 1885.

The problem before the Leblanc maker is a very difficult one, for he not only has to face the competition of the ammonia-soda maker in the price he obtains for his alkali, but if he increases the quantity of bleaching powder made and the consumption remains the same, the price of this product must also fall. A satisfactory position of the trade can only then be approached when the bleaching powder and other chlorine products together are the equivalent of the quantity of salt decomposed, and such a price is obtained for the chlorine as will compensate the Leblanc maker for his loss on the alkali produced. I have already pointed out how the manufacturer of alkali was forced to condense the hydrochloric acid produced, and indicated the various modes in which he made use of that acid. As by far the larger quantity of the hydrochloric acid produced is used for the manufacture of bleaching powder, Table G is interesting.

It will be seen that the production of bleaching powder has been stationary for the last five years, since it has been regulated by the manufacturers, and as the stocks are about the same, it is clear the consumption has been stationary also. When we further consider that one ton of bleach can at present be made by the consumption of two-and-a-half tons of salt, and that by improved processes the quantity of salt required will be still further reduced, we must look forward to a still further curtailment of the decomposition of salt by sulphuric acid. It is true, there are other uses for hydrochloric acid than the manufacture of bleaching powder, but these do not seem to increase, nor are they likely to do so. As

* Of this, 16,230 tons were decomposed by the ammonia process, producing a corresponding amount of alkali.

† In addition to this there were made in the Liverpool district about 12,000 tons caustic soda more than returned to the Association.

the price of hydrochloric acid is necessarily higher than it was, it may be superseded in some directions by sulphuric acid, which is much lower than formerly. It has been estimated that during the year 1884 hydrochloric acid was utilised for other purposes than the making of bleaching powder to the equivalent of 170,000 tons of salt, leaving 408,874 for the manufacture of bleach; but as the quantity of bleach produced, owing to the restriction, was only 128,651 tons, it is evident the acid from 87,247 tons of salt was not utilised. During that year the price of salt-cake left a small profit to the Leblanc manufacturer, but since then the price of alkali in all its forms having fallen, the quantity of salt decomposed without the utilisation of the acid, is decreasing rapidly.

sulphate of sodium by bicarbonate of ammonia, or substituting salt-cake for salt in the ammonia process, with the consequent utilisation of the chlorine, is still in the experimental stage, but since the Newcastle meeting a new process for uniting the Leblanc and ammonia-soda manufactures has been patented by Messrs. Parnell & Simpson, and is about to be worked on a large scale by the Lancashire Alkali and Sulphur Company, Limited.

This process is based on the decomposition of a mixture of solutions of common salt and ammonium sulphide by means of carbonic acid gas, the result of which is that sodium bicarbonate is precipitated as in the ordinary ammonia process, and sulphuretted hydrogen gas evolved, ammonium chloride being left in

If the consumption of chlorine products bore the same proportion to the consumption of soda products as the chlorine does to the sodium in the salt, the future of the alkali trade would be less gloomy. The peculiar position of the soda industry since the development of the ammonia process is well known to the members of this Society, from the paper read by Mr. W. Weldon before the London Section in 1883, and the address he delivered as President at Newcastle. In the latter, he threatened both the Leblanc and the Solvay process with extinction by a third process, which was being worked out by Messrs. Pechiney et Cie., at Salindres. I have not been able to ascertain what progress has been made by Messrs. Pechiney since 1884, nor has any further information been given to the world as to the commercial success of Mr. Mond's and Mr. Solvay's various methods for utilising the chlorine in combination with the manufacture of alkali by the ammonia process.

The beautiful process of Messrs. Carey, Gaskell & Hurter for obtaining alkali by the decomposition of

solution. To recover the ammonium in the form of sulphide, the chloride solution is boiled with Leblanc alkali-waste, when a certain proportion of sulphuretted hydrogen gas is first evolved, and later ammonium sulphide and ammonia, which is condensed in brine for fresh treatment with carbonic acid gas. Since Leblanc alkali-waste is of no value, the advantages of this process over the ordinary ammonia process are—first, an entire saving of the lime used for the recovery of the ammonia in the latter process; and secondly, the recovery of the sulphur in the alkali waste in a form that at all events can be employed for the manufacture of sulphuric acid. It will at once be seen that there are drawbacks to the employment of the dilute carbonic acid obtained from the limekilns in this process, partly on account of the portion of oxygen that the limekiln gas nearly always contains, which would cause an oxidation of a portion of the ammonium sulphide, and partly from the difficulty of dealing with the dilute sulphuretted hydrogen that would be evolved after

the treatment of the brine and ammonium sulphide. The patentees have several alternative plans of meeting this difficulty, but the one which they have decided to work, and for which they are now erecting plant, is the employment of pure carbonic acid gas obtained by heating and decomposing ammonium bicarbonate. The latter is produced in an ordinary Solvay tower by treating a saturated solution of ammonium carbonate with limekiln gas; the crystals of ammonium bicarbonate are drawn off into a suitable vessel and heated to a temperature of about 160°F. , when nearly one equivalent of carbonic acid gas is driven off.

This gas after cooling contains only a fraction of a per cent. of ammonia, which is recovered in a wash tower in the usual way. The remaining solution of ammonium carbonate is then cooled, and returned to the towers for fresh treatment with lime-kiln gas, and thus the ammonia is kept constantly circulated. The carbonic acid thus produced is collected in a gas holder for use in the ammonium sulphide tower, while the sulphuretted hydrogen evolved from the latter is collected in another gas holder; this in both cases being necessary in order to have the process under proper control. It may at first appear that this preliminary preparation of pure carbonic acid gas will involve twice as much work in the towers as is the case in the ordinary ammonia process, and that consequently a greater loss of ammonia may be anticipated. The total amount of gas escaping, however, is only increased by the amount of sulphuretted hydrogen produced, or say about 25 per cent. of the total volume passed into the towers, so there is no serious ground for apprehension on this score. The ash produced by this process seems to be in no way inferior to that obtained by the ordinary ammonia process.

The process is very interesting both from a scientific and practical point of view, as it combines the Leblanc and ammonia processes, and proposes to recover the sulphur in the alkali waste in a mercantile form, and so extinguish the nuisance from the waste heaps to which I have already alluded. But it has one defect, and that is it will produce a larger quantity of alkali, and this is serious, as there is apparently more produced at present than the market will bear. It is true the alkali made by the Leblanc method will take the form of caustic soda, and that by the decomposition of bicarbonate of ammonia the form of soda ash, but for every 70 tons of caustic soda we shall have an additional 100 tons of alkali.

It is clear therefore that if the process is successful, both the present ammonia soda works and the Leblanc alkali works must still further reduce their output.

I have in the foregoing given a short account of the alkali industry in this neighbourhood, with its allied industries of copper and chlorine products. It has of course attracted round it other industries such as the manufacture of glass and soap, but these are now principally in St. Helens, Warrington, and Widnes, whereas in Liverpool, where there were seven or eight soap works in 1827, there are now only two small ones.

At St. Helens, in 1829, the first alkali works was erected, and there were then only five small glass works; now there are eight alkali works, nine large glass works, four of them manufacturing plate glass. Of copper-smelting works there was only one in 1829; to-day there are five, and two copper-extracting works, and the population has increased from 14,251 to 61,472 at the last census.

In Widnes the progress has been still greater, as its rise as a manufacturing town dates from about 1848, and it now contains 15 alkali works, most of them of large size, four copper works, and the large soap works of Messrs. W. Gossage & Sons.

All this is now placed in jeopardy by the advance of chemical industry. Professor Dumas, in addressing the Société d'Encouragement pour l'Industrie, in 1860, at a time when by the Treaty of Commerce with England the French manufacturers were about to be brought into competition with their English rivals, made use of these remarkable words, which contain a great truth:—

“Europe has always accepted our supremacy in the chemical arts. Let us preserve it with care. It is by means of it, and of its unforeseen conquests, that the balance of trade is often overthrown.”

France since then has seen her supremacy in this particular direction rudely shaken by Germany, which has made enormous strides in all chemical manufactures.

We in England at that time thought ourselves quite safe from all foreign competition, but we are now also beginning to recognise that by the conquests of science the balance of trade may be altered. The Leblanc may have to succumb to the ammonia soda, and under these new conditions foreign countries are becoming less dependent upon us for alkali. If chloride of magnesium is used to replace salt as the raw material for chlorine, this great chemical industry will, of necessity, have its seat in Stassfurt, and not in Lancashire. In a paper read before the Manchester Section, Mr. Levinstein quotes from a speech by Professor Bayer (the discoverer of artificial indigo), in which the learned professor showed how Germany had succeeded by means of her intellectual achievements in wresting from France and England, countries superior in natural resources, a source of national wealth in the colour industry. Mr. Levinstein seems to be of opinion that at the present time English colour manufacturers are placed in a worse position than their German rivals, owing to the higher price obtained by English alkali makers for their products, and that the latter are unable to compete with the Germans because for special reasons sulphuric acid and soda ash are at present dearer in England than in Germany. Although I have no reason to doubt his statements so far as the price of alkali in Germany is concerned, the fact that the German manufacturers sent a parcel of caustic soda to England, and that ammonia soda of German make is offered at £5 10s. per ton in London, proves nothing as to the normal price of alkali in the two countries. I have no doubt the Leblanc makers themselves would sell 58 per cent. soda ash in London at £5 10s. per ton, if they could not dispose of their alkali to better advantage in the shape of caustic soda, and it is well known that Messrs. Brunner, Mond & Co. are prepared to meet any competition of the German alkali manufacturers either in this country or abroad.

But Mr. Levinstein's second and more serious complaint refers to sulphuric acid. I think he rather exaggerates the advantages we possess in the price of the raw materials, pyrites and nitrate of soda, since freights to Antwerp are as low as to our own ports, and the internal carriage throughout Germany, whether by canal or railway, is very reasonable. Although German labour in this department is lower than in England, I think any of our large alkali manufacturers are able to make sulphuric acid as cheaply as his German rival, and if it pays the German manufacturer to deliver acid of 66 Beaumé at £3 per ton, it can only be because the cost of delivering from the Griesheim works to Frankfort is less than from the English alkali works to the place where the acid is consumed. The question of transportation is a very serious one, and English manufacturers are undoubtedly heavily handicapped by the difficulties put in their way by the railway companies.

If the quantities of sulphuric and hydrochloric acids consumed in one German colour works are generally so large as the figures given by Mr. Levinstein indicate, the English alkali manufacturer will pray that several of these works may be erected in England and so relieve the Leblanc makers of their acids.

As to the remedy, I quite agree with Mr. Levinstein, that it is not the theoretical chemist, but the chemical engineer that fails us.

The records of the progress of the alkali manufacture show that most of the processes now used are old, and that it is in the apparatus employed that the greatest improvements have been made; but while a few of our manufacturers have shown that they fully recognise this, it is very difficult to find a manager who has a knowledge of engineering combined with a knowledge of chemistry. Such men must be educated, and it is only now, after the Germans and French have shown the way for forty years, that we are beginning to follow in the path.

This laboratory, in which we are met, is but a sign of the movement that is in progress, and our Chair of Engineering in Liverpool has only been founded one year, but I look forward to the not distant day when by means of improved secondary education, and the work of institutions like Owens College, and University College, Liverpool, our manufacturers will be able to find men ready to carry on, with even greater success than in the past, a large portion of the great chemical industry of the world.

Sir HENRY ROSCOE, M.P., moved that the hearty thanks of the Society be accorded to the President, Mr. E. K. Muspratt, for his valuable address. He said it was a matter for congratulation that one who bore the name of Muspratt should have presided on that occasion, for that name was connected intimately with the birth, rise, and progress of one of the greatest of English chemical industries. He took, moreover, that opportunity of expressing the sincere sympathy of the Society with the family regarding the death of Mr. James Muspratt, the originator of that great industry.

Mr. DAVID HOWARD (the President-elect) seconded the motion, and it was carried with acclamation.

THE NEXT ANNUAL MEETING.

Mr. E. C. C. STANFORD then moved that the Society should meet next year in Glasgow, the seat of the Glasgow and Scottish Section, and he assured the members that they would there receive a hearty reception and a warm welcome.

Mr. TYRER seconded the motion, and it was unanimously adopted.

VOTES OF THANKS.

On the motion of Mr. TYRER, seconded by Mr. LUDWIG MOND, a hearty vote of thanks was then passed to Mr. E. K. Muspratt for his valuable services to the Society as President during the past year. Votes of thanks were also given to Mr. R. Weldon for the presentation, in accordance with the known wish of his father, of the valuable collection of the scientific books of the latter to the Society, and to the Council and Senate of the University College for the use of the lecture theatre.

ALTERATIONS IN BYE-LAWS, AND THE RAISING OF THE ANNUAL SUBSCRIPTION OF MEMBERSHIP.

Upon the motion of Mr. JOHN SPILLER, seconded by Mr. C. C. HUTCHINSON, it was resolved, "That the following alterations be made in the Bye-laws"—

Bye-law 1. —That the words "and is established in accordance with the provisions of the Literary and

Scientific Institutions Act, 1854," be added after the word "Industry."

Bye-law 5. —That the word "or" be inserted in the third line thereof between the words "Council" and "a professional."

Bye-law 27. —That the words "One Guinea" in the first line thereof be replaced by the words "Twenty-five Shillings."

Bye-law 29. —That the words "is more than four months in arrear," in the second line thereof, be replaced by the words "has not been paid."

Bye-law 37. —That the word "President" in the second line thereof be replaced by the word "Chairman."

Bye-law 42. —That the words "is in arrear with" be replaced by the words "has not paid."

Bye-law 49. —That the date "31st of December" be replaced by the date "15th of June."

Bye-law 54. —That the word "given," in the last line but one thereof, be replaced by the word "posted."

Mr. DAVID HOWARD proposed the reappointment of Messrs. Theobald Brothers & Miall as auditors, a proposal which was seconded and carried.

The result of the scrutiny of the balloting papers was now reported by the scrutineers, and showed that the following had been elected ordinary members of Council:—

Dr. John Evans, F.R.S.	S. A. Sadler.
Henry Doulton.	John Calderwood.
Ivan Levinstein.	John Pattinson.
Sir Bernhard Samuelson, Bart., M.P.	Eustace Carey.
Sir Chas. Tennant, Bart.	Lewis T. Wright.
R. Forbes Carpenter.	S. H. Johnson.

The nominations of Council for President, Treasurer, Foreign Secretary, and Vice Presidents are confirmed.

(Signed) ALFRED E. FLETCHER.
A. NORMAN TATE.
AD. LIEBMANN.

The following is therefore the composition of the Council for 1886—1887:—

President: David Howard.

Vice-Presidents:

Sir I. Lowthian Bell, Bart., F.R.S.	Sir H. E. Roscoe, M.P., F.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
Dr. Peter Griess, F.R.S.	E. C. C. Stanford.
Dr. Ferdinand Hurter.	J. C. Stevenson, M.P.
E. K. Muspratt.	John Williams.
Dr. W. H. Perkin, F.R.S.	Philip J. Worsley.

Members of Council:

John Calderwood, F.R.S.E.	John Pattinson.
Eustace Carey.	S. A. Sadler.
R. Forbes Carpenter.	Sir B. Samuelson, Bart., M.P.
Henry Doulton.	Sir Chas. Tennant, Bart.
Dr. John Evans, F.R.S.	Lewis T. Wright.
S. H. Johnson.	
Ivan Levinstein.	

Treasurer: E. Rider Cook.

Foreign Secretary: Ludwig Mond.

THE ANNUAL DINNER.

The Annual Dinner of the members of the Society of Chemical Industry was held in the Adelphi Hotel, Liverpool, on Wednesday evening. There was a fair attendance, but it was scarcely so large as on some previous occasions of a similar character. The chair was occupied by the President (Mr. E. K. Muspratt), who was supported by Sir H. E. Roscoe, M.P., F.R.S., Sir James Picton, Mr. David Howard (the President-elect), Mr. Ludwig Mond, Prof. J. Campbell Brown, Mr. Ivan Levinstein, and Dr. Hill (Mayor of Bootle), and others. The usual loyal toast having been proposed and duly honoured.

Sir HENRY ROSCOE, M.P., F.R.S., proposed "The City and Trade of Liverpool," coupling with it the name of Sir James Picton. He referred to the fact that it was intended to hold a Jubilee Exhibition next year in Manchester, in which the illustration of

the chemical industries and their advance during the Victorian era will be a principal feature.

Sir JAMES PICTON, in response, referred to the connection of the Roscoes with Liverpool, and said that the family showed no signs of falling off in the third generation. He defined the science of chemistry, or perhaps applied chemistry, as the bringing to bear of certain of the forces of nature upon natural substances, so modifying them as to render them serviceable for mankind. As an outsider, he thought that, much as chemists had done, they were still open to reproach in regard to the state of affairs in the neighbourhood of some of their works: for, although he had been informed that in some cases Widnes and St. Helens were regarded as sanatoria, and patients were occasionally taken there to inhale the atmosphere, people did not take their families there as they took them to Buxton. Cologne, too, with its three hundred stinks, was the home of the manufacture of the queen of perfumes. The story of chemical discovery was far from being yet told, and the man who could reduce the metal aluminium from the abundant clay at a low cost would deserve a good reward.

In proposing the toast of "The Guests," which was responded to by Dr. HILL, Mayor of Bootle, Dr. CAMPBELL BROWN said that on one occasion he had actually been asked to prepare some Widnes gas for administration to a person who was ill.

The PRESIDENT next gave the toast of the evening—"The Society of Chemical Industry." He said the fact that it now numbered over two thousand members showed that it filled a void in the world of societies which had sprung up during the present century. As Sir Lyon Playfair said in his address to the British Association, the competition of nations now was a competition of knowledge and of science, and it was only by the possession of these, in an equal if not superior degree, that we could expect to hold our own with the other industrial nations of the world. By the application of science, and particularly of the science of chemistry, we had seen in those parts of Russia only lately conquered from the Turks a wonderful extension of trade and commerce. The port of Batoum, where there was an enormous trade in petroleum, was an instance of how the application of science was gradually altering the balance of trade; and there were many other instances of it. The application of petroleum instead of coals as a motive power in vessels would certainly effect a remarkable change in the commerce of the world. In coupling with the toast the name of Mr. David Howard, the President-elect, he alluded to the fact that Mr. Howard was a member of a firm established so far back as the year 1789, or about thirty years after the birth of modern chemistry in the discovery of oxygen.

Mr. HOWARD, in responding to the toast, said he thought the Germans were our most dangerous rivals in chemical science, but he did not think we need fear them if we devoted patient, unceasing work and indomitable courage to the development of chemical science and chemical industry combined. The rivalry must, however, be a friendly one, for how could they be at enmity with a people from whom they had learned so much. He himself had received his chemical training from Professor Hofmann, in the glorious old cockpit of the College of Chemistry. Undoubtedly, the study of pure science was much more attractive than the development of applied science. Pure science was the Pegasus that soared aloft, but we were bound to put him to the plough; and though he might not like it, we should find that he would be an invaluable animal for the most homely and useful work. Pure science could tell us what was

the composition of the stars, but it could also tell us what to do with our sewage. So, if only we were content to take the teachings of pure science, and put to them all that hard work which used to characterise Englishmen—and he did not think it would be found that the race had degenerated—he thought we should find that there was a future of great prosperity for our commercial industry, even greater than it had enjoyed in the past.

The toasts finally proposed and responded to were, "The Health of the President," and "The Officers of the Society."

THE EXCURSIONS, ETC.

The International Exhibition in Liverpool was visited by a number of the members on *Wednesday afternoon*, whilst others visited and inspected the Sugar Works of Messrs. Crofield, Barrow & Co.

On *Thursday morning* a considerable number of members embarked at the Prince's Landing Stage, on a special saloon steamer, for a trip on the River Mersey. The North Docks were entered, and the New Floating Docks, Graving Docks, with the Hydraulic Machinery, were visited and inspected. The New Grain Warehouses and Elevator were then visited, and a large Transatlantic Steamer, on which lunch was provided. Another portion of the visitors called at Seacombe,* and lunched there. The party then proceeded to the Ship-building Yard of Messrs. Laird Bros.

On *Friday* two parties were organised, one for visiting Widnes, the other St. Helens. The former visited the Soap Works of Messrs. Gossage & Sons, the Alkali Works of Messrs. Gaskell, Deacon & Co., and Messrs. The Tharsis Sulphur and Copper Co., Limited; the latter, the Collieries at Sherdley, of Messrs. Bourne & Robinson, and the Glass Works of Messrs. Bishop & Co. In the afternoon the London and North-Western Steel and Railway Works at Crewe were visited, and on the return to Liverpool an informal Wind-up Dinner was partaken of at the Adelphi Hotel.

THE CONVERSAZIONE AND RECEPTION.

On *Thursday evening*, at eight o'clock, the President held a Reception at the Walker Art Gallery. Some excellent instrumental music and singing were provided, and the Conversazione was attended by about four hundred ladies and gentlemen.

A NEW SYSTEM OF FILTRATION FOR LARGE QUANTITIES OF WATER.

BY ALPH. STEIGER,

Consulting Engineer.

FROM the earliest up to the present times the supply of pure water for the population of towns has always been considered a question of the utmost importance; it is a question which even now-a-days occupies the minds of engineers, chemists, sanitary officers and magistrates.

When our ancestors of many centuries ago began to settle down in enclosed colonies called towns, the latter could not be more favourably situated than on rivers, and all over Europe we find traces of such towns, while away from rivers there was hardly anything found to prove the former existence of colonies. In these times the rivers were almost the only way of transit of commerce, and may at the same time have been sufficient for the supply of water for domestic purposes. In any case there were not the same difficulties and circumstances which in the present time accompany the question before us. In consequence of civilisation and the development of industries the density of the population of towns is continually increasing, and while the want of water necessarily increases in the same proportion, the water of the rivers, ponds, etc., becomes polluted by the waste of all kinds of manufactories and even animal excrements. Water from wells is very seldom abundant near towns, and therefore, acknowledging the necessity of clear water, without odour or taste, for drinking and other purposes, the question of a large supply of such water is rendered very difficult.

Two ways have hitherto been followed to provide towns with a sufficient quantity of water: *firstly*, by conducting the water from distant places, lakes, or rivers to the towns, as has, for instance, been done for the water supply of Vienna, Paris, Liverpool, etc.; and *secondly*, by the erection of large sand-filters as have first been erected in Chelsea for the water

supply of the metropolis, now over fifty years ago. Enormous sums have been expended by large and even small communities for carrying out both projects, and give ample evidence of the importance of the object in question. However, the result in many cases was not in proportion to the cost, and the excellent report of the River Pollution Committee in 1874 has clearly shown that the sand-filters do not remove the soluble organic matter from the water. But it has been reserved to the last few years to discover something much worse than even this. It is the undeniable fact that the water contains a large amount of micro-organisms, the originators of epidemic diseases.

In many places and on different occasions it has been observed that people using a certain kind of water were infected by these diseases, whilst others using water from another source were not infected; it has even been possible to trace the water supply from the way the disease followed. It is unnecessary to prove these facts here; but we may be allowed to mention that in the town of Zurich, a few years ago, when the typhoid fever raised the percentage of mortality considerably—which was attributed to the quality of the water drawn from the lake of Zurich and filtered through sand-filters, used in some parts of the town—it was taken into consideration whether better water could not be obtained from the wells in Waeggithal, Ct. Schwyz, which project would have cost tremendous sums of money, and besides, it was stated, that during some parts of the year even this water was not free from bacilli, and might convey the origin of epidemic diseases.

In most places where sand-filters are used, the water from the supply is found to have a distinct taste and odour of organic matter in a state of putrefaction during warm weather, as, for instance, in Manchester, rendering the water almost unfit as a beverage. In consequence of this we find in all the houses of the better class special carbon filters, through which the water is again filtered, but these small filters are only for the privileged classes which can afford to pay for them, while the poorer people have to be satisfied with the water as it issues from the sand-filters, containing certain quantities of suspended organic matter.

As regards the small house-filters, of which the filtering substance consists mainly of animal charcoal or spongy iron, it must be said that they are so far excellent filters during a certain time, retaining even micro-organisms, but they do not prevent the development of the latter, and become occasionally a real eldorado for the growth of micro-organisms. The same occurs in sand-filters. The best and purest water from them is obtained a short time after they have been in action, when the pores have been rendered finer by the deposits of suspended matter. But the organic matters begin to grow, prevent the whole amount of water from passing through the filtering substances, or it forces its way through, carrying with it organic matters which are deposited in the main-pipes conducting the water to the place of consumption. It is then found necessary to clean the filters, for which purpose the whole filtering mass, sand and stones, must be taken out, carefully washed, and afterwards put into the place again, a work which requires a considerable length of time, during which the filtration is interrupted and which also causes great and continued expense. When the filters are at work again, the source of growth of micro-organisms is not only in the water before and in the filter, but also afterwards, and the filtered and pure water will become infected by organic matter; this may have been the case in Zurich, in Manchester, and many other places. But even if not, micro-

organisms appear again in filtered water, as we learn from Dr. P. Frankland's interesting paper on "New aspects of filtration and other methods of water treatment," even if immediately after filtration no such organisms could be found. This must necessarily raise the question whether the presence of these organisms in the water could not be prevented, or whether they could be destroyed in such a way that they offer no more danger of epidemic disease.

We have taken into consideration above the high value of pure water for the supply of the population in general, and I must now turn to the different industries requiring also a pure water, at least to a certain degree. I mention, in the first instance, the breweries, for which a pure water is of vital importance.

The process of fermentation in brewing still remains in mystic darkness, and it has as yet not been scientifically established why in one case the yeast thrives well and produces an excellent fermentation, while in another case the development of the yeast is most incomplete and insufficient. It has only been confirmed that foreign substances, and chiefly low organisms suspended in the water, are the principal cause of preventing the growth of the yeast. The principal breweries of Frankfort-on-the-Maine, which are using the very pure water of the abundant wells which supply that town, obtain an excellent and quick fermentation, while other breweries, less fortunate in the resources of their water, cannot obtain such satisfactory results without erecting perfect sand-filters, taking up an area, which can only be done at great expense, and further, causing continued and considerable working expense.

Paper mills also require a very pure water, and in such large quantities as would be sufficient for a small or middle-sized town. 80 to 120 gallons of water are required for the manufacture of one pound of paper, and it is evident that such large quantities can hardly be obtained without a perfect system of filtration. The value of pure water for the manufacture of certain of the better qualities of paper is best illustrated by stating that 1 *per mille* of certain impurity in the water may render the paper unsaleable; in other words, a perfect filtration is capable of raising the value of the manufactured goods.

Chemical works, bleaching, dyeing and finishing works also require pure water, and in many cases, not having their own filters, draw their water from the supply of the town, paying heavy rates for it.

From the foregoing the following facts are derived: (1) pure water is of an absolute necessity for almost any purpose; (2) the ordinary sand-filters do not answer in most cases, because they are not able to remove the organic matter; (3) they take too much space and cause too much expense for the erection and the working; (4) filters using spongy iron, charcoal and other material are too expensive if used for large quantities of water, and the small house-filters are a privilege of those who can afford to pay for it.

This at once tells us what we must expect from a really good system of filtration, and what the conditions of a perfect filter are; we may number them as follows:—

1. The filters must purify the water chemically and mechanically.
2. They must destroy the life of germs and micro-organisms.
3. Their cleansing must be made easy and without causing great expense.
4. They must be more economical with regard to space and cost.

Since the introduction of sand-filters scarcely any improvement in their construction has been made,

and the sand-filters of the present time are of the same style as fifty years ago. The system of filtration which I am going to describe may be mentioned as the first and most important progress in the filtering of large quantities of water. It fulfils all the above-mentioned conditions in a most efficient and satisfactory manner, and its use in several places on the continent for many years proves it to be a great success. It is the filtering system of Dr. Gerson in Hamburg.

According to the above conditions of a good filtration, the characteristics of this system are as follows:—

1. The filtration is divided into a preliminary and a secondary filtration.
2. In both the preliminary as well as the secondary filters, the water passes through the filtering substances from bottom to top.
3. The filters are cleansed by reverse currents of filtered water, the changing of the filtering substances consequently avoided or only exceptional.
4. It removes and destroys most of the micro-organisms suspended in the water by the peculiarity of the filtering substances.

The impurities in the water being of different size and character, the preliminary filters are intended to remove the coarser matter, while the very fine low organisms are retained by the secondary filters. The filtering substances can thus be selected accordingly, and are of different kinds and fineness in both filters. It is evident that thus a greater filtering capacity is obtained, and that the preliminary filters for the mechanical action can be working under high pressure. Their capacity is 200 times larger than the capacity of the ordinary sand-filters, which means that for the same quantity of water they take only $\frac{1}{200}$ of the space of the latter. They always work under high pressure, which, however, does not exceed 13 feet, and consist of two tanks, of either masonry or iron, which are connected to each other, and form one set; they can alternately be cleansed by reverse currents of filtered water while the other tank is working.

The secondary filters, which remove the fine organic matter suspended in the water, can, according to local circumstances, be worked either under high pressure or low pressure; in the first case, their capacity is about half the capacity of the preliminary filters, and the total pressure for both filters 25 to 29 feet, while, in the second case, under low pressure—namely, about 32 inches—they require 10 times the surface of the preliminary filters, but still exceed the capacity of sand-filters 25 times.

In some cases, where it is sufficient to remove only the coarse matter, or where the water does not contain much impurity, a preliminary filter alone will suit the purpose, as, for instance, in breweries, for the soaking of malt and washing purposes, whilst the water for the brewing process proper can pass through a secondary filter specially put in for this purpose.

It is evident that by the arrangement of this double filter the water is thoroughly freed from all the suspended matter, and the water has to pass a longer way through the filtering mass than in ordinary sand-filters. This process is similar to the process which takes place in nature in the filtration of rain-water. We shall soon see that, while the mechanical filtration takes place principally in the preliminary filters, the chemical action upon organic matters is accomplished in the preliminary as well as in the secondary filters.

The chemical action must obviously not be caused by soluble substances, as their presence in the filtered water would render it unfit for almost any use, because of the odour or taste or chemical action of the antiseptic. The filtering substances in Dr. Gerson's

filters are impregnated with the almost insoluble tannate of iron, and thus the sponges used in the preliminary filters, and which otherwise are liable to decomposition and putrefaction, become impregnable. Microscopical examination of such sponges shows all the fibres filled with amorphous tannate of iron. They are used in the preliminary filters in a compressed state, and can easily be washed without losing their quality. Also, the sand and pumice-stone used in the secondary filters are impregnated in the same way, and the water is exposed to the action of the tannate of iron all through both filters.

The antiseptic qualities of the tannate of iron were known for a long time, but could not possibly be better demonstrated than by the following striking fact:—The population of a small village in France, called Bessé-sur-Braye, was often afflicted by typhoid and mucons fever about fifty years ago, and the mortality was very considerable. Since the erection of dyeworks on the river above the village, in which tannate of iron is continually used, cases of the above-named diseases are very scarce, and seldom prove fatal. The waste water from the dyeworks goes into the river which supplies the village with water filtered through the soil, which becomes impregnated with the tannate of iron. The manager of these works, Mr. Rolland, wrote at once to Dr. Gerson, when he heard of his filtration system, stating that he could only attribute this fact to the action of tannate of iron.

We have already pointed out the necessity of keeping the filters clean, and the difficulties and expense incurred in this respect by the sand-filters. Dr. Gerson provides different means for cleansing his filters, which are most efficient, and secure a better result at less expense in money and time. As the water enters the filters at the bottom, where consequently the suspended matter is caught and retained, a reverse current of water is quite sufficient for removing the suspended matter. The pipes supplying the filter with water, as well as the bottom of the filter, are provided with valves specially for this purpose, and while the admission of water to the filter is stopped, the filtered water passes through the filtering substances in the opposite direction, and is emptied with the suspended matter through the valve at the bottom of the filter. In six to ten minutes the operation is finished, and the filter again ready for use. During the cleaning, the filtering substances, which are placed in layers between sieves, may be compressed, and thus more thoroughly cleaned. Should it be found necessary to change the filtering substances, or to inspect them, this can be done in the short time of two or three hours, after which the filter will be ready again for use. This, however, occurs only exceptionally, and in one case the filtering substances had to be taken out for a thorough washing only after two years' use.

I have already stated that the capacity of Dr. Gerson's filters is much higher than that of the ordinary sand-filters. The illustrations Figs. 1A and 1B, in the scale of 1 : 200, shows the space required for the same capacity by the sand-filters, and, with Dr. Gerson's system, the preliminary filters in the latter working under high pressure and the secondary filters under low pressure. For the preliminary filters, basins of concrete may also be used, allowing existing filtration plants to be converted to Dr. Gerson's system.

Fig. 2 illustrates a filtration plant for breweries, in the scale of 1 : 50, for a capacity of 400 hectolitres (90,000 gallons) per twenty-four hours—*a* being the receiving tank, about 16 to 20 feet above the top of the preliminary filters, *b* the feeding pipes, *c* the preliminary filters, *d* pipe conducting the water from the preliminary filters to a small tank, *e*, above the

FIG. 1A.—ORDINARY SAND FILTRATION.

FIG. 1B.—DR. GERSON'S FILTER

FIG. 2.

FIG. 4.—BATTERY OF SIX PAIRS OF FILTERS.

secondary filters, *f* and *g* pipes feeding the secondary filters, *h*, *i* discharging pipe for the filtered water, and *k* pipes discharging the cleaning water from the reverse currents.

Fig. 4 represents a battery of preliminary filters, with six pairs of cylinders, which take up a space of only 1050 square feet, while the secondary filtration is performed in a tank of 1016 square feet of surface.

FIG. 3.

FIG. 4A.—ONE SINGLE PRELIMINARY FILTER FOR ASTRACHAN.

Fig. 3 (scale 1:12) shows a set of preliminary filters and a set of secondary filters, both working under high pressure, for a capacity of 150 hectolitres (33,600 gallons) per twenty-four hours.

This plant was erected for the city of Astrachan, in Russia, several years ago, and corresponds to a capacity of 5000 hectolitres (1,120,000 gallons) per twenty-four hours.

Fig. 5 gives another instance for the use of this filtration system—namely, for the supply of troops with drinking water on the march or in camp. It is a pump connected with the filters fixed on a vehicle. With such an apparatus, a battalion can, in the shortest time, be supplied with clear and pure water, taken from whatever it may be, river or pond. Official trials with this portable filter have already been made by the German and Italian armies, and proved most satisfactory. Their introduction depends, of course, upon the possibility to augment the number of vehicles for the army; but the great service which these filters

	Un- filtered.	Filtered through Dr. Gerson's system.
Residue after evaporation (130° C.) ...	4·800	3·540
Ammonia	—	—
Nitric Acid	traces	traces

Oxygen required for the oxidation of organic matter	0·097	0·076

FIG. 5.—PORTABLE FILTERING PUMP FOR QUARRY PURPOSES.

would render, in hot climates principally, preventing diseases spreading amongst the troops, is of greater importance than the economy, often going too far, in such useful implements.

Before concluding my description of these filters, I will give a few analyses of water, giving the results obtained from sand-filters in comparison with Dr. Gerson's filters. The quantity of organic matter has been determined by the consumption of oxygen for their oxidation:—

	Oxygen.

No organisms found.

NOTE ON SACCHARINE.

BY IVAN LEVINSTEIN.

At the meeting of the Liverpool Section held on May 5, 1886, the question was raised by Mr. Brunner as to the therapeutic action of saccharine, and Mr. Tate promised to make experiments on this substance, and to communicate the results to the Society. Now, without in the least intending to forestall any of Mr. Tate's results, I thought that it would be of interest to many, and also possibly of assistance to Mr. Tate, to briefly refer to the hitherto published evidence of the innocuous character of saccharine. Two Italian physiologists, Arduceo and Mosso, have studied the physiological action of this body some time ago. An abstract of their investigation is published in that excellent Journal, *The Medical Chronicle* (the April number, 1886). They found that frogs could be kept for days, and without the least injury, in a neutralised aqueous solution of saccharine. Dogs showed no ill effects when saccharine was administered in increasingly large doses, up to 5grms. per diem for several

days together. The body weight remained unaltered. The saccharine was discovered unchanged in the urine, apparently undergoing no change in its passage through the body. It does not influence the quantity or specific gravity of the urine, nor does it cause any change in the urea and sulphuric acid excreted. The chlorides are slightly increased. The presence of saccharine in the urine delays decomposition. Dr. Stutzer of Bonn, as well as Arducco and Mosso, obtained similar results with the human subject, 5grms. daily being found to have no ill effect, passing away by the kidneys, and appearing neither in the saliva, in the milk, nor in the feces; the appetite remained unaffected. Now, 5grms. of saccharine, as already stated in my former paper (this Journal, 1886, 76), are equal in sweetening power to more than two and a quarter pounds of sugar. Stutzer's investigations have been quite recently confirmed by Professor E. Salkowski (*Firchow's Archiv*, vol. 105, p. 46). In diabetes, Professor Dreschfeld, of the Victoria University, the Owens College, Manchester, has determined that no alteration takes place either in the quantity of urine or the quantity of sugar passed. Saccharine has scarcely any retarding effect on the digestion of either proteids or carbohydrates, and in two cases of acid dyspepsia Dr. Dreschfeld found that it relieved some of the troublesome symptoms. Stutzer has noticed that, added in small quantities, it increases the diastatic action of malt in presence of sugar.

THE VOLUMETRIC TEST FOR MANGANESE.

BY JOHN PATTINSON, F.L.C., F.C.S.

IN a paper on the Estimation of Manganese, read by Mr. R. W. Atkinson at the April meeting of the Bristol and South Wales Section, and published in the June number of the *Journal of the Society of Chemical Industry*, the author calls in question the accuracy of the volumetric test for manganese published by me in a paper read before the Chemical Society, and printed in the *Journal of the Chemical Society* for June, 1879. The test experiments made by me at that time to establish the accuracy of my volumetric process were made with known quantities of manganoso-manganic oxide (Mn_2O_4), the absolute purity of which was proved by repeated careful analyses, and also by comparison with the results obtained by carefully conducted gravimetric analyses. These test experiments are fully described in my paper, and I need not refer to the results further here than to say that they show that the volumetric process indicates the whole of the manganese present in any sample operated on. An experience of seven years, and repeated confirmations of the exactness of the method made during that time, still further

satisfy me that, when carefully conducted, the process yields absolutely correct results.

It is of course impossible for me to point out exactly how, in Mr. Atkinson's hands, the volumetric process has apparently failed to indicate the whole of the manganese supposed to be present; but a few particulars may be indicated which may probably account for the deficiency he has observed. In the first place, there is not sufficient evidence given to show that the sulphate of manganese used in his test experiments was not contaminated with alumina, lime, or some other base, which would be carried down with the manganese in the sodium carbonate and bromine-ammonia precipitations, and thus cause the gravimetric tests to indicate more manganese than the substance really contained. In my own experience I have recently had a well-crystallised sample of sulphate of manganese supplied to me as being pure, which was found to contain a notable quantity of sulphate of alumina. I would here point out that in Mr. Atkinson's paper there is obviously an error in the statement of the composition of the sulphate of manganese he used. The "manganese oxide (MnO)—23.61" there mentioned should, I presume, be "manganese—23.61" and the "sulphuric oxide (SO_3)—41.04" should be, I suppose, " SO_4 —41.04." The water given—35.35 per cent.—to make up the hundred parts is doubtless obtained by difference. Then, as tending towards deficiency in his volumetric test, if Mr. Atkinson added too much carbonate of lime to the solution before bromine was added, some of the iron would be precipitated as peroxide and carry down with it a small quantity of the manganese as protoxide. It is also possible that a somewhat large quantity of permanganate may have been formed in Mr. Atkinson's experiment which, being afterwards reduced by alcohol, would be precipitated in a lower form of oxidation than MnO_2 . When using bromine water it is difficult to see by the colour whether permanganate is formed or not. With solution of chloride of lime, which I always use, there is no such difficulty. When much permanganate is formed, the test should be rejected in very exact experiments, and a smaller quantity of chloride of lime used. But the formation of permanganate is altogether avoided and the subsequent addition of alcohol rendered unnecessary by the addition of some soluble salt of zinc, as well as iron, to the solution containing the manganese to be precipitated, and this is perhaps the safest plan to follow.

Since I have seen Mr. Atkinson's paper, I have again tested my method as applied to pure Mn_2O_4 . Two tests indicated respectively 99.96 and 100.07 per cent. of the manganese actually present. I know of no process of analysis which gives more exact results, and very few which give such exact results as this. In my opinion it would be as reasonable to revert to the precipitation methods for the determination of iron in iron ores as to return to the gravimetric methods of determining manganese in manganese ores.

But the testimony as to the accuracy of the volumetric process for determining manganese does not rest with me alone. Mr. Atkinson quotes Dr. C. R. Alder Wright's paper on the Oxides of Manganese as to the difficulty of obtaining pure peroxide of manganese; but he is perhaps not aware of the fact, as he does not mention it, that Dr. Wright and Mr. Menke have carefully investigated my process, and have confirmed its accuracy (see *Journal of the Chemical Society*, vol. xxxvii. pages 22 and 49). In Germany also Professor Ledebur has investigated the process, and he also confirms its accuracy. His results are published in the *Chemiker Zeitung* (vol.

viii. pages 910, 927, 963; translated and abstracted in the *Journal of the Iron and Steel Institute*, 1884, No. 1, page 269). According to this chemist, a sample of ferro-manganese which, by careful gravimetric analysis, was found to contain 46.22 per cent. of manganese, indicated 46.28 per cent. in each of two determinations by my process.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in the Separation or Filtration of Solid and Liquid Matter. W. Hucks, London. Eng. Pat. 8162, July 6, 1885. 11d.

THE inventor constructs a filtering surface by making of filtering cloth an endless travelling band, which, at one point, is caused to pass into and out of a trough containing the liquid from which the suspended solid particles are to be removed. The arrangement is such that the torpid liquid can touch the upper side only of the inserted travelling cloth, the filtered or cleansed liquid passing through, whilst the solid particles are retained upon its surface. As the cloth continues to travel, the adhering solid matter is raised out of the filtering trough, and may then be successively pressed, treated chemically or otherwise, and finally removed, thereby leaving the cloth ready for the next operation without stoppage of any kind. Instead of the continuous movement, the cloth may receive a reciprocating or other convenient motion, the important point to be kept in view being that of providing for carrying on the operations of filtering, of cleansing the filtering surface, and of dealing with the deposit, continuously and simultaneously, without interfering the one with the other.—B.

Improvements in Preparing Milk of Lime, and in Apparatus to be used therefor, and for other such like Purposes. S. H. Johnson and C. C. Hutchinson, Stratford. Eng. Pat. 8623, July 16, 1885. 8d.

THE apparatus consists of a cylindrical vessel having a conical bottom, the interior provided with a perforated grating, a pipe for the admission of compressed air covered by a cone for the distribution of the air through the apparatus, and an outlet valve. The unslaked lime is put into the apparatus resting on the grating, the requisite quantity of water added, and the whole well agitated by compressed air. The clinker and unburnt stone remain on the grating and can be removed. The patentees claim that by this method and apparatus a concentrated milk of lime of even composition, free from inert matter, can be produced in a less time, with less power and with less wear and tear than by any other method.—C. C. H.

Improvements in Apparatus for effecting the Absorption of Gases or Vapours by Liquids. E. Edwards, London. From L. Rohrmann and M. Hiller, Germany. Eng. Pat. 8630, July 16, 1885. 8d.

THIS invention contemplates the absorption of gases by suitable liquids, through the passage of the gas over an extended surface of the liquid. The apparatus consists of a number of superposed flat trays ranged within a closed vessel. Each tray is sealed all round by a water joint, and has two small tubes projecting from the

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader LACK, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.	4d.
Above 8d., and not exceeding 1s. 6d. . .	1d.
" 1s. 6d., " " " 2s. 4d. . .	1½d.
" 2s. 4d., " " " 3s. 4d. . .	2d.

bottom, one constituting the overflow from the tray at a fixed level and dipping into the liquid of the next lower tray, the other forming the passage for the ascending gas. The tubes are placed alternately in successive trays. The liquid is admitted above, and, after having absorbed the gas, flows away from the lower part of the vessel, whilst the gas is admitted below, and ascends from tray to tray through the appointed tubes.—B.

Improvements in Metallic Drums for containing Chemical and other Substances. H. W. Todd, St. Helens. Eng. Pat. 9231, August 1, 1885. 6d.

GREATER rigidity and strength are given to metal drums by corrugations arranged circumferentially, and by corrugated V-shaped hoops over the ends.—G. H. B.

Improvements in Filters applicable for Caustic Soda Solution. W. P. Thompson, Liverpool. From Solvay & Co., Brussels. Eng. Pat. 8723, July 20, 1885. 8d.

THE filtration of lime residues in the manufacture of caustic soda has hitherto been performed through beds of limestone or flint, filtration through tissues having not been found practicable. This invention consists in the employment of asbestos or other mineral fibre, woven into sheets or webs, which is used in the following manner: A rectangular iron box has a bottom slightly curved or sloping downward to the point of exit. At this point a half-round collecting conduit with notched edges resting on the bottom collects the liquor which has passed through the filtering media. The lower part of the filter is protected by a lining of brick. Beds of broken inert mineral matter decreasing in size toward the top fill the lower part of the filter. The asbestos cloth is disposed in bands resting flat on the upper part of the finely-powdered mineral matter, consecutive bands overlapping each other. The joints rest on perfectly level beds of refractory bricks. The asbestos cloth is fastened to the edges by means of a movable iron frame which goes all round the filter. This frame does not rest directly upon the asbestos, but rests on perforated sheets of iron which cover the whole area of asbestos with the object of protecting the asbestos, and allowing the sediments to be cleared away without damaging the tissue.—S. H.

An Improvement in the Manufacture of Ice. Charles D. Abel, London. From C. Linde, Wiesbaden. Eng. Pat. 9612, August 12, 1885. 8d.

THIS invention relates to a new method of agitating the water in the moulds for the purpose of securing cleanness and transparency in slab ice formed in removable moulds placed vertically in a congealing liquid. The ends of the moulds are partitioned off, the partitions having numerous lateral perforations. The water is drawn away from one end of the mould, fresh water being admitted at the other end, thus causing a stream or horizontal movement and agitation of the water through the whole height of the mould, with the effect of retaining the transparency of the water on freezing. Instead of partitions, perforated pipes may be employed. The ends of the blocks of ice, which are imperfectly formed, are cut off when the slab is removed from the mould.—B.

II.—FUEL, GAS, AND LIGHT.

Improvements in Making and Utilising Water and Oil Gas. C. J. C. Bailey, Fulham, and S. C. Dean, Fulham. Eng. Pat. 7457, March 1, 1886. 6d.

THIS invention consists in utilising the heat said to be at present wasted in the walls and roofs of furnaces and kilns by constructing these walls with flues or channels, which serve for the production of water gas by the decomposition of steam.—A. R. D.

Improvements in the Means of Generating Fired Gases for Illuminating, Heating, and Metallurgical Purposes. T. S. Lindsay, London. Eng. Pat. 6938, March 8, 1886. 1s. 1d.

THIS is a process for superheating steam, mixing it with liquid hydrocarbon, and subjecting the mixture to a further heating process to "fix" it. The superheating and fixing is performed by passing the steam or mixed gases through a heated retort, packed with cones, the apex of one being within the interior of the next. The cones have each a flanged base, fitting the interior of the retort, and this flange is perforated for the passage of the gas. By this arrangement, the gas is forced to pass in close contact with the heating surface of the retort, and being also continually broken up by passing through the small flange apertures, is thereby conveniently superheated and rendered perfectly homogeneous. The resulting product is a gas that can be conveyed for any practical distance without fear of condensation.—A. R. D.

Improvements in the Method of Illuminating by means of the Incandescence of Refractory Substances. O. Palmehjelm, Stockholm. Eng. Pat. 7573, March 19, 1886. 11d.

THIS invention consists of improvements in the details of the system of lighting for which Letters Patent No. 5646 of 1883 were granted. The specification and drawings describe various constructions of incandescence bodies, with arrangements for suspending these in the flame of a water-gas burner.—A. R. D.

A New or Improved Apparatus for Purifying and Enriching Coal-gas. A. Dempster, Elland, Yorks. Eng. Pat. 4099, March 24, 1886. 6d.

ON its way to the ordinary purifiers the gas passes through a chamber subdivided by vertical perforated plates reaching nearly to the bottom, and, impinging upon these plates, deposits a large quantity of tarry matter which overflows into another chamber or carburetter placed beneath. This lower chamber is provided with a steam coil to keep the tar warm, and with a pipe perforated with small holes for passing jets of warm air through the oils floating on the surface of the tar. The warm air for this coil is heated by being driven into a separate chamber, partly filled with tar, kept at the requisite temperature by a steam pipe immersed therein. The air thus impregnated with volatile hydrocarbons rises into the chamber above, and mixes with the other gas going forward to the purifiers. The air orifices in the carburetter are covered with caps, which cause the air to pass downwards and be distributed before rising upward through the floating oils.—A. R. D.

Improvements in Processes of and Apparatus for Manufacturing Gas. B. Loomis, Hartford, Connecticut, U.S.A. Eng. Pat. 4469, March 30, 1886. 1s. 3d.

THIS is practically a continuous process for making gas of any desired illuminating power. The apparatus consists mainly of two generating chambers and two superheating and fixing chambers. These latter are so divided by transverse vertical partitions of fire-brick as to form one long length of flue space. In working the plant air is forced downwards through the fuel in each generator, and the products of combustion, supplied with air by suitable arrangements, pass through the fixing chambers and away under a steam boiler. When all is heated to the requisite degree, the air supply is entirely cut off, and superheated steam is passed into fixing chamber No. 1, whence it finds its way upwards through the fuel in generator No. 1, and is thereby decomposed. The mixed gases next travel downwards through the fuel in generator No. 2, where the decomposition is completed, and finally pass through fixing chamber No. 2, where oil is added to produce the required illuminating power, and where perfect homogeneousness is effected. When the temperature has fallen below the point required

for decomposing and fixing, the process of heating up is again performed and is followed by the production of gas as before. For details of the apparatus the Blue Book must be consulted.—A. R. D.

An Improved Artificial Fuel. H. H. Lake, London. From Leon Cline, Chicago. Eng. Pat. 5024, April 10, 1886. 4d.

THREE parts of ground charcoal are mixed with one part of ground charred cork. When required for disinfecting, one-hundredth part of chloride of lime is added. This fuel burns downward from the top, and is applicable wherever a slow moderate heat is required.—A. R. D.

The Relative Calorific Effects of Tar (with and without Steam) and Coke for Retort Firing. F. G. Dexter. Proc. Gas Institute. J. Gas Lighting, June 29, 1886, 1242–1244.

FOR the relative heating values of the substances under consideration, the numbers given by Favre and Silbermann are taken. These are:—Hydrogen = 34,462 cal., carbon 7770 cal., coke (desiccated) 7000 cal., and carbonic oxide 2400 cal. To obtain the relative calorific value of tar and coke, the author classified the constituents of tar according to their respective boiling points under the different periods of distillation and took the average formulae of the hydrocarbons coming under these

It will be seen that the latent heat of the steam produced is deducted from the heat of combustion in each case. In the case of combustion in the furnace this is necessary as the steam escapes in a highly attenuated state and carries its latent heat with it. The high specific heat of steam, its latent heat, and the fact that the weight of the products of combustion is about three times greater, serve to reduce the calorific intensity of hydrogen to practically the same as carbon, a question of considerable importance in furnaces where very high heats are required. The relative calorific intensities of tar and coke are as follows:—

Coke .. $5250 - 134 = 5116 \div 2.42 = 2114$ C. calorific intensity.
Tar .. $8550 - 291 = 8256 \div 3.32 = 2486$ C. " "

The practical heating value of tar is therefore due in great measure to its form and ease of manipulation. It can be introduced in a small constant quantity, and in a condition much more favourable for intimate mixture with the supply of air than is possible with coke, and as a consequence the excess of air supply required is much less, the intermittent cooling effect produced by fresh charges of coke is avoided, and the carbon being burnt to carbonic anhydride a much higher heating effect is necessarily produced. The use of steam with tar should be avoided if possible, as it tends to reduce the temperature in the furnace.—D. B.

CONSTITUENTS.	Average Formula.	Weight per cent.	Boiling Points.	Proportionate Weight of Constituents.		Calorific Value.	
				Carbon.	Hydrogen.	Carbon (Units).	Hydrogen (Units).
First Runnings	C_9H_{10}	3.0	up to 110°	.025714	.004286	260	148
Light Oil	$C_{11}H_{14}$	7.0	110 to 210	.061091	.008910	474	307
Middle Oils	$C_{13}H_{18}$	27.0	210 to 270	.237073	.032927	1842	1145
Heavy Oils	$C_{14}H_{18}$	7.0	240 to 270 and upwards	.063913	.006087	497	210
Pitch (56 p.c.), composed of—							
Oils	C_7H_{10}	17.5	360° and upwards	.166336	.008663	1292	298
Carbon	C	27.5	—	.275000	—	2137	—

				.829127	.060873	6442	2108
Total				0.89		8550	

divisions as representing the constitution of the oils obtained. The results are shown in the above table.

Coke when drawn from the retort and slaked contains fully 25 per cent. of water in addition to ash and sulphur. By disregarding these impurities and deducting merely 25 per cent. for water from the value of desiccated coke, we obtain $0.75 \times 7000 = 5250$ units per pound of coke, or a relative heating value of coke and tar as 5:8. It is necessary, however, to take into account the amount of heat absorbed by the products of combustion, which, considering the nature of the fuel, is necessarily very different. This alters the ratio to 1:2 as illustrated by the following tables, in which the temperature of the gases leaving the retort setting is taken at 1082° :—

PRODUCTS OF COMBUSTION OF LB. OF COKE.

Specific Heat.

2.75lb. $CO_2 \times 0.2163 = 0.5948$ unit.

7.00lb. N $\times 0.2438 = 1.7066$ " (latent heat 291 units).

0.25lb. $H_2O \times 0.4805 = 0.1201$ " (latent heat = 134 units).

2.4215 " calorific value.

Then $5250 - 134 = 5116 - 1082 \times 2.42 = 2198$ units for coke.

PRODUCTS OF COMBUSTION OF LB. OF TAR.

Specific Heat.

3.400lb. $CO_2 \times 0.2163 = 0.73542$ unit.

0.547lb. $H_2O \times 0.4805 = 0.262392$ " (latent heat 291 units).

9.702lb. N $\times 0.2438 = 2.36544$ "

3.32178 " calorific value.

Then $8550 - 291 = 8256 - 1082 \times 3.32 = 4664$ units for tar.

On the Application of Tar and Breeze to Retort Furnace Firing. Proc. Gas Institute. W. R. Jones. J. Gas Lighting, June 29, 1886, 1241.

DIFFERENT systems have been employed for burning tar, one of the earliest consisting in allowing it to run on an iron shoot, which discharges it on to the coke fire. A modification of this system has been in use for many years on the Continent. It consists of a sloping table of fire tiles with an opening at the back through which any deposit is removed, and by which a supply of air is obtained. This arrangement may be applied to ordinary furnaces by removing the fire doors and furnace bars. Briquettes formed of tar and coke dust are also used as fuel on the Continent. In some cases tar and coke dust are mixed on the floor of the retort house and thrown on the coke fire. Where briquettes are used pitch must be employed to give the material the necessary degree of adhesion, 10 per cent. of pitch to 1 per cent. of breeze being the proportion usually required. As breeze contains much earthy matter and but little carbon, it is best to burn it in regenerative furnaces on account of the high heat attainable therein. The consumption of fuel in generator furnaces varies between 18 and 30 per cent. of the quantity of coal carbonised, whilst regenerators, for instance Siemens' regenerative furnaces, consume only 16 per cent. of fuel. According to Ellissen's experiments on the Didier settings of six retorts (regenerators), the consumption of fuel is 15.94 per cent.; Didier's settings of nine retorts burn 14.26 per cent., and Schilling's

settings of nine retorts burn 13.54 per cent. The author has constructed a generator furnace consuming 14 per cent. of fuel calculated on the quantity of coal carbonised. The system consists in the production of a deep fire in the "high temperature furnace." Fire bars are not required, the hearth floor contains two openings, and a second fire or "low temperature furnace" is used, which is caused by the hot scoria and small fuel falling through the openings. This second fire heats all the air introduced through the lower fire bars, which afterwards passes through the openings into the high temperature furnace, where the combustion is completed.—D. B.

A Recent Experience with Purification by Oxide of Iron.
T. Travers (Proc. of the Gas Institute). J. Gas Lighting, June 29, 1886, 1252.

SEVERAL trials have been made for the purpose of re-oxidising the spent oxide in the purifiers, but the results have hitherto been without success, the problem to be solved being how to effect the revivification so as not to cause a heating in the vessels or injury to the illuminating power of the gas. A process has been patented by J. G. Hawkins, in which carburetted air is supplied to the oxide in the purifiers, the patentee claiming that by this means the spent material can be reoxidised without difficulty. The author has tried this method at the Cork Gas Works. The apparatus consists of the following parts:—(1) A small steam engine and air pump; (2) a carburetter, which consists of a horizontal box about 12ft. long and 18in. by 12in., in which is laid a steam coil. The tar to be used for carburetting purposes enters at one end of the box, and is made to pass to the other end by zigzag partitions. It is thus kept for a long period in contact with the steam coil and maintained at 170°, at which temperature the lighter hydrocarbons are given off. These are taken up by the air drawn in by the pump and passing through the meter and carburetter. The outlet from the carburetter is connected to the inlet of the purifier. The saving in labour may be estimated from the fact that for three months the purifiers were changed four times, whilst with the ordinary process eleven changes were made during the same period. About five gallons of tar per ton of coal are used. As the tar enters the carburetter it has a sp. gr. of 1.196, which is increased to 1.218 as it leaves the vessel. The illuminating power of gas is tested regularly twice every day at the company's office, situated about one mile from the works. The gas purified in the ordinary manner showed an average illuminating power of 16.49 candles for three months, and the gas made by the new process showed an average of 16.55 candles for a similar period.—D. B.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Improvements in the Treatment of Carbonaceous, Bituminous, Calcareous, and other Substances, such as Ores, in order to Obtain Products therefrom. Henry Aitken, Falkirk, N.B. Eng. Pat. 6048, May 16, 1885. 8d.

INTO retorts, which are heated externally, or into chambers, or gas-producers, heated by the combustion of a portion of the charge, air, steam, or gas (or mixtures of these) are introduced at different levels, for the purpose of regulating the temperature and the combustion of the material under treatment—the precise arrangements depending upon the purpose to be accomplished in the distillation.—W. G. M.

Improvements in and Apparatus for obtaining Carbolic Acid and other Tar Acids from Tar Oils. J. Hardman, Milton. Eng. Pat. 7079, June 10, 1885. 8d.

TAR oils are treated with a solution of caustic soda, and the alkaline phenates, cresylates, and other compounds thus formed are allowed to run slowly down a tower

filled with stones, coke, or other suitable material. In this tower the solution meets an ascending stream of carbonic anhydride, a mixture of sodium carbonate, carbolic, cresylic and higher boiling tar acids being obtained. On reaching the base of the tower, the mixed solutions are run into the ordinary separating tanks. The carbonic anhydride is obtained from the waste gases formed in the manufacture of ammonium sulphate. The gases are cooled, the sulphuretted hydrogen extracted by means of iron oxide, and the remaining gases, representing almost pure carbonic anhydride, are allowed to pass up the tower. The solution of sodium carbonate is reacidified with lime, the solution of caustic soda obtained being used for extracting a further quantity of tar acids from tar oils. This solution contains from 2 to 3 per cent. of tar acids, which in the ordinary process of decomposing the alkaline phenates by means of sulphuric acid would be lost by being run off with the waste sodium sulphate liquors.—D. B.

The Utilisation of Residual Products in Gas Works.
J. T. Lewis (Proc. of the Gas Institute). J. Gas Lighting, June 29, 1886, 1247—1252.

IN discussing the utilisation of coke, the author refers to the advantages gained in supplying broken coke. He shows that the sale of coke is increased by this means, hence the average price realised per ton is greater. The reason for this is that broken coke is applicable for many purposes that large coke is not, such, for instance, as kitchen ranges, slow combustion stoves, smiths' forges, etc. The cost of breaking coke is about 8d. per ton, and to this it is necessary to add the difference in the value of dust made in breaking, which is about 4d., making a total cost of 1s. per ton. The extra price obtained for broken over large coke is about 2s. per ton. As regards the value of coal-tar the author shows that in 1883 the price varied between 1s. 8d. and 3s. 4d. per ton of coal carbonised, whilst at the present time tar is only worth from 4d. to 7d. The following figures give the value of tar to tar distillers, taking the prices of the different products at the present market value. The statements have been obtained from two sources, one distiller carrying the process further than the other:—

PRODUCTS FROM ONE STILL OF EIGHT TONS OF TAR.

		£	s.	d.
Naphtha	60 gallons at 9d. per gallon	2	5	0
Light oil	60 " 3d. "	0	15	0
Cresote	500 " 0½d. "	1	11	3
Anthracene	1 cwt.	1	11	8
Pitch	5 tons at 15s. per ton	3	15	0

	£	s.	d.
Wages on the above	2	0	0
Coals	0	6	0

Wear and tear, rent, etc., not known

Giving value of 1 ton as nearly 19s.

PRODUCTS FROM ONE TON OF TAR.

		£	s.	d.
Benzene (50.90)	5 gallons at 1s. 5d. per gallon	0	7	1
Naphtha	2 " 9d. "	0	1	6
Carbolic acid	5 " 1s. 8d. "	0	8	4
Cresote oil	50 " 0½d. "	0	3	1½
Anthracene	30lb. of 35 per cent.	0	8	0
Naphthalene	2 cwt. at 3s.	0	6	0
Pitch	11 cwt. at 9d.	0	8	3

	£	s.	d.
Sulphuric acid, caustic soda, slack, and labour for working	0	10	6
Wear and tear, rent, etc., not known	—		

£1 12 9½

These statements show that tar is not at the present time very valuable to tar distillers for the purpose of distillation. Where the annual quantity of coal carbonised is below 30,000 tons the distillation is said to be unremunerative. In considering the utilisation of tar as a fuel the author gives the following particulars illustrat-

ing the varying values of coke and tar in different localities:—

(1) Cost of coke for one furnace per 12 hours.....	£0 7 4
Cost of coke and tar for ditto	0 5 2

Saving£0 2 2

Showing a saving of 4s. 4d. for each furnace per 24 hours.

(2) Coke saved in 24 hours, 1 ton	£0 16 8
Tar used, 90 gallons at 1½d. per gallon	0 3 9

Showing a saving of 12s. 11d. per 24 hours. Tar equal as fuel up to 2d. per gallon.

(3) Coke saved, 13cwt. at 4d. in 24 hours	£0 4 4
Tar used, 68 gallons at 10s. per ton	0 3 5

Showing a saving of 11d. for each furnace for 24 hours. Tar value 12s. 9d. per ton.

When coke is selling at 5s. per ton, and tar at 7s., one can be sold as profitably as the other; but in the majority of cases it will pay better to sell coke than tar. The manufacture of asphalt from tar is carried on in some gas works with considerable profit, and if more generally adopted by gas works would prove not only a source of direct profit, but would be remunerative indirectly through the reduced quantity of tar for other purposes. Another method in which tar might be more extensively used is for the manufacture of patent fuel. The immense quantity of coke dust in some of the largest gas works, as well as the breeze, can be profitably converted into fuel by the admixture of tar or soft pitch. At the Dover Gas Works patent fuel was manufactured in the following proportions:—

	Tons.	Cwt.	Qr.	Lb.	£	s.	d.
1 chaldron of breeze at 2s. 6d.	1	1	2	7	0	2	6
40 gallons of tar at 3d.	0	4	1	11	0	10	0
Labour for working					0	1	8
Coke as fuel					0	0	8
	1	5	3	18	0	11	10

The cost of the manufacture was 11s. 4d. per ton, with tar at 3d. per gallon. This fuel was used in the re-ort furnaces and steam boilers, and is said to last double the length of time that coke does for this purpose. In conclusion the author discusses the utilisation of ammoniacal liquor by converting it into ammonium sulphate.—D. B.

IV.—COLOURING MATTERS AND DYES.

Improved Manufacture of Ink from Waste Dye-liquors. T. Frusher, Trowbridge. Eng. Pat. 8241, July 7, 1885. 4d.

SPENT liquors of bichromate of potash or soda and logwood are boiled together for a few hours to produce the ink.—G. H. B.

The Production of New Azo-colours. Meinhard Hoffman and Arthur Weinberg, Mainkur, Frankfurt-on-Main, Germany. Eng. Pat. 9214, July 31, 1885. 4d.

THESE COLOURS are produced by the action of diazo-sulphonic acids upon α -naphthylamine, the diazotising of the amido-azosulphonic acid and the combination of the tetrazo-compound with phenols and their sulphonic acids. The new colours are thus diazo-azo-compounds. As an example the inventor gives the following: α -naphthyl-aminedisulphonic acid is diazotised and combined with α -naphthylamine and the violet colouring matter again diazotised and allowed to act upon an ammoniacal solution of β -naphtholdisulphonic acid. The secondary azo-colouring matter, which has the formula

is salted out, collected and dried. Other α - or β -sulphonic acids may be used instead of the disulphonic acid of α -naphthylamine and mono- or di-sulphonic acids of the

naphthols or the unsulphonated naphthols. The colouring matters obtained are said to vary from reddish violet to dark blue.—R. M.

A New Manufacture of Violet and Blue Azo-dyes. Herbert John Haddan, 67, Strand, Westminster. From the "Farbenfabriken vorm. Bayer & Co.," Elberfeld, Germany. Eng. Pat. 9510, August 10, 1885. 6d.

THE colouring matters here described are obtained by combining tetrazoditoly with the naphthols or their sulphonic acids. The tolidine may be obtained by the alkaline reduction of ortho- or para-nitrotoluene or a mixture of the two. The colours are described as being acid proof and applicable to unmoirated cotton in a slightly alkaline bath, whereas the corresponding dyes from benzidine are said to be only suitable for wool, and are moreover dull and not fast. The chief compounds claimed are those obtained from α -naphtholmonosulphonic acid (blue), β -naphthol- α -sulphonic acid (Bordeaux), Schaeffer's β -naphtholmonosulphonic acid (blue violet), β -naphthol-disulphonic acid (R salt, reddish blue; G salt, dull blue) and α - and β -naphthol, blue or violet compounds insoluble in water. The colours are formed in the usual way by diazotising the base and adding it to the alkaline solution of the naphthol or sulphonic acid.—R. M.

Improvements in the Manufacture of Yellow and Orange Colouring Matters suitable for Dyeing and Printing from Dioxytartaric (Carboxytartaric) Acid. John Henry Johnson, 47, Lincoln's Inn Fields, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen-on-Rhine, Germany. Eng. Pat. 9858, August 19, 1885. 6d.

THE patentees claim a new class of colouring matters formed by the action of phenylhydrazine or its sulpho-derivatives, or other primary hydrazines upon the dioxytartaric acid. On adding the primary hydrazine to an acid solution of the dioxytartaric acid, a reaction gradually takes place in two stages, the first step being the formation of a condensation product between one molecule of each of the constituents, this product possessing little or no colouring property. The next phase of the reaction is the formation of yellow or orange colouring matters produced by the condensation of the first product with another molecule of the hydrazine. The colouring matters generally separate out spontaneously, and can be filtered off: when they have a tendency to remain in solution, sodium carbonate and common salt effect the precipitation of the dye. The three following examples illustrate the working of the process:—(1) Phenylhydrazine hydrochloride is mixed with the necessary quantity of the sodium salt of dioxytartaric acid dissolved in cold water and previously acidulated with hydrochloric acid. The reaction may be assisted by a gentle heat, and is complete in about 12 hours. The resulting colouring matter is but sparingly soluble in cold water, but readily soluble in alcohol or alkalis. Similar compounds are produced by the homologues of phenylhydrazine and α -naphthylhydrazine. (2) The solution of the acid is in this case mixed with a solution of the sodium salt of phenylhydrazine-para-sulphonic acid, and the mixture kept at 80° C. for 1 hour and about 12 hours at the ordinary temperature. The colouring matter is filtered and purified by solution in sodium carbonate, filtration and reprecipitation by common salt. The product, termed "tartrazine," is soluble in water, and dyes animal fibre with acids or acid mordants a fast golden yellow. Similar products are obtained from the isomerides and homologues of the hydrazine-sulphonic acid. (3) In this example mixed products are obtained by the successive action of different hydrazine-compounds upon the dioxytartaric acid. The inventors consider that "tartrazine" is the most useful of the compounds described in the specification. The dioxytartaric acid was first obtained from tartaric acid by Kekulé (*Ann. der Chemie*, vol. 221, p. 245).—R. M.

Improvements in the Manufacture of Azo-dyes. James Yate Johnson, 47, Lincoln's Inn Fields, London. From the "Farbenfabriken vorm. Friedrich Bayer & Co.," Elberfeld, Germany. Eng. Pat. 14,424, November 24, 1885. 6d.

THESE colouring matters are produced by the combination of tetrazo-compounds of alkyl-ethers of diamidodiphenol and its homologues upon phenols or amines and their sulphonic acids. The amido-ethers are prepared by the alkaline reduction of nitrophenol and nitroresol ethers, and the subsequent intra-molecular transformation of the hydrazo compounds. As examples, the following compounds are described:—(1) By the action of tetrazo-dianisole or tetrazo-diphenetol upon α -naphthol-monosulphonic acid in alkaline solution, an acid-proof blue dye is obtained which is greener than the "azo-blue" obtained from diazotised tolidine and dyes unmordanted cotton from an alkaline bath. (2) The foregoing tetrazo-compounds are combined with β -naphthylamine- β -monosulphonic acid in the presence of acetic acid, and after the formation of the colour is complete the solution is neutralised with alkali. The colour, when purified, dyes cotton from an alkaline bath of a fine bluish-red colour. In the foregoing processes one molecule of the tetrazo-compound is combined with two molecules of the phenol or amine. It is possible, however, to form the secondary azo-compound in two stages by acting upon the tetrazo-compound first with one molecule of a phenol, amine, etc., and then with another dissimilar phenol or amine so as to produce a mixed secondary azo-compound. The following examples illustrate this production of mixed azo-dyes:—(1) Diamidodianisidine is converted into its tetrazo-salt in the usual way and combined with one molecule of α -naphthylamine-monosulphonic acid. A brown intermediate product is formed which is then combined with another molecule of α -naphthylamine. The colour thus formed dyes cotton of a deep bluish red. (2) A reddish blue is similarly obtained by combining the tetrazo-compound, first with one molecule of β -naphthylamine-monosulphonic acid and then with a molecule of α - or β -naphthol or their sulphonic acids. (3) Greenish blue dyes are obtained by combining the tetrazo-compound first with α -naphthol and then with the sulphonic acids of α -naphthol. (4) Reddish-yellow dyes are obtained by combining the tetrazo-compound, first with sulphanilic and then with salicylic acid. A list of the phenols, amines, sulphonic and carboxylic acids claimed is given in the specification.

—R. M.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

An Improved Process for Removing Resinous, Gummy and Oily Matter from Fibrous, Spun or Woven Materials. B. Fiegl, Berlin. Eng. Pat. 4323, March 27, 1886. 4d.

AN improved isolation process for the preparation of spinning fibres, spinning material, spun and woven goods of all kinds, by the action and use of pepsin or pancreas as set forth.—H. A. R.

VII.—ACIDS, ALKALIS, AND SALTS.

Improvements in Apparatus for Burning or Calcining Ores and Minerals containing Sulphur or Arsenic, for the Manufacture of Sulphuric Acid, or Arsenious Acid, or White Arsenic. Robert Oxlard, Plymouth, and Charles Oxlard, Sydenham. Eng. Pat. 7285, June 15, 1885. 8d.

THIS is a modification of Oxlard and Hocking's calciner (Eng. Pat. 2950, 1868), so arranged that the gaseous products of calcination shall pass to the condensers unmixed with burnt gases from the heating furnace. At the lower end of the rotating calcining tube is a cast-iron prolongation, heated externally by a grate beneath, and a system of flues around it. The amount of air necessary to the calcination of the ore is admitted by a regulator in the end plate of the prolongation, which

is also fitted with a door for the removal of the calcined material. When the calcination is once fairly started, but little extraneous heat is necessary for complete roasting.—W. G. M.

Improvements in the Manufacture of Peroxide of Barium, and its use in Making Oxygenated Water for Bleaching, or for other Purposes. Arthur Brin, Paris. Eng. Pat. 7867, June 29, 1885. 6d.

CAUSTIC BARYTA is produced by heating the nitrate, and a partial vacuum is afterwards employed to remove nitrous vapours. Then oxygen or air, freed from moisture and carbonic acid, is passed over the baryta at a suitable temperature, preferably under pressure. The barium peroxide thus formed is dissolved in acidulated water for use.—G. H. B.

Improvements in the Manufacture of Hydrate, Sulphate and other Salts of Alumina. H. Richardson, Jarrow-on-Tyne. Eng. Pat. 8382, July 11, 1885. 4d.

BAUXITE, blast-furnace slag or other substances containing alumina are treated with hydrochloric acid until alumina, together with iron, lime and other bases are dissolved. After separating the insoluble matter, a sufficient quantity of any reducing agent, such as sodium sulphite or hyposulphite, is added to the clear solution, for the purpose of reducing the iron to ferrous chloride. The liquor is then treated with milk of chalk, when aluminium hydrate is precipitated, iron and lime remaining in solution. The precipitate is separated and well washed with water. The aluminium hydrate may be dried and used as such, or dissolved in acids for the manufacture of the different salts of alumina.—S. H.

An Improved Process for the Production of Carbonate of Potassium from Chloride of Potassium or Sulphate of Potassium. F. Brünjes, Strassfurt, Germany. Eng. Pat. 8993, July 25, 1885. 6d.

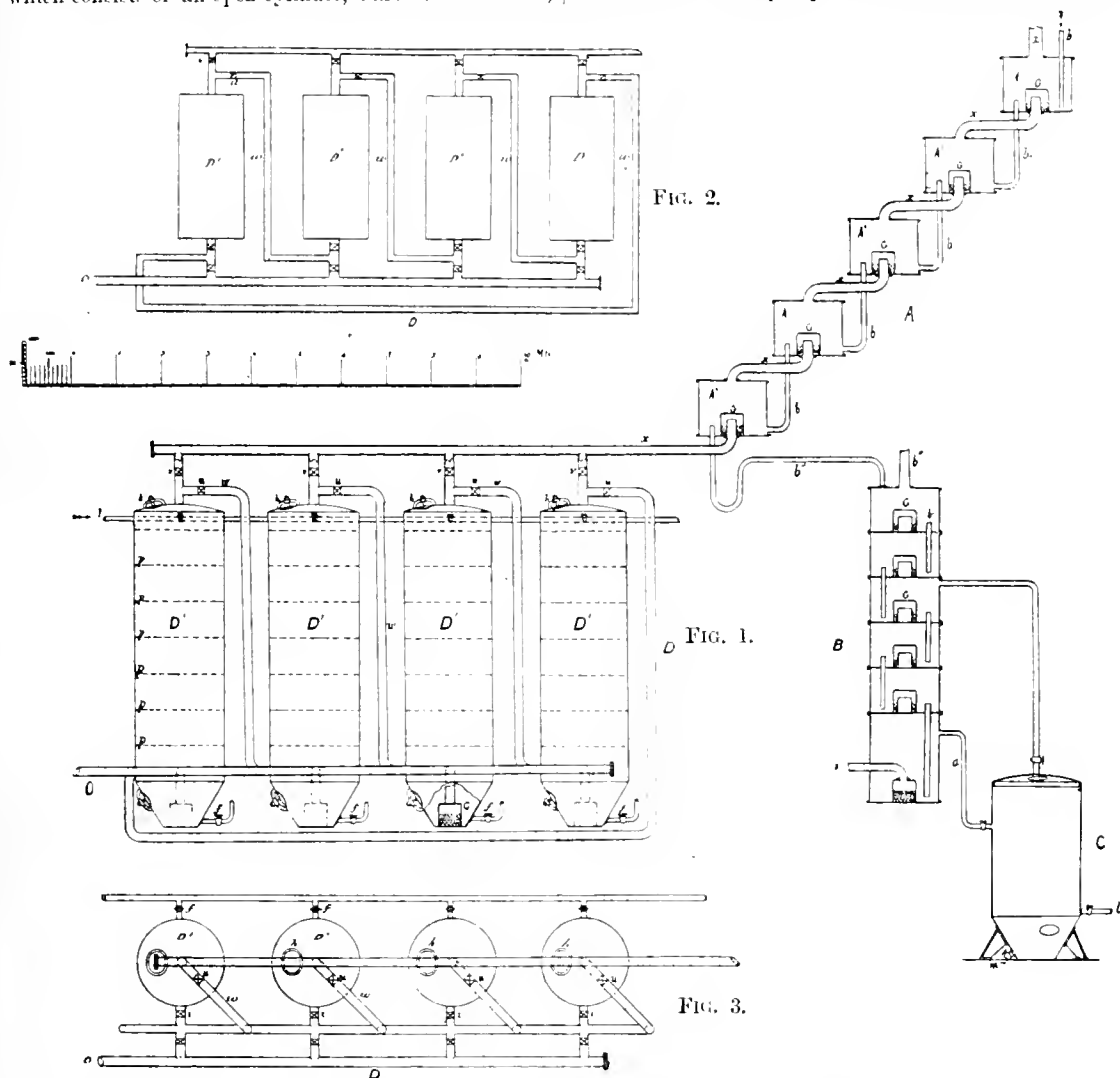

CARBONIC ACID and ammonia or ammonium carbonate is conducted into a solution of a magnesium salt, into magnesia or magnesium carbonate in suspension, and after some time the double salt of ammonium-magnesium carbonate ($MgCO_3 + (NH_4)_2CO_3 + 4H_2O$) separate out. This double salt is mixed with potassium chloride or sulphate and as much water as will dissolve the said salts. This solution, after standing for six hours, is treated with carbonic acid. After some time crystals of magnesium-potassium carbonate are deposited, whilst ammonium chloride or sulphate passes into solution. This double salt is decomposed with water, magnesium carbonate remaining behind, and is used again in the first stage of the process. The operations for the production of ammonium-magnesium carbonate, and the conversion of the same into potassium-magnesium carbonate may be combined by, for example, finally conducting ammonium carbonate and carbonic acid into a solution of carnallite or into a solution of potassium-magnesium sulphate or into magnesia or magnesium carbonate in suspension, potassium chloride being afterwards added and carbonic acid passed through the solution. In this way crystals are obtained which yield, by the decomposition with water, a solution of potassium carbonate and a precipitate of magnesium carbonate.—S. H.

An Improved Method of Manufacturing Soda Crystals and Caustic Soda direct from the Bicarbonate resulting from the Ammonia Soda Process, and Recovery of Ammonia and Carbonic Acid, and Apparatus employed therefor. F. B. Cheesbrough, Liverpool. From J. Hawliczek, Vienna. Eng. Pat. 9425, August 7, 1885. 8d.

THE sodium bicarbonate obtained by the ammonia soda process is mixed with water and heated to boiling point, at which temperature it is retained until its partial decomposition to mono-carbonate takes place, which under the best circumstances reaches 40 per cent. For the complete decomposition an increased pressure of steam is employed, a strong agitation of the soda liquor

being kept up at the same time, which has a marked influence on the entire expulsion of the carbonic acid and ammonia in the liquor. The liquor thus obtained is generally of a greenish colour, arising from tarry matters. By using such oxidising agents as free chlorine or a solution of chlorine in water, the tar pigments are destroyed, and a clear liquor yielding white crystals is obtained. The apparatus for carrying out this process consists of a cylindrical vessel with a conical bottom. A cast-iron bell, the edge of which is serrated, facilitates the even distribution of steam, which is supplied under the bell from a steam pipe. The vessel is provided with a central shaft which runs in a footstep on the top of the steam distributor, the other end of the shaft passing through a stuffing box. This shaft carries the agitator, which consists of an open cylinder, flared at both ends,

cess. The brine enters the apparatus through the pipe *b* (Figs. 1, 2 and 3) of the top compartment of A, which consists of a set of cylinders. It leaves them by another pipe *b'* of a higher level, so that there is always a layer of brine at the bottom of the cylinders, which is used for washing the carbonic acid and other gases not absorbed in the apparatus D, in order to retain the last traces of ammonia. The brine then flows into B, another set of cylinders used for absorbing the ammonia entering by the pipe *S* into the brine. The brine thus ammoniated leaves B through the pipe *a*, and passes into the settling vessel C, where, after settling, the clear liquor is pumped through the pipe *l* into the carbonising cylinders D. These vessels consist of a cylindrical and a conical part. The former contains perforated plates *p* for distributing the carbonic acid pumped into it through *o*, and dis-

on the outside of which is a spiral blade with a right-hand pitch, and on the inside a spiral blade with a left-hand pitch. The carbonic acid, ammonia and steam are led by a pipe to a condensing apparatus, where the ammonia is obtained in solution and the carbonic acid passed on for further use.—S. H.

Improvements in Apparatus for Making Bicarbonate of Sodium. T. Capper, Northwich. From S. Pick, Szcakowa, Austria. Eng. Pat. 7831, June 27, 1885. 11d.

THIS invention relates to improvements in plant for making sodium bicarbonate by the ammonia soda pro-

cess. Salt rests on the highest perforated plate, and the ammoniated brine entering through pipe *l* is compelled to pass through the salt and dissolve it. Whilst one vessel D is filled with salt, the rest is saturated with carbonic acid, which passes from the bottom upwards through the liquor and the perforated plates, and leaves through the pipe *ic* in order to ascend the next vessel in the series, and so forth until, after being deprived of the greatest part of the carbonic acid, it travels into A, to be washed free from ammonia. When the saturation of the ammoniated brine has gone far enough, its liquor, containing ammonium chloride and sodium bicarbonate in suspension, is run out by the tap *g*, and the latter separated

from the former in any convenient manner. The ammonia from the ammonium chloride is regenerated in the apparatus shown in Fig. 4. The liquor is passed into E through the pipe *g*, it drops on a plate *pl*, which rests on another plate *g'*, having a large hole in the centre to allow steam to go upwards and the liquor to pass downwards. The lowest compartment of E contains a cap G, and an overflow pipe *g'*, through which the liquor, freed from volatile ammonia compounds, runs into the highest compartment of the apparatus F. Here it meets with milk of lime which enters at *m l*. The liquor gradually descends the apparatus F, meeting steam and giving off its ammonia, until it is exhausted, when it is run to waste by means of the pipe *s t*. The ammonia leaves at the top at *s*, to pass into the bottom compartment of B (Fig. 1).—S. II.

Improvements in obtaining Chlorides of Barium and Strontium. J. Mactear, London. Eng. Pat. 1915, February 10, 1886. 4d.

BARIUM (or strontium) sulphate and calcium chloride, mixed with charcoal or other suitable carbon, and a little lime or limestone, are strongly heated in a furnace, the waste fire-gases of which are utilised for drying the calcium chloride. The resulting product consists of barium (or strontium) chloride and calcium sulphide or oxysulphide, and by lixiviation yields barium (or strontium) chloride free from sulphides.—S. II.

Improvements in the Manufacture of Hydrates of Strontia and of Baryta. J. Mactear, London. Eng. Pat. 5170, April 14, 1886. 4d.

STRONTIUM (or barium) sulphate is mixed with rather more than the equivalent quantity of sodium sulphate, and also with carbonaceous or other reducing matter. This mixture is heated in a furnace in order to reduce the sulphates to sulphides. The resulting mass is dissolved in hot water and strontium (or barium) hydrate

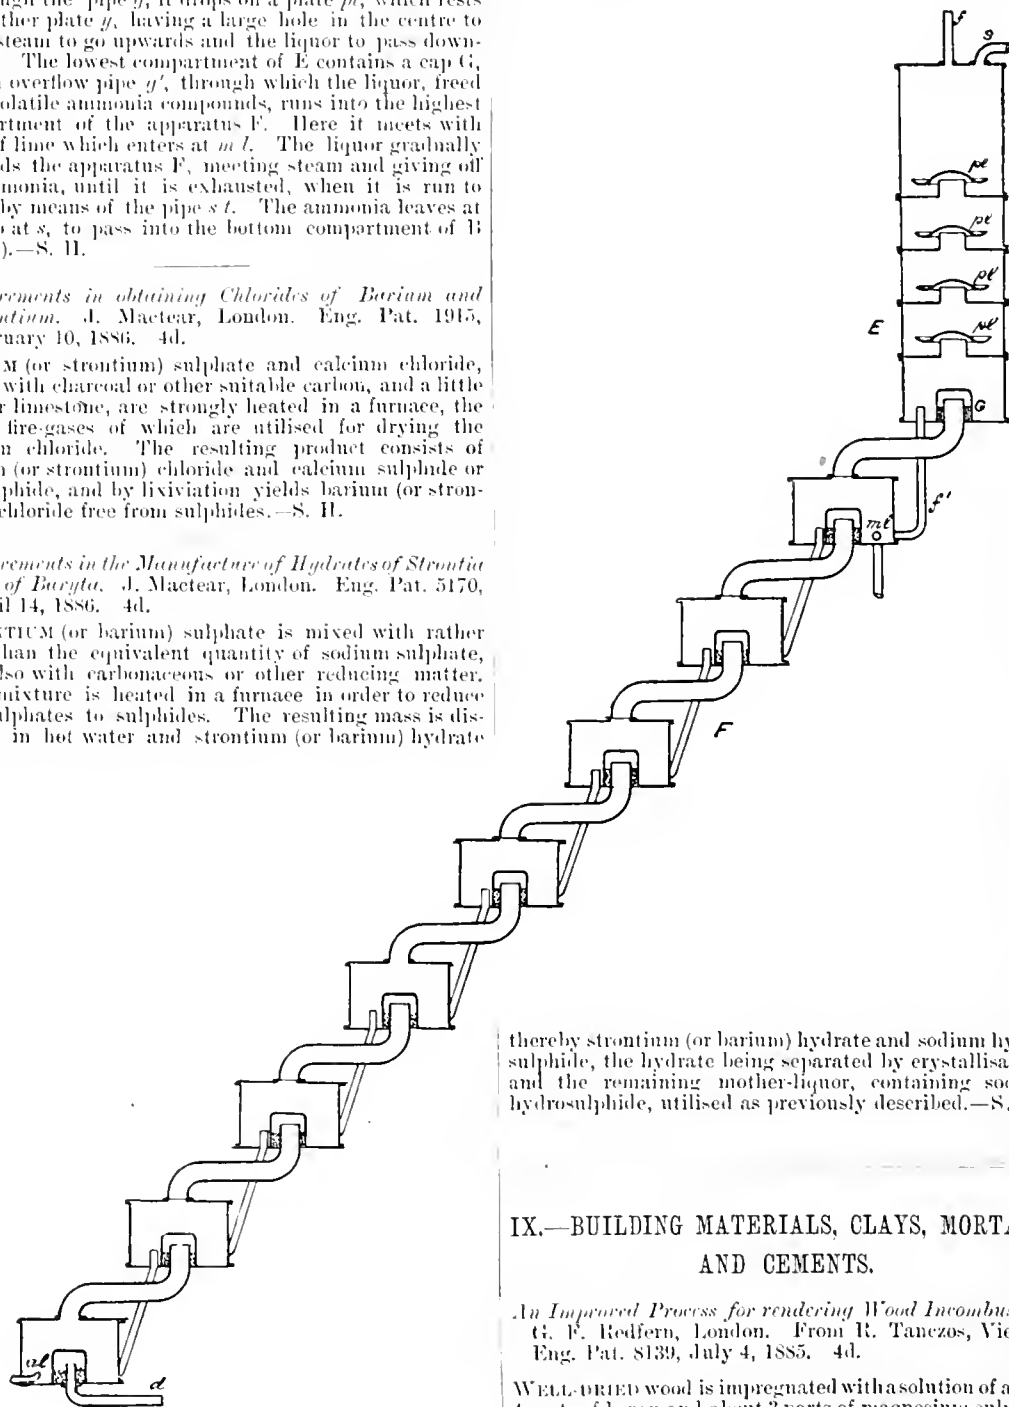

FIG. 4.

crystallised out. By this treatment the sodium salt is converted into sodium hydrosulphide, which remains in the mother-liquor, and after boiling down may be used with carbonaceous matter for reducing another batch of strontium (or barium) sulphate. In the usual process of manufacturing strontium (or barium) hydrate the strontium (or barium) sulphide is split up by solution into

hydrate and hydrosulphide, which latter becomes a by-product. By this process this by-product may be utilised by mixing it with sodium sulphide solution, obtaining

thereby strontium (or barium) hydrate and sodium hydrosulphide, the hydrate being separated by crystallisation, and the remaining mother-liquor, containing sodium hydrosulphide, utilised as previously described.—S. II.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

An Improved Process for rendering Wood Incombustible G. F. Redfern, London. From R. Tanczos, Vienna. Eng. Pat. 8139, July 4, 1885. 4d.

WELL-DRIED wood is impregnated with a solution of about 4 parts of borax and about 3 parts of magnesium sulphate in about 20 parts of hot water. It is then coated with a mixture of washed clay and a sufficient quantity of liquid silicate of soda to enable the mass to be applied by means of a paint brush. After drying the wood is covered with paper or linen previously impregnated with the above solutions. Finally the whole is coated with a mixture of from 30 to 40 parts of ammonium sulphate, and from 35 to 45 parts of gypsum diluted with a sufficient quantity of water.—D. B.

An Improved Process for Preserving Timber. G. Mancion, Rome. Eng. Pat. 5994, May 3, 1886. 4d.

THE wood to be preserved is subjected to the action of low-pressure steam in a closed vessel, in order to swell the wood and create a vacuum for the reception of a solution containing the following ingredients:—156grms. of crystallised arsenic acid, 3600grms. of crystallised carbolic acid, and 100 litres of water. The mixture is rendered alkaline with potash, and introduced into the cylinder, and the wood subjected to its action for about half-an-hour, under a pressure of ten atmospheres. The liquid is then withdrawn, and replaced by the following solution:—10·6kilo. of ferrous sulphate in 1000 litres of water. For one cubic metre of wood, about 50grms. of arsenic acid, 1280grms. of carbolic acid, and 3498grms. of ferrous sulphate are required.—D. B.

X.—METALLURGY, Etc.

An Improved Process and Apparatus for Separating Metals from their Ores, especially Refractory Gold Ores, Mordic, and Sulphurous Ores. Annie Eliza Scott, South Kensington. Eng. Pat. 6674, June 2, 1885. 8d.

THE ore is to be mixed with chloride of lime, and, after standing for some time, to be introduced into a porous vessel placed within an iron or zinc tank, and there covered with brine; brine is also poured into the outer tank. The latter is in metallic connection with carbon plates suspended in the porous cell, and electric action is set up between them; dissolved gold is precipitated by the metal forming the outer vessel. The ore is to be stirred frequently by a freshly amalgamated zinc stirrer. When finished, base metals in the solution may be recovered in the usual way. This is an improvement upon Eng. Pat. 944, 1883.—W. G. M.

Improvements in Apparatus for Lead Burning. P. J. Davies, Kensington. Eng. Pat. 8295, July 8, 1885. 8d.

THIS patent relates to the apparatus employed for generating hydrogen, and to that for supplying the air for its combustion, in the process of autogenous soldering. In principle, the hydrogen generator, which is constructed entirely of lead, resembles Kipp's constant laboratory gas generator, but the details of its construction are modified in various ways. The air supplying arrangement is similar in its action, the pressure of air forced into a lower chamber intermittently by an air pump, being rendered constant by means of a tube from a water tank above, communicating with the bottom of the lower compartment. In each case the volume of gas disposable is indicated by the level of a float in the upper chamber. The air apparatus need not be of lead, since no acid is employed in this case.—W. G. M.

Improvements in the Treatment of Copper Liquors. Nicholas Glendinning, St. Helens, Lancashire. Eng. Pat. 8602, July 16, 1885. 6d.

THE cuprous chloride present in the liquors is converted into the cupric salt by blowing air through the solution in the presence of at least two molecules of free hydrochloric acid to one of the salt; the operation is facilitated by the addition of ferrous chloride (not less than 3FeCl_2 to $2\text{Cu}_2\text{Cl}_2$), otherwise a cuprous precipitate is produced; too much ferrous chloride, however, interferes with the silver precipitation. The liquors may then be desilverised in the usual way with a soluble iodide. If arsenic be present, with much free hydrochloric acid, the excess of the latter should be removed, either by adding alkali or by passing the liquid through a bed of cupric oxide, or of copper precipitate (to increase the quantity of cuprous salt). On passing the air through, the bulk of the arsenic is then precipitated in combination with ferric oxide. The precipitate is allowed to subside, and

the liquid, if necessary, finally cleared by passing through a sand filter, is conveyed to the silver precipitating tank, and afterwards to the copper vats.

—W. G. M.

Improvements in the Manufacture of Steel in Regenerative Open-hearth Furnaces. James Riley, Glasgow. Eng. Pat. 8677, July 18, 1885. 4d.

THE air or the gas (or both) are introduced at increased pressure by connecting the casings of the valves with suitable blowing machinery.—W. G. M.

Soldering Aluminium, and the Preparing of Aluminium for such Soldering. O. M. Thowless, Acocks Green, Warwick. Eng. Pat. 10,237, August 29, 1885. 6d.

A SOLDER, preferably of the following composition, is prepared—tin, 55 parts; zinc, 23 parts; silver, 5 parts; aluminium, 2 parts, by melting the silver with the aluminium, then adding the tin, and lastly the zinc. The bright metallic surfaces to be joined are immersed in dilute caustic alkali or cyanide solution, washed and dried. They are then heated in a spirit lamp, coated with the soldering alloy and clamped together, small pieces of the alloy being placed around the joints. They are now heated to the melting point of the solder, and any excess of the latter is removed by a suitable tool. No flux is used.—W. G. M.

Improvements in the Manufacture of Metallic Alloys. Henry Kesterton, Birmingham. Eng. Pat. 4956, April 9, 1886. 4d.

MANGANESE, first alloyed with some less oxidisable metal, such as aluminium, tungsten, nickel or tin, may be used as a substitute for nickel in German silver or similar white metal alloys.—W. G. M.

An Improved Apparatus for the Washing of Ores and other Minerals. A. R. Gray, Edinburgh. Eng. Pat. 6065, May 4, 1886. 8d.

A RECTANGULAR trough is fitted with a corrugated gun-metal bottom, pierced along the top of each ridge, and the bottom of each furrow, with a number of fine holes, communicating with a water pressure box beneath. At one end the undressed ore is admitted, and at the same end a series of horizontal water jets is so placed that the water may be forced along each furrow of the bottom plate. The overflow for the waste water carrying the lighter particles, and a receiver for the concentrates, are at the other end. The ore, of which the particles should be of uniform size, and which should, therefore, be supplied from classifiers, being admitted at one end of the machine, meets with the fine upward water jets from the bottom plate, which carry the lighter matter into suspension; the heavier granules sink into the furrows, and by the action of the horizontal jets, aided by a slight declivity of the bottom plate, are impelled along these depressions to the lower end of the plate, being throughout their journey subjected to the upward separating motion of the fine jets.—W. G. M.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

Improvements in the Refining or Separation of Glycerine from Fats and Oils. A. G. Brookes. Eng. Pat. 5383, May 1, 1885. 6d.

TO an emulsion of the fat in sufficient water, 0·1 per cent. of carbonate of tin, or carbonate of zinc, are added, and the whole is heated in an autoclave, under a pressure not exceeding 125lb. per square inch. Various metallic oxides, with or without an alkali, or a metallic carbonate with an alkali, may be used. It is claimed that the time and steam pressure are both reduced, and that discolouration of soap stock is entirely avoided.

—W. L. C.

Improvements in the Purification of Glycerine. O. C. Hagemann. Eng. Pat. 7972, July 1, 1885. 8d.

A SERIES of spiral coils, in an air case, whose temperature can be regulated, are interposed between a glycerine still and the ordinary condenser. When about 10 per cent. of the total condensed product is caught in this intermediate apparatus, most of the impurities are caught there also. A drawing is given.—W. L. C.

Improvements in the Manufacture of Oxidised or Solidified Oil, and in the Application of the same to Wires and Strands. F. Walton. Eng. Pat. 8250, July 7, 1885. 8d.

CHAMBERS containing sheets of metal, usually iron, are filled with boiled oil. The oil is soon drained off, leaving a film on the plates, and hot air is then forced by a blowing apparatus through the chambers; the oxidised oil so produced is melted off the plates by being pressed against a moving endless brass band, heated to 400° or 600° F. In covering telegraphic and other wires or strands with such material, the wire, after being coated, is received on a large drum, on which a spiral groove is cut, and the whole is kept warm until the hardening process is completed. A drawing is given.—W. L. C.

Improvements in Purifying and Concentrating Glycerine, applicable also to the Concentration of other Matters. C. O. Hagemann. Eng. Pat. 7973, July 1, 1885. 8d.

THE apparatus employed much resembles that now in use for condensing alcohol, and consists essentially of a series of transverse trays, with perforated shelves arranged in a vertical column; in consequence of suitable progressive cooling (controlled by thermometers) liquids of different degrees of concentration and purity collect, and can be drawn off, whilst steam or water escapes. A drawing is given.—W. L. C.

Improvements in the Treatment of Soap Lyes to obtain Products therefrom. O. C. Hagemann. Eng. Pat. 8051, July 2, 1885. 6d.

THE soap lyes are causticised by lime, and the caustic alkali saponified by an excess of rosin. Perchloride of iron is then added, if necessary, and after the resulting precipitate is removed, hydrochloric acid is added, and air blown through the heated lyes to remove the sulphur compounds. The lyes are then concentrated, and the glycerine is distilled off.—W. L. C.

Improvements in Apparatus for treating Fatty Matters in order to obtain Fatty Acids and Glycerine therefrom. A. Michel. Eng. Pat. 8403, July 11, 1885. 8d.

TWO boilers or autoclaves are employed, in which a mixture of fatty matter and water is maintained for about eight hours, at a pressure of 16 atmospheres. The glycerine, water and fatty acids are separated by simple subsidence, and the latter are then distilled with superheated steam, the condensing coil of the still being provided with a pump for drawing off the vapours. Drawings are given.—W. L. C.

Improvements in Extracting Fat and other Substances from Dissoluble Materials, and in Apparatus therefor. M. Bauer. Eng. Pat. 9352, August 5, 1885. 8d.

THE apparatus consists of a jacketed receiver to contain the substance to be acted on by the solvent, the contents of which are heated by the volatilisation of the solvent, of a chamber whence the solvent is volatilised, and of an automatic syphon and condenser. The jacketed vessel may also contain animal charcoal for bleaching purposes. Drawings are given.—W. C. L.

Improvements in Making Soaps. J. Townsend. Eng. Pat. 3987, March 22, 1886. 4d.

FATTY matters are saponified, without separation of glycerine, by a slight excess of caustic alkali, and when saponification is complete, this excess is exactly neutralised with boracic acid.—W. L. C.

XII.—PAINTS, VARNISHES, AND RESINS.

Indiarubber. T. Christy. New Commercial Plants and Drugs, 9, 17—19.

THE author remarks that in W. Thomson's paper, "Indiarubber and its Decay" (this Journal, 1885, 710), only one quality of rubber appears to be mentioned—viz., that of Para. This is due, he states, to the fact that there are no reliable data showing the difference between South American, African and East Indian rubber gums. The method of treatment described in Mr. Thomson's paper for coagulating the rubber milk in the Para district, equally applies to the milk of the *Hevea Brasiliensis* and the *Mangabeira*. The method now in use is as follows:—Small cups are attached to the trees, and when filled with juice, are emptied into tin pails of a certain size, having close-fitting lids, the cups being again attached to the trees. After going the round of the trees, the contents of this pail are emptied into another a size larger, and so on till the covered pail of largest size is filled and ready to be strapped on to the saddle of a mule for removal. By this plan the natives are saved the trouble of condensing and preparing the milk for market, by smoking. The large can of rubber milk on arriving at the *magasin* is emptied into a bath of water, the temperature best suited to the rubber being a matter of experience. The lumps of rubber that form in the bath are immediately pressed into thin flat sheets, and carefully wiped. By this means the acid is forced out of the cells or pores in the lump, thus preventing the so-called "rotten" appearance. The author is of opinion that the African rubbers yielded by the Landolphias, prepared in this manner, will produce a stronger rubber. The African rubbers now sent here do not yield, when strained and cleaned, more than 30 per cent. to 55 per cent. of pure rubber gum, owing to the natives adulterating with sawdust, bark dust, etc., to overcome the inconvenience of the stickiness of the juice. The amount of resin in milks varies largely.—O. H.

The Utilisation of the By-products or Waste of Lead Ores for the Manufacture of Pigments therefrom. P. C. Bunn, London. Eng. Pat. 8008, July 1, 1885. 4d.

THE claim includes the use, for the manufacture of colours, of the waste from washing ores of lead, known as "waste slimes and blendes." This waste is to be ground with vehicles, such as boiled linseed oil, for body colours, and mixed with other colours if required.—H. A. R.

Improvements in the Manufacture of Resinous Compounds. J. B. Melvin, U.S.A. Eng. Pat. 5270, April 15, 1886. 4d.

THE main feature of this invention is the manufacture of resinous compounds by treating rosin or other resinous substances with oxide of zinc or other metallic oxides.—H. A. R.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

A New or Improved Size for Sizing Raw Silk. Jean François Giraud, Lyons. Eng. Pat. 8402, July 11, 1885.

THE following is the composition of the size for one litre:—Japanese vegetable gelatine, alumi, spermaceti, and glycerine, of each 20grms. These substances are dissolved together in water, and the sizing effected in the ordinary way.—B. H.

Improved Substitutes for Leather, applicable for Driving Belts, Boot and Shoe Soles, Covering Machine Rollers, and other uses. M. Zingler, Belsize Park, Middlesex. Eng. Pat. 8963, July 24, 1885. 6d.

THE inventor takes canvas or similar woven fabric and boils it under pressure, in a solution of tungstate of soda, for three hours. The fabric is then boiled in a solution of acetate of lead, and afterwards drained, dried and stretched. The fabric is coated with composition, by means of a spreading machine, ten, twelve or more coats being applied. The composition is varied according to the purpose to which the article is to be applied. The ingredients are—indiarubber, sulphide of antimony, peroxide of iron, sulphur, lime, asbestos, chalk, sulphate of zinc, and carbonate of magnesia. For the proportions the Blue Book must be consulted. The coated fabric is vulcanised, under pressure, at a temperature of 250° F., or more.—B. H.

Improvements in Tanning Hides. Percy Haddan, London. From the Dobson Patent Tanning Process Co., of Lincoln, Nebraska, U.S.A. Eng. Pat. 5476, April 20, 1886. 6d.

THE hides or skins, after unhairing and washing in the usual way, are immersed in a bath of common salt solution in strength 9–11° salinometer for 24–36 hours. They are then exposed in a suitable chamber, to the fumes of burning sulphur, 8–10lb. sulphur being sufficient for 160 heavysides. The hides are then tanned or coloured, in a liquor containing gambier, common salt and alum. The hides are skived and split, the grain portion put in gambier liquor, fumigated again, washed, and “stuffed” with grease or oil. The flesh portion is put in hemlock liquor for 12–24 hours, dried, and is then ready for sale or use.—B. H.

An Improved Method of Tawing Hides and Skins. Nils Alexander Alexanderson and Leonard Hvass, of Stockholm, Sweden. Eng. Pat. 5491, April 20, 1886. 4d.

THE patentees claim the tawing of hides or skins, prepared in the ordinary way, with strongly basic solutions of salts of alumina, oxide of chromium, or oxide of iron, and subsequent solution of the soluble salts in water. The basic solution is prepared by adding a dilute alkaline solution to the solution of alumina or sesquioxide salt. (Eng. Pat. 15,607, 1884; this Journal, 1885, 747.) —B. H.

XIV.—AGRICULTURE, MANURES, Etc.

Use of Ferrous Sulphate in Agriculture. A. B. Griffiths. Chem. Soc. Journ. 1886; Trans. 114–120.

THE author's experiments were continued in 1885. A plot of wheat (size not stated) without ferrous sulphate yielded 30 bushels of grain per acre; a similar plot with $\frac{1}{2}$ cwt. green vitriol per acre yielded 32 $\frac{1}{2}$ bushels. Hence no certain conclusion can be drawn. The proportion of ferric oxide in the ash of the grain and leaves was, however, undoubtedly increased by the use of ferrous sulphate. In another instance the crop of wheat grown with ferrous sulphate was *entirely free from mildew*, and the ash of the plant showed an increase over the normal proportions of ferric oxide and phosphoric acid. Applied to grass land, ferrous sulphate caused an increase of greenness in the grass, and destroyed the moss. The ash of the mosses before treatment contained 6.62 per cent. of ferric oxide, and after treatment 11.56 per cent.; so that they appear to have absorbed a poisonous dose of the iron salt. The ash of the grasses contained only 0.45 per cent. Fe_2O_3 before treatment, and 2.46 per cent. after treatment. A solution of ferrous sulphate of 0.1 per cent. strength is fatal to the potato blight (*Peronospora infestans*) and the wheat mildew. Striking results were obtained with potatoes. An unmanured plot yielded 3 tons per acre; a plot dressed with 1 cwt. kainite, 1 cwt. nitrate of soda, and 2 cwt. superphosphate, gave 6 $\frac{1}{2}$ tons; whilst a plot receiving $\frac{1}{2}$ cwt. per acre ferrous sulphate,

in addition to the other manures, yielded 8 $\frac{1}{2}$ tons. The ash of the tubers grown on the three plots contained respectively 5.15, 5.42, and 7.00 per cent. of ferric oxide, and 15.63, 16.24, and 17.94 per cent. of P_2O_5 ; the ash of the haulm gave similar results. It appears from experiments that when a solution of ammonium sulphate is allowed to percolate through a layer of soil containing ferrous sulphate, much more ammonium is retained by the soil than is the case when the same soil *minus* the ferrous sulphate is used. Ferrous sulphate appears to be a good manure for rose bushes. It is best applied to crops as a top-dressing to the young plants, at the rate of $\frac{1}{2}$ cwt. per acre. It can be detected in the soil after the lapse of six weeks.—J. M. H. M.

Improvements in Fertilising Compounds and in the Process of Manufacturing the same. H. J. Allison, London. From W. S. Pierce, New York. Eng. Pat. 5686, April 27, 1886. 6d.

THE object of the patentee is the preparation of “superphosphate,” “acid” or “monobasic” phosphate, or “reverted” or “bibasic” phosphate, from phosphates of aluminium or iron, such as Redonda or Grand Connetable phosphates. A difficulty experienced in the manipulation of these phosphates by processes hitherto devised is owing to the production of a wet sticky mass, which even after drying again deliquesces and becomes wet. The present invention proceeds as follows:—The dried phosphorite is mixed with sodium chloride, ammonium sulphate, and water, and then treated with sulphuric acid (chamber acid). Potassium chloride may be substituted for the sodium salt, and in other cases sodium sulphate may replace the chloride. The oxides, nitrates, sulphates, and carbonates of potassium or sodium may be used. The mixture is dried at 60° C. and pulverised.—C. C. H.

Preparing Basic Cinder for Use as Manure. J. M. H. Munro, Downton, Salisbury. Eng. Pat. 7740, June 25, 1886.

THE finely-ground basic cinder or slag from the Thomas-Gilchrist process of steel making is treated with sulphuric acid of sp. gr. 1.485 or thereabouts, in the proportion of about 2 parts of acid to 1 of cinder. When the proportions are properly adapted, a fine, light, dry and friable product is obtained, containing much gypsum and soluble phosphates of lime and iron, together with crystallised ferrous sulphate. This may be used directly as a manure in about the same quantities as ordinary superphosphate, but it is found that the proportion of ferrous sulphate is in some cases too great to be of any advantage to crops. To prepare a similar manure, containing a more beneficial proportion of ferrous sulphate, the cinder is mixed with once or twice its weight of mineral phosphate of lime before being dissolved; or by the use of lime, basic cinder, or similar precipitating material, a portion of the ferrous compounds in the fine dissolved cinder is rendered insoluble.—J. M. H. M.

XV.—SUGAR, GUMS, STARCHES, Etc.

Levulose. A. Herzfeld and H. Winter. Ber. 19, 390–394.

THE authors claim priority for the discovery of *trioxybutyric acid* among the oxidation products of levulose with bromine, a fact which Böning has recently announced (Ber. 19, 171). This acid rotates the plane of polarised light to the right; but the $[\alpha]_D$ has not yet been determined. On passing a stream of hydrochloric acid gas through the calcium salt of the acid suspended in absolute alcohol, a double compound, $[\text{C}_4\text{H}_4(\text{OH})_3\text{CO}_2\text{C}_2\text{H}_5]_2 + \text{CaCl}_2$, is thrown down as a white precipitate. The authors employed a levulose dried by being mixed with powdered glass and placed over phosphoric anhydride in a vacuum at 60°, and which gave on analysis numbers agreeing with the formula $\text{C}_6\text{H}_{12}\text{O}_6$. They found as the mean of two determinations $[\alpha]_D = -c^2$

71.4° ($p = 20.1$). A 7.78 per cent. solution of levulose in absolute alcohol gave $[\alpha]_D = -4.8^\circ$ only. Levulose was also prepared from invert sugar by means of absolute alcohol. By repeated solution in this liquid and fractional precipitation this was obtained as free as possible from dextrose; but the values for $[\alpha]_D$ obtained varied from $-4.5.13$ to -40.18° . The authors conclude from this either that it is not possible to separate dextrose from levulose by treatment with absolute alcohol, or that invert sugar contains another carbohydrate, with a lower left-handed rotation; the latter is the more probable, since the crystalline mass showed no bi-rotation when freshly dissolved, as it would have done had dextrose been present. Peligot's calcium salt, $C_6H_{12}O_6 \cdot CaO \cdot H_2O$, was prepared both from uncrystallised and crystallised levulose; this salt suspended in absolute alcohol, and hydrochloric acid gas passed through, dissolved, and after a time a white precipitate containing 48.47 per cent. calcium chloride, separated out; it is probably an ether of levulose. Bismuth nitrate affords a means of distinguishing between dextrose and levulose. When this salt is added in the dry state to a dextrose syrup, it is decomposed with formation of basic nitrate, but on addition to a levulose syrup it is dissolved, and a compound may be precipitated out by alcohol, which explodes on warming. —G. H. M.

XVI.—BREWING, WINES, SPIRITS, Etc.

An Improved Process of Purifying Yeast. J. J. W. Peters, Hamburg, Germany. Eng. Pat. 8908, July 23, 1885. 4d.

A PROCESS for purifying yeast from insects, animalcules and other impurities by treatment with either dilute alkali, acid, or water alone, and afterwards with a liquid of less gravity than water—alcohol, for instance—in order to separate the pure yeast from mucilage and secondary ferments. —G. H. M.

Maturing of Spirits in Bottles or other Non-absorbent Vessels. W. W. Crawford, Glasgow. Eng. Pat. 9869, August 20, 1885. 4d.

THE object of this invention is the maturing of spirits in bottle by the use of wood—either immersed in the fluid or else in the form of a bottle-stopper. —H. A. R.

An Improved Method of and Apparatus for the Treatment of Beer Returns and other like Alcoholic Liquids. F. Faulkner and G. R. Wilson. Eng. Pat. 1461, February 1, 1886. 8d.

THIS consists of an apparatus in which beer returns and waste fermented liquids generally may be sterilised, after being made bright by artificial fining or filtration, by being heated to 180° , and maintained at that temperature for 10 minutes. In the case of beer returns, all acidity over and above the one-tenth normal to mild beers should, after sterilisation, be neutralised by the addition of a standard solution of pure potassium carbonate. The accompanying illustration shows a vertical section of the apparatus employed:—*a* is a copper vessel; *b* a jacket, in which the bottom of the vessel *a* is enclosed; *c* are supplying columns; *d* is a pipe by which the vessel *a* is filled; *e* is a draw-off pipe; *f* is a pipe supplying steam to the jacket; *g* is a surface condenser occupying the upper part of the vessel *a*—it consists of a nest of parallel tubes between two tube plates *hh*. Cold water is admitted to the space around the tubes and between the tube plates by the pipe *i*, and it passes away by the pipe *j*. The vapour rising from the liquor in the vessel *a* is condensed in the tubes of the surface condenser, and falls back. Air is able to escape by a safety-valve *k* opening outwards, and another safety-valve *l* opening

inwards prevents all risk of collapse. *m* is a man-hole cover; *n* is a coil of pipes through which cold water can

be circulated to rapidly cool the liquid at the end of the operation. —G. H. M.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

A New Process or Method for Preserving all kinds of Vegetable Products. C. H. Sharman, Forest Hill. Eng. Pat. 9053, July 28, 1885. 4d.

THE patentee claims the following method and compound for coating fruit or vegetables so that they may be preserved in their original condition. The fruit or vegetable is dipped into a melted mixture of wax 8 parts, resin or gelatine one part, and sulphur one part. A hard coating is formed on the exterior of the article, and decay and shrinking are prevented. —C. C. H.

(C) DISINFECTANTS.

The Influence of Thalline Salts upon Putrefaction and Fermentation. H. Schnitz. Centralb. Med. Wissensch. 1886, 113.

FROM the special manner in which thalline preparations influence the organism in cases of fever, it might be sup-

posed that they would act similarly in the matter of putrefaction and fermentation. The experiments on the fermentation of animal tissue demonstrated the correctness of this supposition. 0.5 per cent. of thalline sulphate in sterilised gelatine prevent further putrefaction of meat. The yeast fermentation was considerably retarded by the addition of 1 per cent. of thalline tartrate; with a less quantity, however, the activity of the ferment was increased.—J. B. C.

An Improved Disinfectant. W. R. Lake, London. From M. R. Garcia, Paris. Eng. Pat. 9353, August 5, 1885. 6d.

A LIQUID composed of water 5 parts, permanganate of potassium 2 parts, citric acid 1 part, oxalic acid 1 part, and sulphuric acid 1 part, is poured upon a powder composed as follows:—Calcined marble 5 parts, suboxide of manganese 1 part, sulphate of alumina and potassium 0.5 part, permanganate of potassium 1 part, manganate of potassium 0.5 part, and citric acid 1 part.—C. C. H.

Improvements in Disinfectants. A. Boake and F. G. Adair-Roberts, Stratford. Eng. Pat. 12,238, October 14, 1885. 4d.

THE patentees claim "the use of sulphurous acid as a disinfectant, by releasing the same from a closed vessel wherein it has been stored in the liquid state."

—C. C. H.

Improvements in Disinfecting Compounds. H. H. Lake, London. From F. L. Sarmiento, W. G. Grimm, S. P. Sadtler, J. A. Wiedersheim, Philadelphia, and F. J. Sarmiento, Detroit. Eng. Pat. 5151, April 13, 1886. 6d.

DRY bleaching powder is mixed either with coal-tar, "light oil," or "dead oil," or else with a dry carbolate, such as carbolate of lime. The specification points out the difference in action between the mixtures so made and those described by other patents, each of which they specify—viz., that a reaction occurs which results in the formation of "chlorine, carbolic acid vapours, and other gases of great disinfecting value."—C. C. H.

XIX.—PAPER, PASTEBOARD, Etc.

Process for Preparing Fodder from certain Waste-products obtained in the Manufacture of Cellulose or Paper-pulp. H. J. Haldan, London. From C. H. Voigt, Saxony. Eng. Pat. 7495, June 19, 1885. 6d.

THE inventor claims to be able to obtain from the alkaline boiling lye the 40 per cent. of carbo-hydrates, protein substances, etc., contained in straw, by neutralising with dilute sulphuric acid and separating the precipitated matter by the use of the filter-press. It is stated that the product has an agreeable smell and taste, and is readily eaten by cattle. Glauber's salt may be prepared from the mother-liquor by crystallisation after evaporation.—H. A. R.

Improvements in Process for Making Paper Stock. J. D. Tompkins, U.S.A. Eng. Pat. 3472, March 11, 1886. 8d.

THE following are the claims in this specification:—

1. In the manufacture of paper stock, or pulp, the process of treating wood, straw, grasses, or other vegetable substances by the action of pure water, at about boiling temperature, circulated through the mass of material, within a digesting chamber, in alternating reversed directions.

2. In the manufacture of paper stock or pulp from vegetable substances, or materials, the process of separating the dissolved portions from the undissolved portions of the said material, above described, the same consisting of circulating the cooking water, or other liquors with which the material has been treated, in an

upward direction through the mass, or in a direction which will be away from the discharge opening of the digesting chamber, substantially as described.

3. In the manufacture of paper stock or pulp from vegetable substances, or materials, the process of subjecting the material to the action of alkaline, or equivalent disintegrating and dissolving liquor, at high temperature and under pressure, with said liquor circulated through the mass of material in alternating reversed directions.

4. In the manufacture of paper stock, or pulp, from vegetable substances or materials, the process of cleansing the material from all the dissolved substances, or chemicals, or both, left with it from its prior treatment, the same consisting of circulating pure water in alternating reversed directions through the mass of material within the chamber.

5. In the manufacture of paper stock, pulp, or fibre, the process of bleaching the same, consisting in treating the stock, pulp, or fibre, to the action of a bleaching liquor, circulated through the mass in alternating reversed directions, substantially as described.

6. The process of reducing vegetable substances, or materials, consisting in first boiling the same in pure water, at about boiling temperature, which is circulated in alternating reversed directions through the material until the water soluble portions are dissolved, then treating the material to pure water which is circulated alternately in reversed direction for removal of the dissolved substances, and then subjecting the resulting product of the boiling with water to the action of an alkaline, or other known equivalent dissolving or disintegrating liquor, at high temperature and under pressure, and circulated in alternating reversed directions through the treated mass.

7. In the manufacture of paper pulp or stock, the continuous process for treating wood, straw, grasses, or other vegetable substances, or materials, above described, the same consisting in the several progressive steps of treatment of the material by water, alkaline, or equivalent liquor, and bleaching liquor, which are respectively circulated with alternating reversed directions, through the body of the treated material, in the order and under the respective conditions substantially as above set forth.

—W. S.

Improvements in the Construction of Boilers for Treating Wood and other Fibre in the Manufacture of Paper and other Pulp. C. C. Springer, U.S.A. Eng. Pat. 8073, July 3. 8d.

THE new feature in this invention is the use of elastic bands of asbestos or indiarubber in making joints in the combined metal linings of bisulphite wood boilers. The compound lining (lead and iron) is similar to that patented by John Makin, October 24, 1881, 14,071. By this method of making joints the use of the blow-pipe is obviated, and any expansion of the lead only causes the joint to become tighter. Also sections can be conveniently removed from the boiler and replaced if required.—H. A. R.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Downake (Sarcoccephalus esculentus Afzelius). T. Christy. New Commercial Plants and Drugs, 9, 7—9.

AN addendum to a previous paper by Messrs. Heckel and Schlagdenhauffen (this Journal 1885, 570). The alcoholic extract was found to contain, as well as a small proportion of glucose and trace of tannin, three distinct principles of a resinous nature, the first of which being of an orange-yellow colour, very bitter and soluble in water, alcohol, and potash; the second light yellow in colour, soluble in potash but not in water, the third soluble in potash and insoluble in water and alcohol. Treatment with water gave a mixture of starchy and albuminous substances, and the parts soluble in water were found to be, including 2.123 of salts, 44.55. A

rather large proportion of oxide of iron was found. The results were as follows:—

Parts soluble in petroleum ether, wax, fatty bodies	1.200
" " chloroform, wax, fatty bodies and	
" " colouring matters	1.040
" " alcohol, traces of tannin, glucose,	
" " resinous colouring matters	6.950
Fixed salts	23.112
Wood	62.128
Fixed salts	5.570
	100.00

Messrs. Heckel and Schlagdenhauffen say, that so far as doundakine is concerned it is a substance which is not obtainable as a crystalline alkaloid, but that this name may be given to the colouring matter which contains the active principle. The bitterness of this bark, whether that from Boké or that from Sierra Leone, is due to the nitrogenous and resinoid colouring matters diversely soluble in water and alcohol.—O. H.

Essential Oil Plants. T. Christy. New Commercial Plants and Drugs, 9, 11—14.

UNTIL now but little attention has been given to the cultivation of plants yielding fragrant essential oils, partly for the want of information respecting the extraction of the oils, and partly for want of a suitable apparatus for distilling them, such as could be easily and economically worked on the small scale. Flowers can be treated in various ways. The "fat" process consists of placing the flowers and allowing them to remain for a certain length of time upon layers of clarified fat (beef suet), which absorbs the fragrance, the process being

repeated until the fat is thoroughly impregnated with the perfume. This process, which is by no means exhaustive, is suitable for flowers which, like the violet, do not readily yield their perfume when distilled with water. The perfume is obtained by distilling the impregnated fat. Many flowers can be distilled with water, the perfume coming over and condensing with the steam, from which it can be afterwards separated by an oil separator, or the oil may be allowed to pass off, the water being used in the still again.

Various modes of distilling the essences are required, according to the nature of the product to be operated upon. When the material is dry, and its structure is very close like sandal wood, it should be pounded, scraped, broken up, rasped, or, if possible, pulverised and macerated in water. In the distillation of balsams, the addition of a small quantity of salt is requisite if the boiling point of the oil be higher than that of water.

To preserve the essential oils the author recommends the addition of an equal volume of alcohol to the oil, the

mixture being kept in well-stoppered bottles in the dark.

The extraction of the essences of bergamot, citron, orange, etc., can be best accomplished by pressure, since in these particular instances the oils are more fragrant.

The most simple and reliable apparatus for the distillation is shown in the annexed figure.

It is capable of holding 12 litres, and can be heated by any kind of fuel or it can be worked over any ordinary fire or stove.

The distillation of oils and essences is fully treated in Valyn's "Traité détaillé et pratique de Distillation à l'Usage des Familles."

The Ecuelle process consists in rubbing the fruit over a surface of sharp points lining a saucer-shaped vessel, with a hole in its centre leading to a receptacle placed below; the oil glands being pricked by the points, the essential oil runs down and collects in the vessel below.

—O. H.

Eucalyptus Staigeriana F. V. M. T. Christy. New Commercial Plants and Drugs, 9, 14—15.

THIS tree, which is also known as the lemon-scented iron bark, is a native of Queensland, where it was first discovered by Mr. P. F. Selheim. Its leaves possess an odour exactly like that of the lemon-scented verbenia, and the oil they yield is identical in fragrance with that of the so-called verbenia of commerce, which is not derived from the verbenia, but from a grass (*Andropogon citratus* D. C.). The dried leaves yielded 2½ per cent. of volatile oil of sp. gr. 0.901. The odour of the oil of this tree is quite different from that of *Eucalyptus citrodora*, which might be substituted for *citronelle* oil, which it resembles, in the perfuming of soap.—O. H.

Essential Oil of Lime Leaves (Citrus Limetta). Francis Watts. Chem. Soc. Journ. (Trans.), 1886, 316—317.

THIS oil, prepared by distilling the leaves and young shoots of the lime tree in a current of steam, is moderately soluble in rectified spirit, and has a sp. gr. of 0.8777 at 33°. When submitted to fractional distillation, it yields, first a hydrocarbon (170—220°), then a fraction (229—230°) yielding a crystalline mass with sodium bisulphite, but without action on silver nitrate—hence, probably, a ketone. About one-third of the oil boils above 280°, and is viscid, with a green fluorescence. After digesting the lowest fractions with sodium, a hydrocarbon, boiling at 176—177°, was obtained, inactive to polarised light, and with refractive index of 1.4611 at 30° for red light. It resembles the citrenes, forming a hydrochloride with HCl, and giving Ribau's colour reaction with ferric chloride. Terpinol also is probably present in the lower fraction. The ketone above mentioned yields acetic and pelargonic acids by oxidation with chromic acid; hence it is methylmethylketone $\text{CH}_3\text{CO.C}_9\text{H}_{19}$.—J. M. H. M.

XXI.—EXPLOSIVES, MATCHES, Etc.

The Stability of certain Explosives on Heating. O. Hagen. Rep. Anal. Chem. 6, 1.

THE following test is used:—A copper vessel, 20cm. high and 20cm. diameter, is provided with a copper cover, in which 15 to 20 round holes are bored about 20mm. wide. Through one of these a thermometer is inserted, which dips into the water contained in the vessel to a depth of 10cm., the water-level being about 2cm. below the lid. The remaining holes are provided with three thin strips of copper, through which the samples, contained in test-tubes 16mm. wide and 14—15cm. high, are sunk. Chemically pure nitroglycerine does not change in ½—1 hour at 70—75°, although this is not so in the presence of acid. Sulphuric acid splits off one equivalent of nitric acid with the formation of glycerine-sulphuric acid. The latter, on decomposing into glycerine and sulphuric acid, sets free a further quantity of nitric acid from the nitroglycerine, and this is reduced to lower oxides of nitrogen, especially nitrous oxide. Upon this fact the test is based,

potassium iodide and starch-paper being used. The author uses Swedish filter-paper soaked in a solution of 3grms. starch in 276cc. water and 1grm. KI in 276cc. water. For dynamite, Majendie uses 2.7grms. starch (which has been washed with cold water) in 250cc. water, and 0.9grm. KI (crystallised from alcohol) in 250cc. water. Strips of washed filter-paper are soaked in the mixed solutions for not less than ten seconds. These, cut into strips of 10mm. wide and 30mm. long, are kept in dark stoppered bottles, and before use the upper third portion is painted over with a 40 per cent. glycerine solution, 24° B. By means of a cork and platinum wire, to which the strip is fastened, the strip is suspended in a test-tube. The temperature of the water and the duration of heating when the strip becomes tinted is observed. Dynamite nitroglycerine should indicate no change after fifteen minutes at 71°; gun-cotton for the Prussian sappers must stand a temperature of 180° for twenty-five minutes. In the case of compressed gun-cotton, 1grm. is taken and gently pressed with a wooden pestle into the tube; of explosive gelatine and nitroglycerine 3grms. are taken. The water-bath is kept at a constant tem-

perature, an infusion of the matter is prepared, to which some tartaric acid is added. A bank of wool is then dyed in the solution, which is kept on the boil during that time. The wool thus dyed is washed in very dilute sulphuric acid, and the acid afterwards neutralised with ammonia. If the saffron contained any dinitronaphthol at all, the wool or the solution will be coloured yellow, whereas wool dyed with a decoction of genuine saffron and treated in the same manner becomes colourless.

—S. H.

Remarks on the Applicability of Orange 3 and Methylorange as Alkalimetric Indicators. R. Engel. *Bull. Soc. Chim.* 1886, 45, 424.

THE author examined Witt's tropæoline OO (sodium salt of diphenylamidoazobenzene-sulphonic acid), sometimes also called orange 3, and methylorange (sodium salt of dimethylamidoazobenzene-sulphonic acid), as to their applicability as indicators. The latter was found more suitable, the change of colour being far more distinct. To quickly distinguish between tropæoline OO and methylorange, their reaction with gold chloride is made use of, the former turning violet and afterwards green on addition of gold chloride, whereas methylorange becomes red under the same circumstances. The presence of iron salts interferes with the colour reaction of methylorange, the change of colour being less distinct. If a potash solution be treated with a ferri-compound, the light yellow colour of methylorange turns orange at first and afterwards pink. Sulphuric acid can be very accurately determined with methylorange, even in the presence of sulphuretted hydrogen. This reaction is applied in estimating sulphuric acid in copper sulphate. After precipitating the copper with sulphuretted hydrogen, the liquid is filtered and the sulphuric acid titrated in the filtrate. This method is of general application with metals precipitated by sulphuretted hydrogen.

—S. H.

perature, and the test-tube is sunk in to a level with the bulb of the thermometer. A faint brown line between the dry and the moist portion of the test-paper indicates the end of the reaction. In the case of dynamite, the oil must be separated from the siliceous matter and tested separately. The English Government demands that 24grms. finely-powdered dynamite should be firmly pressed on a loose plug of cotton-wool into the funnel-tube B. On pouring on to this a few cc. of water, the nitroglycerine is expelled, and filters through. This may be accelerated by a vacuum pump in connection with C. The test-tube D must be removed before the layer of water comes through the funnel. The author finds that dynamite often indicates no nitrous oxide when the oil expressed from it gives the reaction distinctly. Temperature of explosion was tested by the author in a paraffin-bath, each result being the mean of ten determinations. Trinitroglycerine, 183.7°; explosive gelatine, 183.9°; ordinary dynamite (75%), 182.3°; English dynamite (73.8% nitroglycerine, 25.4% calcined sand, 0.8% soda), 184.7°; compressed gun-cotton, 162.9°; collodion, 158.4°—J. B. C.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

New Colour Reactions of some Alkaloids. W. Lenz. *Zeits. Anal. Chem.* 25, 29.

THE quinine alkaloids and cocaine give characteristic colour reactions on fusion with caustic potash. Quinine and quinidine give an intense grass-green colouration, cinchonine and cinchonidine a blue-green, and cocaine a greenish-yellow, which on further heating becomes bluish and then dirty rose-red. Quinine also gives by this treatment a characteristic pleasant aromatic odour. The reactions are given distinctly with 0.5mg. of alkaloid.—G. H. M.

Detection of Manchester Yellow (Dinitronaphthol) in Saffron. Cazeneuve and G. Linossier. *Journ. Pharm. Chim. Sér. 6*, 13, 413.

DINITRONAPHTHOL-YELLOW has lately been used to artificially colour natural saffron. To detect the adultera-

New Books.

JAHRESBERICHT ÜBER DIE LEISTUNGEN DER CHEMISCHEN TECHNOLOGIE MIT BESONDERER BERÜCKSICHTIGUNG DER GEWERBESTATISTIK FÜR DAS JAHR 1885. Von Dr. FERDINAND FISCHER. Leipzig: Verlag von Otto Wigand. 1886. London: H. Grevel, 33, King Street, Covent Garden.

OCTAVO VOLUME, in the paper cover usual with German publications, containing Table of Contents and full Alphabetical Indexes to authors and subject matter. The volume is a large one, containing 1375 pages of matter, and it is illustrated by 478 woodcuts. The work is subdivided by the following groupings of the entire subject:—I. GRUPPE: Chemische Metallurgie. II. GRUPPE: Chemische Fabrikindustrie; Unorganisch. III. GRUPPE: Chemische Fabrikindustrie; Organisch. IV. GRUPPE: Glas, Thon, Cement, Mörtel und Künstliche Steine. V. GRUPPE: Nahrungs- und Genussmittel. VI. GRUPPE: Chemische Technologie der Faserstoffe. VII. GRUPPE: Sonstige Organisch-chemische Gewerbe. VIII. GRUPPE: Brennstoffe und Elektrizität.

REPORT by Prof. WRIGHTSON and Dr. MUNRO, of the College of Agriculture, Downton, Salisbury, on Experiments made by them to test the Manurial Value of the Basic Cinder, made at the Works of the North-Eastern Steel Company, Limited, Middlesborough. Middlesborough: *Daily Exchange Office.* 1886.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

- 8276 W. Briggs, Bradford. Improvements in the method of and apparatus for preventing the issue of smoke from furnaces. Complete specification. June 23
- 8375 W. C. Nickels, London. Improvements in filtering funnels. June 25
- 8422 J. Lyle, Glasgow. Improvements in air or gas compressors. June 26
- 8481 H. H. Salomons, London. Improvements relating to retort covers, lids, or doors. June 28
- 8523 A. Myall, London—Communicated by J. McIntyre, United States. Improvements in surface condensers. June 29
- 8548 H. H. Lake, London—Communicated by J. E. Benninghoff and C. F. Jewell, United States. Improvements in furnaces for the combustion of gaseous fuel. Complete specification. June 29
- 8626 W. Horsfield, London. Improvements in centrifugal drying machines. July 1
- 8630 F. B. Daring, London. Improvements in the means or apparatus for preventing incrustation on the heating surfaces of evaporating vessels, and depositing the particles which cause incrustation in receptacles formed for the purpose. July 1
- 8646 G. Seagrave, London. Improvements in apparatus for inducing the flow of large volumes of air, gas, or other fluid by means of a smaller volume at high velocity. Complete specification. July 1
- 8679 W. A. F. Wiegner, London. Improvements in drying apparatus. July 2
- 8905 S. Vickers, Liverpool. Improvements in apparatus for separating impurities or objectionable matter from solids and liquids. July 8
- 8935 A. M. Clark, London—Communicated by M. Honigmann, Germany. Apparatus for utilising the heat of the exhaust steam from steam engines. July 8
- 9038 A. Myall, London—Communicated by J. McIntyre, United States. Improvements in surface condensers. July 10
- 9098 E. Fischer and M. W. Weber, London. Improvements in amalgamators. July 12
- 9181 J. G. Galley, London. Improvements in apparatus for preventing the deposit and formation of incrustation upon the surface of boiler flues, and for removing such incrustation if formed. July 14
- 9198 A. Harrison, Barrow-in-Furness. Apparatus for charging and drawing heating, smelting, and other furnaces. July 15
- 9199 A. Haacke, London. Non-conducting covering for marine, locomotive, and stationary boilers, to prevent the escape of heat. July 15
- 9220 E. Edwards, London—Communicated by J. Quiri, Germany. A new or improved volatile liquid especially applicable for use in ice-making or refrigerating machines. July 15
- 9259 J. Brown, London. Improvements in apparatus for rapidly heating or cooling liquids. July 16
- 9274 C. J. Galloway and J. H. Beckwith, London. Apparatus for heating feed water for boilers, and effecting deposit of impurities therefrom. July 16
- 9306 F. Skevington, Birmingham. Improvements in illuminating steam, vacuum, compound, and other like gauges. July 17
- 9307 B. P. Walker, Birmingham. Improvements in the construction of apparatus for the distillation of solid materials. July 17
- 9312 B. D. Healey, Liverpool. Improvements in refuse furnaces and apparatus therefor, partly applicable to other furnaces. Complete specification. July 19
- 9355 W. H. Akester, London. Improved means for obtaining solutions of soluble materials. July 19
- 9394 W. S. Mackie, London. Iadiarubber covering for blow-off pits. July 20
- 9465 J. Bonthron and R. B. Bonthron, Glasgow. Improvements in and connected with furnaces. July 21
- 9488 F. W. Brownlow, Manchester. Improvements in filters. July 22
- 9497 R. Johnson, Manchester. Improvements in supplying atmospheric air to combustion chambers or flues of steam boiler and other furnaces. Complete specification. July 22

COMPLETE SPECIFICATIONS ACCEPTED.*

1885.

- 9225 W. F. R. Weldon—Communicated by A. R. Pechiney et Cie. Apparatus for heating solid substances out of contact with the products of the combustion of the fuel employed. July 13

- 9876 J. Murrie. Method of generating vapour. July 9
- 9963 S. Robertson. Filters, and apparatus connected therewith. July 16
- 10028 D. Fulton—Communicated by E. Laroche. Means for interrupting the flow of fluids in pipes or conduits. July 16
- 10112 A. Reis. Apparatus for producing draught in furnaces, and for purifying the products of combustion. June 29
- 10143 J. A. Drake and R. Muirhead. Improvements in and connected with filter presses. July 2
- 10355 E. Edwards—Communicated by G. Lunge and L. Rohrmann. Apparatus for effecting the absorption of gases by liquids or solids. July 8
- 10577 W. L. Wise—Communicated by L. Pommeraye. Improvements in filters. July 6
- 10581 J. S. Edwards and J. Edwards. Apparatus for drying animal matter, etc., and for evaporating liquids. July 2
- 10593 R. Hainesworth. Means of condensing the steam arising from set-pans. June 25
- 10642 E. Edwards—Communicated by E. Rothe. Centrifugal machines. July 16
- 10607 J. Murrie. Apparatus for separating vapours from liquids. July 6
- 10942 J. B. Allfott. Filter-presses and apparatus connected therewith. July 20
- 11143 J. Patterson and M. Sandison. Application of forced draught to furnaces. July 6

1886.

- 6673 E. Fales. Smoke consuming furnaces. July 6
- 6812 T. T. Mathieson and J. Hawliczek. Improvements in and in connection with distilling apparatus. July 13
- 7406 G. Criner. Furnaces for the combustion of fuel. July 9
- 8276 W. Briggs. Method and apparatus for preventing the issue of smoke from furnaces. July 23

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

- 8259 H. G. Walker, London. Improvements in the manufacture of night-lights, and in apparatus therefor. June 22
- 8291 H. D. Cunningham, London. Improvements in the production and application of hot air. June 23
- 8305 R. Henderson and S. Levy, London—Communicated by G. H. Kohn, United States. Improvements in or relating to furnaces for the manufacture of water-gas. June 23
- 8312 P. Fariaux, London. An improved apparatus for the manufacture or production of carbonic acid and other gases. June 23
- 8348 J. Hammond, London. Improvements in the method of, and in apparatus for the complete purification of coal-gas, by concentrated liquid ammonia, and the recovery of sulphur and ammonia for the manufacture of sulphuric acid and sulphate of ammonia. June 24
- 8349 A. M. Clark, London—Communicated by G. E. Wéry, France. Improved means of consuming smoke and economising fuel in furnaces and fire-places. June 24
- 8357 S. Butler, London. Improvements in machinery for the manufacture of compressed fuel from coal. Complete specification. June 24
- 8411 J. Dredge, London. Improvements in apparatus for producing intense heat by gas. June 26
- 8474 J. Heydon, Mansfield, Notts. Improvements in the means and apparatus for burning gas-tar, which is applicable for heating steam boilers. June 28
- 8484 G. Symes, London. Improvements relating to the purification of gas, and the impregnation of the same with hydrocarbon or other vapour, and to apparatus therefor. June 28
- 8494 R. Tervet, Glasgow. Improvements in apparatus for distilling or refining mineral oils. June 29
- 8548 H. H. Lake, London—Communicated by G. E. Benninghoff and C. F. Jewell, United States. Improvements in furnaces for the combustion of gaseous fuel. Complete specification. June 29
- 8549 H. H. Lake, London—Communicated by G. E. Benninghoff, United States. Improvements relating to the utilisation of gas or vapours for lighting and heating purposes, and to apparatus therefor. Complete specification. June 29
- 8583 A. J. Boulton, London—Communicated by S. Bond, Turkey. Improvements in apparatus for consuming smoke and saving fuel. June 30
- 8756 R. Tervet and F. Alison, Glasgow. Improvements in treating and purifying paraffin wax, and in apparatus therefor. July 5
- 8761 W. C. Haigh and A. A. Haigh, Manchester. Improvements in artificial fuel. July 5
- 8825 H. Cockey and F. C. Cockey, Westminster. Improvements in gas washers. July 6
- 8878 W. Moffatt, Glasgow. Improvements in apparatus for heating and cooking by gas. July 7
- 8880 H. J. Hadden, London—Communicated by H. Welsh, United States. Improvements in apparatus for promoting the combustion of fuel. Complete specification. July 7
- 8895 H. Williams, Manchester. Improvements in and apparatus for obtaining gas for illuminating, heating and other purposes. July 7
- 8902 A. J. Boulton, London—Communicated by A. Blancfort. An improved method of or apparatus for effecting the decomposition of hydrocarburet and water vapour mixed in closed vessels. July 7

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Specifications thus advertised are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

8918 R. Tervet and F. Alison, Glasgow. Improvements in treating and purifying paraffin wax, and in apparatus therefor. July 9

9025 C. Oswald, Liverpool. Improvements in and connected with burning inflammable oils or liquids for heating or lighting purposes. July 10

9017 J. Blum, London. The instantaneous generation of steam. July 12

9082 A. R. Upwards and C. Pridham, London. Improvements in gas batteries, and in the application of the same to electric lighting and other uses. July 12

9116 J. Roberts, London. Process of and apparatus for manufacturing heating and illuminating gas. Complete specification. July 13

9260 H. Clay Bull, Liverpool. Improvements in the manufacture of gas, and in apparatus therefor. July 16

9262 J. Hammond, London. Improvements in the method of and in apparatus for supplying liquid fuel to furnace and other fires. July 16

9275 J. C. Grant, London. A method and apparatus for distilling solid materials for the production of gases and vapours therefrom. July 16

9291 R. Ashton, Manchester. Making self-extinguishing candles. July 17

9312 F. Sahlfeld, London. A process and apparatus for distilling and rectifying raw fatty acids and residues, or waste containing fatty acids. July 17

9158 R. Stone, London. Improvements in the application of various inflammable fluids and substances to all kinds of materials requiring high temperatures in their manufacture. July 21

9167 H. Süss, Liverpool. Improvements in or appertaining to magnesium lamps. Complete specification. July 21

9173 J. Livesey and W. Whitehouse, London. An improvement in apparatus for enriching gas by admixture of hydrocarbon vapour. July 21

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

9679 H. J. Rogers. Gas retorts, and apparatus connected therewith. June 25

9071 J. J. Royle. Improvements in and apparatus for heating water and generating steam by gas or other fuel, and automatically controlling the same. June 25

1886.

3300 J. H. Campbell. Using binary liquids, especially aqua ammonia, as a motive power. July 6

4163 A. Thomas. Means for regulating the flow of gas tar to be used as fuel in gas and other works. July 6

6317 O. Inray—Communicated by J. B. Archer. Apparatus for conversion into gas and combustion of liquid hydrocarbons. July 2

6811 J. Maclear. Appliances for increasing the illuminating effect of gas. June 29

8091 B. J. B. Mills—Communicated by C. T. Burchardt. Applying auxiliary heat to steam boilers. July 20

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

8528 C. P. Anderson, London. Improvements in detergents and dyes. June 29

8992 C. D. Abel, London—Communicated by The Farbwerke vormals Meister, Lucius, and Brünning, Germany. Improvements in the production of green colouring matters or dyestuffs. July 9

9176 L. J. B. A. J. Bouillet, London. Improvements in the manufacture of ultramarine, and in furnaces or ovens, and apparatus to be used in this manufacture. Complete specification. July 11

9489 J. Crawford and J. Crawford, Glasgow. Improvements in apparatus for treating and supplying or distributing coloured or other powders. July 22

V.—TEXTILES, COTTON, WOOL, SILK, ETC.

APPLICATION.

8196 J. Dawson, Manchester. An improved composition or mixture to be used for glossing linen. June 29

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2817 G. W. H. Brogden and E. Casper—Communicated by E. Fremy and V. Urbain. Treating fibres from the barks of plants of the urtica family, etc. June 29

6908 W. B. Ritchie. Manufacture of bituminous and other felts. June 25

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

8249 T. Hauschell, Glasgow. Improvements in apparatus for washing, dyeing, drying, or similarly treating wool, cotton, and other textile or fibrous materials. June 22

8125 J. T. Sawney and C. E. Quick, Hull. Improvements in sizing loose coloured wall-paper and distempered decoration, and showing each colour perfectly distinctly. June 26

8903 L. M. Lardière, London. Improvements relating to the printing or colouring of yarns for the manufacture of woven fabrics. July 7

9286 F. A. Gatty, Manchester. Improvements in dyeing wool or other animal fibres in either the raw or manufactured state. July 17

COMPLETE SPECIFICATION ACCEPTED.

1885.

12534 J. H. Ashwell. Apparatus applicable for dyeing, scouring, and other like purposes. July 13

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

8217 J. H. Dennis and N. Glendinning, Liverpool. Improvements in obtaining sulphide of zinc from solutions. June 22

8308 L. Mond, Liverpool. Improvements in obtaining chlorine. June 23

8312 P. Farinaux, London. An improved apparatus for the manufacture or production of carbonic acid and other gases. June 23

8599 J. Magnall and W. Bratby, Blackley. Apparatus for generating carbonic acid gas. July 1

8602 J. Park, Glasgow. Improvements in the manufacture of bichromate of ammonia. July 1

8723 E. Solvay, London. A new or improved process for the simultaneous manufacture of assimilable phosphates, and of sulphate of ammonia. July 2

8819 L. A. Chevalet, London. Improvements in apparatus for distilling and purifying ammoniacal liquids. July 6

8832 A. Schanschietz. See Class XVIII.

8860 A. M. Clark, London—Communicated by M. Honigmann, Germany. Improvements in the manufacture of caustic soda. July 7

8906 G. A. Jarvis, Wellington, Salop. Improvements in the manufacture of carbonates of soda and potash. July 8

8971 S. Bowen Bowen, London. Improvements in apparatus for the concentration of sulphuric acid. July 9

9032 J. Marx, London. Improvements in the manufacture of alkalis. July 10

9208 H. W. Deacon and F. Hurter, London. Improvements in apparatus for producing ammonia from sulphate of ammonia. July 15

9218 W. Cooper, Salford. An acid-box for regulation of vitriol and prevention of blow-backs. July 16

9276 E. Böhlig and G. O. Heyne, London. An improved process for separating waste lye containing chlorate of magnesium into magnesia and hydrochloric acid, for manufacturing carbon magnesia as material for cleansing feed-water for boilers for clarifying and decoloring all kinds of fluids, and especially for cleansing all kinds of factory spent lye and sewage waters, and rendering the same innocuous. Complete specification. July 16

9566 O. Inray, London—Communicated by La Société Anonyme pour l'Étude et la Création des Soudières, France. Improvements in apparatus employed in the ammonia-soda process. July 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

8721 W. P. Thompson—Communicated by Solvay et Cie. Manufacture of chlorine from by-products of the ammonia-soda process, or similar chemicals from other sources. June 25

9227 W. F. R. Weldon—Communicated by Pechiney et Cie. The decomposition of the magnesia of the residual ammonium chloride of the ammonia-soda process. July 6

9831 W. F. R. Weldon—Communicated by Pechiney et Cie. Decomposing by magnesia the mother-liquor of the ammonia-soda process. July 6

9833 T. H. Cobley. Manufacture of carbon-alum and application of the same to useful purposes. June 25

10700 J. J. Hood. Manufacture of ammoniac bichromate. July 9

11192 J. Brock and E. Saye. Means or apparatus for distributing or conveying acids or other liquors to the cisterns or tanks of chemical towers, vats, etc. July 16

1886.

6999 W. C. Wren. Process and apparatus for distilling ammonia. July 9

7355 H. H. Lake—Communicated by U. Cummings. Manufacture of sulphuric acid. July 13

7125 C. Petri. See Class XVIII.

7663 C. Toppan. Bleaching compounds. July 9

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

- 8477 W. Kent and C. Cope, London. Improvements in machinery or apparatus for working or mixing plastic materials, such as potters' clay. June 28
- 8526 J. H. Windmill, London. Improvements in and apparatus for the manufacture of glass bottles and glass jars, and other like glass articles. June 29
- 8677 J. C. Arnall and H. M. Ashley, Ferrybridge, Yorks. Improvements in the manufacture of bottles and other articles in blown glass. July 2
- 8713 M. H. Blanchard, London. Improvements in the manufacture of ornamental and other tiles. July 2
- 8797 T. Thorp, Whitefield, Lancashire. A new or improved glass enamelling process. July 6
- 9015 W. H. Jones, B. Jones, W. Hall Jones, and B. H. Jones, Wolverhampton. An improved apparatus connected with the fusing of enamel-ware. July 10
- 9137 A. Moore and W. E. Moore, London. The production of ornamental transparent and semi-transparent glass letters and ornamental glass. July 13
- 9217 O. C. Hawkes, London. New or improved machinery for bevelling and moulding the edges of plates of glass and for ornamenting the surfaces of plates of glass. July 15
- 9226 H. H. Lake, London—Communicated by M. P. H. Beconlet and L. J. O. Bellet, France. Improvements relating to the manufacture of sheets or plates of glass and other glass articles. July 15

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 6579 J. D. Denny. Improvements in tiles, and appliances for making the same. June 29
- 11084 H. Venables. Glazing china, porcelain, earthenware, and Parian. July 9
- 11208 A. Laudier and C. Hondaille. Decorating objects of glass, crystal, or ceramic ware. July 6

1886.

- 8023 F. S. Shirley. Manufacture of glass and articles therefrom. July 16

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

- 8339 R. Steinau, London. Improvements in facing bricks, and in the manner of setting the same. June 24
- 8118 W. G. Wodson and R. Skeoch, Birmingham. Improvements in the process of manufacturing bricks, ridge-tiles, and other such like clay articles. June 26
- 8836 E. H. Bassett, London. An improvement in asphalt pavement. July 6
- 8934 F. C. A. Meier, London. Improvements in centrifugal apparatus for moulding or casting clay, cement, plaster, and other similar materials. Complete specification. July 8
- 8957 R. Skeoch and W. G. Wodson, East Heaton. An improved escape kiln for the burning of all classes of bricks and other clay goods. July 9
- 9108 H. H. Leigh, London—Communicated by B. Dubois, France. An improved method of constructing ornamental masonry columns. Complete specification. July 20
- 9136 J. A. Parker, London. An improved composition for paving or covering roads and ways, floors, and other surfaces. July 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 10541 M. B. Parrington. Kilns, etc., employed in the manufacture of lime and cement. July 13
- 11001 W. Hassall. Composition or cement specially applicable for use in jointing stoneware, concrete, or like pipes. July 9
- 11008 R. Stone. Manufacture of cement. July 23
- 11270 E. W. Killick. Manufacture of cement. July 23
- 11271 E. W. Killick. Kilns. July 20
- 11239 A. Cochran. Apparatus for making clay bats. July 20
- 11589 R. B. Lee and J. Hodgson. Construction of fireproof pillars and columns. July 2
- 11725 R. B. Lee and J. Hodgson. Manufacture of concrete fireproof building materials and parts of buildings, etc. July 9

1886.

- 7361 H. H. Lake—Communicated by U. Cummiogs. Manufacture of cement. July 9
- 7675 H. Mathey. Manufacture of cement. July 23
- 7676 H. Mathey. Method of colouring cement. July 23

X.—METALLURGY, Etc.

APPLICATIONS.

- 8320 J. Webster, London. An improved metallic alloy. Complete specification. June 23

8324 A. Gutensohn and J. M. James, London. Improvements in the process of pickling or cleaning the surface of iron or other metal previous to coating such surface with tin or other metal. June 23

8338 T. Twynam, London. Improvements in and connected with refractory linings, particularly adapted for metallurgical furnaces, but applicable also for other purposes. Complete specification. June 21

8339 T. Twynam, London. Improvements in and connected with refractory linings, particularly adapted for metallurgical furnaces, but applicable also for other purposes. June 21

8387 G. Francis, Liverpool. Improvements in and relating to tamping blast holes in mines and other places. June 25

8390 R. Heathfield, London. Improvements in apparatus used for coating sheet iron with zinc or alloys of zinc or other coating metal or alloy. June 25

8397 W. Baker, J. Baker, and W. H. Baker, London. Improvements in coating or covering surfaces of sheet iron or steel, and of tin andterne plates, and of articles made of such iron and steel and plates. June 25

8408 G. Baron de Overbeck, London—Communicated by H. de Groussilliers, Germany. Improvements in the production of aluminium chloride. June 25

8424 A. R. Ormiston and J. Ormiston, Glasgow. Improvements in processes and apparatus for testing miners' safety lamps. June 26

8491 G. Baron de Overbeck, London—Communicated by H. de Groussilliers, Germany. The treatment of aluminous minerals, especially bauxite, to separate iron therefrom. June 28

8531 F. J. R. Seaver, London—Communicated by E. C. Keiner-Fiertz, Switzerland. Improvements in and connected with the manufacture of aluminium and other light metals. June 29

8564 G. Baron de Overbeck, London. Communicated by H. de Groussilliers, Germany. Improvements in the electrolytic production of aluminium. June 30

8608 M. Settle, Manchester. Improvements in electric safety lamps for use in mines. July 1

8833 C. B. Heady, London. Improvements in gold-covered alloy. Complete specification. July 6

8844 E. Morand, London. Improvements in instruments or apparatus for detecting and signalling the presence of carbonated hydrogen in mines and other places. July 6

8881 P. M. Justice, London—Communicated by H. T. Rode, Germany. Improvements in the manufacture of steel and ingot iron. July 7

8888 H. Bonser and T. G. Marsh, London. Improvements in apparatus used in blasting for mining and other like purposes. July 7

8962 E. Martin, London. Improvements caused in the extraction of precious metals. July 9

8966 D. Owen, London. Improvements in the manufacture of tin and such like metal-coated plates and in the apparatus employed therein. July 9

8988 T. Fenwick, London. Improvements in the treatment of waste tin cuttings to recover tin and also iron in a state fit for re-manufacture, also in apparatus to be employed in this treatment. Complete specification. July 9

8989 E. Cottam, London. Improvements in the manufacture of German silver. July 9

9138 P. Higgs, London. An improved process and apparatus for obtaining spelter and other products by the treatment of zinc ores. July 14

9327 R. Kirkman and H. J. Kirkman, London. Improvements in the manufacture of tinned plates and of other tinned articles. July 17

9132 H. Leipmann. See Class XVIII.

9486 L. Grabau, London. Improvements relating to the production of aluminium and alloys thereof. July 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

8112 J. Sedgwick. Miners' safety lamps, with nickel or other reflector. July 2

8574 H. R. Cassel. See Class XVIII.

9003 H. Grimshaw. Process for treating galvanised iron or steel. July 2

10018 H. H. Lake—Communicated by The Verein Chemischer Fabriken. Separation of tin from tin-plate, and production of protochloride of tin. July 9

10119 S. H. Stephens and S. Rodda. Machinery for the reduction of tin stuff and other partially pulverised ores, to extract the metal therefrom, and for grinding other hard substances. July 20

11067 W. Beaton. Recovering tin from waste tinned iron. July 9

11113 G. Hertzog. Moulding apparatus for foundry purposes. July 13

11280 D. Davis. Apparatus employed in coating metal plates with tin, terne, or other metals or alloys. July 13

11005 W. Galloway. Tamping shot-holes for blasting in mines. July 2

1886.

8326 J. Webster. An improved metallic alloy. July 23

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

- 8615 P. Gill, Liverpool. Improvements in or appertaining to soap frames. July 1

8636 P. J. Davies, London. Improvements in oil bleaching or refining apparatus. July 1
 8717 A. Macqueen, Tunbridge Wells. Soap manufacture by the introduction of Fuller's earth to make it the best quality for domestic, nursery, and toilet purposes. July 2
 8921 J. Whittle, London. Improvements in apparatus for extracting or separating oil or grease from cotton waste and similar materials. Complete specification. July 8
 8933 J. L. Mott, jun., London—Communicated by Dreher & Co., United States. Improvements in lubricating compounds. Complete specification. July 8
 9257 J. Baird, Glasgow. A new or improved machine, or arrangement of mechanism, for slicing or cutting soap. July 16
 9115 H. H. Lake, London—Communicated by W. B. Albright, United States. Improvements relating to the bleaching of fats and oils. Complete specification. July 20

COMPLETE SPECIFICATION ACCEPTED.

1885.

12192 A. T. Hall. Extracting oils from certain waste products. June 25

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

8112 F. Greening, London. A new or improved manufacture and process of production of material that can be used as or in the making of substitutes for indiarubber, varnish, ivory, whalebone, and other substances. June 26
 8725 J. M. Benoett, Glasgow. Improvements in the manufacture of pigments. July 3
 8747 J. Aniello, J. Kennedy, and J. B. Barket, London. An improved anti-fouling and preservative paint or varnish. July 3
 8837 F. Maxwell Lyte, London. Improvements in the production of white lead. July 6
 9001 E. O. Eaton, London. Improved blacking and varnish. July 10
 9027 E. School, London. Process for the production of resin-acid esters applicable as substitutes for the resins or gums usually employed in the manufacture of varnishes and lacquers. Complete specification. July 10
 9101 E. Tuteur, London. A new or improved method of and material for coating, lacquering, or enamelling metals for resisting atmospheric influences, water, acids, alkalis, and the like. July 20

XIII.—TANNING, LEATHER, GLUE AND SIZE.

APPLICATIONS.

8363 J. Hurry, London. Crocodile leather floor covering made from real crocodile skins. June 25
 8143 T. N. Ashman, London. An improved composition for treating leather and leather articles. June 26
 8582 A. J. Boulton, London—Communicated by Count V. de Nydpruck, Belgium. Improvements in tanning. June 30
 9017 F. J. Pohl, Bootle. Improvements in tanning hides and skins. July 10

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

8626 G. F. Redfern—Communicated by A Buckingham. A material to be used as a substitute for leather, etc. July 6
 11864 A. Hitchon. Boiling size under steam pressure. July 6

1886.

6011 F. R. Maggs. A substitute for urine or "sig" for use in preparing leather and skins for dyeing. July 6

XIV.—AGRICULTURE, MANURES, ETC.

APPLICATIONS.

8723 E. Solvay. See Class VII.

Communication.

ON THE COMPOSITION OF THE COAL OF THE SOUTH STAFFORDSHIRE COAL-FIELD.

BY E. W. T. JONES, F.I.C.

Owing to the kindness of the late Mr. W. Bowkley, who personally selected all the samples, I am enabled to give analyses of representative specimens of all the various seams of coal met with in the South Staffordshire coalfield. The results, as tabulated on p. 445, to make them thoroughly comparable, are all on the coal dried c. 212° F., and it must be remembered the samples were all clean or free from extraneous earthy matter. The coal nearest the surface is placed first on the list, and that farthest from the surface last. See section as at Coseley, which is about the centre of the South Staffordshire coalfield.

		Thickness.
		ft. in
Brooch Coal		3 9
Flying Red Coal		4 0
THICK COAL	White Coal	2 6
	Tow Coal	2 9
	Brazils	2 0
	Foot Coal	1 9
	Bat	2 0
	Slips Coal	2 6
	Stone Coal	2 3
	Patchels Coal	1 6
	Sawyer Coal	2 6
	Slipper Coal	2 0
	Bat	2 0
	Benches Coal	2 0
Heathen Coal		3 3
New Mine Coal		6 0
e-clay Coal		5 6
Bottom Coal		4 0

NOTE.—Flying Red Coal, West of Dudley, lies close upon and is part of the Thick Coal, and is called Top Slipper and Roofs.

I wish to record my thanks to my assistant, Mr. A. E. Johnson, A.I.C., for his careful work in connection with the deduction of the foregoing results.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

New Form of Syphon. F. W. Dafert. Chem. Zeit. 10, 821.

THE accompanying figure shows a very convenient form of syphon, which hardly requires description. The cups at each end of the syphon require to have more than twice the capacity of the syphon tube. To start the syphon, it is only necessary to fill one cup with liquid,

then to lower the other until the liquid reaches it; then, on bringing the cups to the same level, the syphon is charged and ready for work. The figure shows an arrangement by which the syphon prevents the overflowing of a couple of vessels, C and D.—J. T.

Improvements in Filters. James and John Clayton, Manchester. Eng. Pat. 8986, July 25, 1885. 8d.

THE improvements described relate to filters formed from porous sandstone, and consist in making the filtering vessel cylindrical, cut from a single piece of stone. One or both ends may be cemented on by Portland or other cement.—C. C. II.

Improvements in Filter-presses. D. K. Clark and W. J. E. Foakes, London. Eng. Pat. 9204, July 31, 1885. 8d.

THE plates of the filter-press may be made from a sheet of wrought iron, to which a rim is rivetted, perforated or sub-channelled radially so as to afford an easy escape for the filtrate round the entire circumference; or the plates may be cast with radial drainage grooves, a plain rim covering them at the circumference, rivetted thereto, affording a similar exit for the filtrate as in the first plan described.—C. C. II.

Improvements in Filters. A. Bell, Manchester. Eng. Pat. 9959, August 22, 1885. 8d.

AN earthenware vessel is separated at its centre by a ledge upon which is placed a diaphragm, and resting thereon a carbon filtering block, covered in its turn by a shield; the whole is held down by a spring clip. The lower part of the vessel forms a reservoir for the filtered water which has passed through the carbon block, and the upper part acts as a reservoir for the unfiltered water. When the block of carbon has become foul it can be removed and either cleansed or replaced.—C. C. II.

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader LACK, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.	4d.
Above 8d., and not exceeding 1s. 6d.	1d.
1s. 6d., " " 2s. 1d.	1d.
" 2s. 1d., " " 2s. 1d.	2d.

Reichling's Electrical Safety Apparatus for Steam Boilers. Chem. Zeit. 10, 822.

THE diagram on p. 446 illustrates the apparatus. This consists of a tube, about 40mm. internal diameter, the lower, open end of which stands at the lowest permissible water-level in the boiler, and the upper end of which stands about 1½m. above the boiler. This upper end contains a double-seat valve, the seats of which are of equal diameter. The ribbed H-shaped valve has about 2mm. play between the two seats, and is pressed down on to the lower seat by means of an internal easily-fusible ring, which is again controlled by a terminal bush, screwed internally. The movable valve carries an isolated junction plate, whilst the terminal bush carries two isolated binding screws.

When the water is at the normal level the tube is filled with cooled water; but if the water runs short the tube becomes filled with steam, and the fusible ring is melted. The valve is now pressed against its upper seat, thus preventing further escape, and electrical contact is made at the same time between the binding screws. The alarm

An Improved Filter. C. I. C. Bailey, Fulham. Eng. Pat. 2472, February 19, 1886. 6d.

THE apparatus consists of a tube passing through two plates, between which the filtering medium is placed. Round the lower end of the tube, which is perforated, a conical block of carbon is placed, and this is surrounded by loose charcoal. The water passes through the upper plate, which is perforated, through the charcoal and carbon block, by the holes into the tube, and so into the reservoir for filtered water. The filtering medium can be readily replaced, and the filtered water is in contact with the air.—C. C. H.

II.—FUEL, GAS, AND LIGHT.

Claus's Ammonia Process of Gas Purification. C. Hunt (Proc. Gas Institute). J. Gas Lighting, June 22, 1886, 1181—1191.

IT will be seen by the drawings on pp. 147 and 148 that the plant consists of a number of scrubbers and towers, all

current thus set up by means of a small battery can be made to indicate the condition of the boiler in any desired place. There are no moving parts within the boiler. The fusible ring is loaded with the boiler pressure, so that its destruction, when heated, is certain. The ring, contact plate, and poles are protected both from the influence of the boiler and of the air, thereby ensuring certainty of action.—J. T.

Improvements in and connected with Filter-presses. J. A. Drake and R. Muirhead, Maidstone. Eng. Pat. 10,143, August 27, 1885. 8d.

THE improvements specified relate to the mode of forming the chambers in filter-presses used for materials such as sludge or slurry. Wrought-iron slotted plates are covered with coir, bass, or like fibre, which is laced on through the slots in the form of cord or plait so as to cover the surface of the plate; it may also be applied previously woven. These are placed between distance rings which overlap them, forming a fillet or recess into which the liquid exuding from the "filtering mat" passes and is carried away.—C. C. H.

of which are square in shape, with the exception of the last scrubber. The scrubbers in which the gas is purified are marked A₁, A₂, A₃, A₄, and A₅. Five of them are 4 feet square and 20 feet high, and are filled with broken ganister bricks supported on crossed angle irons, the liquor being distributed at the top of each by a tumbling box arrangement. The sixth scrubber is of the Mann and Walker type; it is 5 feet in diameter and 25 feet high, and serves as catch-vessel, being supplied for the purpose with spent liquor from the tower C₁. The foul gas, having previously passed through a Livesey washer, travels up the scrubber A, and then descending enters at the bottom of A₂, towards the top of which it meets with ammonia gas from the distilling towers; it then passes up through A₃, A₄, A₅, and A₆ in succession, being entirely freed in its passage from carbonic anhydride and sulphuretted hydrogen, whilst of ammonia there remains at the outlet of the last scrubber only the usual faint traces, and the carbon disulphide is reduced by from 20 to 70 per cent. Parallel with the scrubbers are placed eight towers, 2 feet square and 18 feet high. Five of these—B₁, B₂, B₃, B₄, and B₅—are decomposing

towers, and the remaining three—C, C₁, and C₂—distilling towers. In the B towers the scrubber-liquor is heated to a carefully-regulated temperature to expel the carbonic anhydride and sulphuretted hydrogen with as little loss of ammonia as possible. B is a washing or catch tower, supplied with spent liquor at the rate of about 40 gallons per hour, in which is retained any ammonia that the acid gases may bring with them from B₁. The strong liquor from scrubber A enters the tower B₁ (which, together with B₂, is further distinguished as a carbonating tower), and mingles with the spent liquor

FIG. 2.

FIG. 1.

after this has passed through the tower B, becoming almost supersaturated with the acid gases which are on their way to B. The temperature of this tower is very little above that of the air, and the liquor passes from thence to tower B₁, the temperature of which varies from about 71° at the bottom to about 38° at the top. The sulphuretted hydrogen is by this means wholly, or almost wholly, expelled, and the ammonia obtained as ammonium carbonate, which may be drawn off at the bottom of B₁. If desired, automatic production of ammonium sulphate may be set up by the substitution for the wash

ing tower B of an acid saturator, through which the gases would pass on their way to the sulphur kiln, D, and to which the surplus ammonia might be conveyed from B₂. In the next towers—B₃ and B₄—which are the heating towers of the series, the actual separation is effected; both are fitted with horizontal cast-iron trays, thirty in each tower, in which are placed wrought-iron steam coils. The liquor enters at the top, and falls from tray to tray, rising gradually in temperature to from 80° to 85°. This drives ammonia forward to B₅, but it is all returned. In B₅, which is constructed in a similar manner, the temperature varies from 87° at the top to 90° at the bottom where the steam enters. The liquor from this tower, which is mainly liquid ammonia, is ready for distillation in towers C, C₁, and C₂. These are, in reality, scrubbers filled with broken ganister. From the bottom of B₄ the liquor passes to the top of C, meeting in its descent the vapours and gases given off in C₁. At the base, it attains a temperature of about 100°, by which the greater part of the ammonia (except that in the form of thiocyanate), carbonic anhydride, and sulphuretted hydrogen still remaining in combination are expelled. These, together with a considerable quantity of vapour, are driven forward to C₂. To liberate the fixed ammonia an equivalent proportion of caustic soda is mixed with the liquor. The heat of the waste liquor is utilised in raising the temperature of the strong liquor from the scrubber A, or of the feed-water for boilers by passing it through a series of jacketed tubes. From the top of C the hot vapours enter at the base of C₂, into which no liquor is pumped; they are there partly condensed, the temperature in the tower ranging from about 86° at the bottom to about 44° at the top, and the liquor which accumulates therein, and consists of ammonium carbonate and some free ammonia, is pumped into B₄. The average strength of this liquor is nearly ten ounces. Ammonia gas, with some carbonic anhydride, is conveyed by a pipe from the top of this tower to the top of the scrubber A₁, where it meets the foul gas already once washed in A and A₁. The last operation relates to the acid gases which, after passing through the washing tower B, are conveyed to an apparatus for the recovery of sulphur, consisting of a kiln, K, built of cast-iron tank plates lined with fire-brick and filled with oxide of iron, a depositing chamber, D, a wash tower filled with pebbles and surplus spent liquor, and an open oxide purifier. The gases from B consist of about 40 per cent. of sulphuretted hydrogen and 60 per cent. of carbonic anhydride. With these an equal volume of air is mixed, and the mixture passed through a 15-inch bed of oxide of iron heated to redness in the kiln K. By this means sulphur is set free in a state of vapour, which, together with the gases, passes into D, where the sulphur settles out. To prevent the escape of unaltered sulphuretted hydrogen, or of sulphurous anhydride formed, of both of which there is generally a small quantity present in the gases leaving D, the latter are passed through a 2-feet wash tower, and then into an open purifier. The exit gases from this consist of carbonic anhydride and nitrogen. From 10 to 14 lb. of pure sulphur is stated to be obtained per ton of coals carbonised.

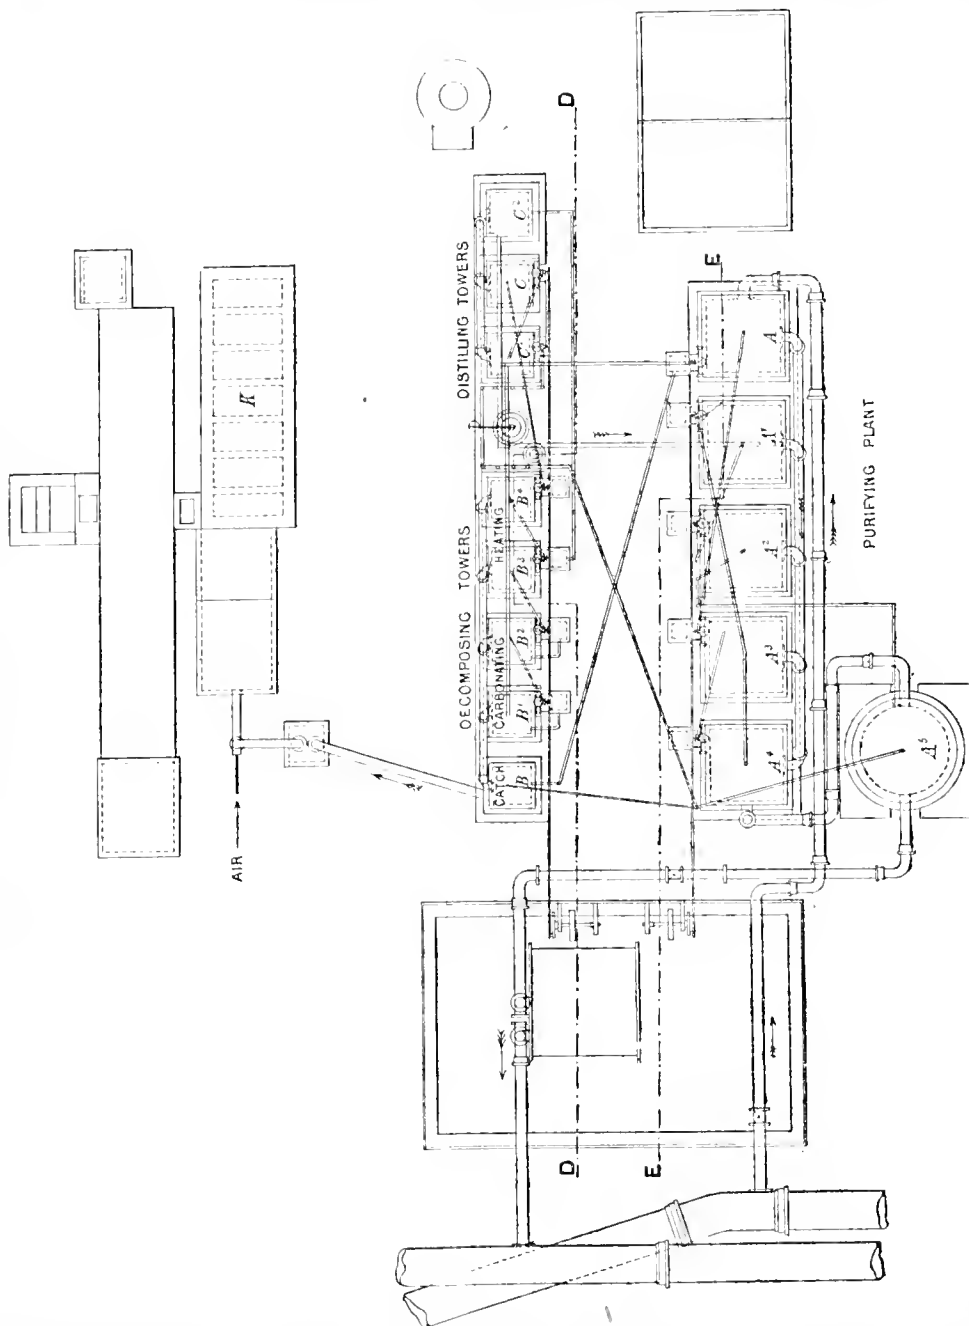

This apparatus, which has been erected at the Windsor Street station of the Birmingham Gas Works, is said to compare favourably, as regards occupation of ground-space, with the ordinary system of dry purification. It is capable of purifying about 250,000 cubic feet of gas daily, requiring only the attendance of one man by day and another by night. As the success of the method depends largely on the proper working of the pumps, it would be desirable to provide them in duplicate. The loss of ammonia is estimated at about 10 per cent. of the quantity actually passed through the apparatus, which, being about one-third of the entire quantity produced, is equal to a little over 3 per cent. of total loss.

It was stated above that the spent liquor which is pumped over the scrubber A₂ is derived from the free steam used in the distilling towers. Of this, as of the ammonia, there is, however a surplus, which is collected in a tank holding about 24 hours' make. This contains thiocyanate and ferrocyanide of sodium; to it a solution of a salt of iron is added, a precipitate of iron ferrocyanide being formed, which is either Prussian blue or can readily

be converted into it. The clear liquor from this precipitate is drawn off and pumped through the sulphur wash tower, where it becomes impregnated with sulphurous acid. Sulphate of copper is then added to the solution, whereby insoluble cuprous thiocyanate is formed. After settling, the clear liquor containing sulphate and chloride of sodium is run away. One ton of coal yields about $\frac{1}{2}$ lb. of Prussian blue and $\frac{1}{4}$ lb. of copper thiocyanate.

the by-products from the waste liquor, which are at present entirely lost to gas suppliers. The only disadvantage of the apparatus is that the sulphur compounds are not sufficiently reduced to come regularly within the standard required by the London Gas Referees. This is illustrated by the following results:—160,000 cubic feet of gas passing per diem contained 143 grains of ammonia per 100 cubic feet, 2.95 per cent. of sulphuretted hydro-

AMMONIA GAS PURIFYING PLANT—CLAUS'S PROCESS.

The advantages of this process may be summarised as follows:—(1.) The recovery of the sulphur in the solid form, in which state its value must be much greater than when combined with iron oxide. (2.) The saving of oxide of iron and lime, together with the labour required for their preparation. (3.) The production of the surplus ammonia in a much more marketable form than when obtained as ordinary gas-liquor. (4.) The recovery of

gen, and 2.04 per cent. of carbonic anhydride in the crude state; the purified gas containing 3.39 grains of ammonia, no sulphuretted hydrogen, no carbonic anhydride, and the sulphur compounds reduced to from 28 to 21 per cent.

The author recommends that until a larger proportion of the sulphur compounds can be removed, the working of this process on a large scale should not be undertaken.

without purifiers to fall back upon. By passing either the foul gas or the acid gases diverted from the sulphur kiln through catch purifiers charged with lime, the ear-

meets the liquid hydrocarbon, and transforming this into vapour passes along with it through the outlet pipe for combustion under the boiler or elsewhere.—A. R. D.

AMMONIA GAS PURIFYING PLANT—CLAUS'S PROCESS.

bonic anhydride would first be arrested and the sulphuretted hydrogen allowed to go forward and form calcium sulphide.—D. B.

Apparatus for Conversion into Gas and Combustion of Liquid Hydrocarbons. O. Imray, London. From J. B. Archer, Washington, U.S.A. Eng. Pat. 6347, May 11, 1886. 6d.

THIS apparatus consists of a vertical cylindrical boiler with a firebox beneath, communicating with a heating chamber above, by means of a flue, running vertically upwards through the centre of the boiler. In this heating chamber a water pipe, disposed in any number of coils, for heating the boiler feed-water, and a coil of steam pipe, are situated, wherein steam taken from the upper part of the boiler is superheated before entering the gas generator. This last consists of a spherical chamber from which a pipe projects downwards into a hollow casing. An oil supply-pipe delivers liquid hydrocarbon into the body of the chamber, and an outlet pipe from the top of this latter forms a means of exit for the gas produced. The generator, with its outer casing, is situated partly within and partly above the central vertical flue, so that it is heated by the products of combustion passing upwards from the firebox. Steam is forced into the hollow casing of the generator where it is superheated, and whence it passes upwards through the pipe above-mentioned into the spherical chamber. Here it

Improvements in Appliances for increasing the Illuminating Effect of Gas. Jas. Maclear, London. Eng. Pat. 6811, May 20, 1886. 4d.

THIS invention relates to increasing the luminosity of a flame by heating therein a material capable of becoming incandescent. The materials used are strontia, baryta, thorium and zirconia. Cotton wicks or wicks of other fibrous material are employed as vehicles for carrying the incandescent bodies. They are wound or twisted round a thin platinum wire into suitable forms, such as spiral, helical, etc., and are then saturated with a solution of strontia, for instance. When dried and ignited they are ready for use.—A. R. D.

III.—DESTRUCTIVE DISTILLATION. TAR PRODUCTS, Etc.

Thionaphthen. V. Meyer. Ber. 19, 1432.

By the condensation of thiophen aldehyde (Ber. 19, 636) with succinic acid, according to Fittig's method, Biedermann obtained, in the author's laboratory, the α naphthol of the thiophen group—*hydroxythionaphthen*, $C_8SH_6.OH$. This substance closely resembles α -naphthol in properties and reactions, and is described in the next abstract. The author is experimenting on the conversion of conmarone $C_{10}H_8O$ into thionaphthen C_8SH_6 by the action of phosphorus trisulphide.—D. B.

Thiophenol and α-Naphthol of the Thiophen Group.
A. Biedermann. Ber. 19, 1615—1620.

HITHERTO it has been impossible to obtain the phenol of thiophen; the author has, however, prepared its thiophenol—*thienylmercaptan*, C_4SH_3 —SH. For this purpose thiophen was converted into thiophenmonosulphonic acid, $C_4SH_2SO_3H$, and this into thiophensulphonic chloride, $C_4SH_2SO_2Cl$. The latter was then subjected to the action of zinc-dust, in order to obtain thiophensulphinic acid, according to the method adopted by Otto for preparing benzenesulphinic acid (Ber. 10, 939). The zinc-salt of the thiophensulphinic acid was gradually introduced into a mixture of granulated zinc and hydrochloric acid, thienylmercaptan being formed. It is a pale-yellow oil, having a disagreeable odour, resembling that of phenylmercaptan, and boils at 166° (uncorr.). On exposure to the air it gradually solidifies to a crystalline mass, which is probably *thienyldisulphide*, $C_4SH_3 \cdot S \cdot S \cdot C_4SH_3$. Thienylmercaptan yields azo-dyes with diazo-compounds, and in this respect differs from phenylmercaptan, which does not react with diazo-compounds.

Hydroxythionaphthen, $C_{10}SH_7OH$, was prepared by heating a mixture of 6·8 grms. of thiophenaldelyde, 10 grms. of finely-powdered sodium succinate (dried at 140°), and 6 grms. of acetic anhydride to 135° , dissolving the product in dilute caustic soda, extracting the unattacked aldehyde with ether, and precipitating the naphthol in the alkaline solution with hydrochloric acid. It crystallises from alcohol and ether in long white needles, which melt at 72° , sublimes in the same crystalline form, is sparingly soluble in water, but dissolves freely in dilute alkalis. A number of characteristic colour reactions are given.

The alcohols of thiophen known at the present time are—

Nitrothiēnol, $C_4SH_2(NO_2)(OH)$. (Meyer and Stadler.)
Thienylalcohol, $C_4SH_2CH_2OH$. (Biedermann.)
Thiēnol (methylthiēnol), $C_4SH_3(CH_3)(OH)$. (Paal.)
Hydroxythionaphthen, $C_{10}H_7(C_2SH_2)(OH)$. (Biedermann.)—D. B.

On Pyrene. E. Bamberger and M. Philip. Ber. 19, 1427—1431.

It has been demonstrated by Graëbe that pyrenequinone belongs to the class of diketones. From investigations of Hinsberg's reaction for ortho-diketones—namely, their property to form quinoxalines with ortho-diamines (this Journal, 1885, 511)—and from the colour reaction exhibited by ortho-diketones with alcoholic potash (this Journal, 1885, 370), the authors infer that pyrenequinone does not contain the two carbonyl groups in direct combination with one another.

Pyrenic Acid, $C_{15}H_8O_5$.—On oxidising pyrene with chromic acid, Hintz and Goldschmidt obtained, besides pyrenequinone, a substance soluble in sodium carbonate, having the formula $C_{15}H_8O_5$. The authors now find that this body, as analysed by these chemists—*i.e.*, recrystallised from glacial acetic acid—has the formula $C_{15}H_8O_4$ assigned to it. During the process of recrystallisation, however, the original substance, which is separated from the soda solution by the addition of an acid, is changed in chemical constitution, being deprived of water. The composition of the product obtained by direct precipitation is $C_{15}H_8O_5$; it is a well-defined acid, which the authors have named *pyrenic acid*. When heated to 120° , or recrystallised from glacial acetic acid, the anhydride $C_{15}H_6O_4$ is obtained. Pyrenic acid separated from its saline solutions by means of an acid, forms gold-coloured shining laminae; its anhydride crystallises from glacial acetic acid in short yellow needles having a vitreous lustre. The acid is dibasic, as proved by the constitution of the silver and barium salts; hence, the formula $C_{15}H_8O_5 = C_{15}H_6O(COOH)_2$, whilst the ease with which the anhydride and imide are formed affords proof to the ortho-position of the two carboxyl groups; hence, the acid $C_{15}H_8O_5 = C_{15}H_6O(COOH)_2[CO_2H:CO_2H = 1:2]$, and the anhydride $C_{15}H_6O_4 = C_{15}H_6O \begin{Bmatrix} CO \\ CO > O \end{Bmatrix}$. By dissolving the acid in ammonia, and heating the solution

gently, a yellow precipitate is obtained, which is the imide of pyrenic acid, having the formula $C_{15}H_7O_3N = C_{15}H_6O \begin{Bmatrix} CO \\ CO > NH \end{Bmatrix}$. —D. B.

Improvements in treating Hydrocarbon Bodies or Substances. J. K. Field, London. Eng. Pat. 10,139, May 27, 1886. 6d.

THIS is a process for purifying either solid or liquid hydrocarbons such as earthwax, paraffin seal, or mineral lubricating oil. The material is freed from water and dirt preferably by heating over an open fire, and is then agitated with fuming sulphuric acid. It is next freed from acid, and digested with a suitable solvent such as naphtha in the presence of say fifteen per cent. of bleaching material or decolorant such as bone-black. After settling out, the clear solution is run off and treated with more decolorant. The naphtha is now distilled off, and the solid residue again acidified and treated with decolorant, which leaves it thoroughly bleached. In some cases the acidifying may be dispensed with, and, with mineral oil, the addition of a solvent is not always required.—A. R. D.

IV.—COLOURING MATTERS AND DYES.

Constitution of α-Naphthylaminesulphonic Acid (Naphthionic Acid) and of Congo-red. O. N. Witt. Ber. 19, 1719—1722.

CLÈVE has already shown that α-naphthylaminesulphonic acid probably has the constitution $C_{10}H_7(NH_2)(SO_3H)$ [$NH_2:SO_3H=1:4$], for by treatment with phosphorus pentachloride it is converted into dichloronaphthalene, of melting-point $67\cdot5^\circ$. As this proof is not quite beyond doubt, a further confirmation of the formula appeared desirable. This was afforded by the reaction of the acid with diazo-compounds. As is well known, when phenols, amines, or their sulphonic acids are combined with diazo-compounds, the diazo-residue takes by preference the para position to the OH or NH_2 group; but when this place is already occupied it takes an ortho position.

α-Naphthylaminesulphonic acid readily combines with diazo-compounds, and if it has the constitution assigned to it by Clève, these azo-products will have the formula $C_{10}H_5(NH_2)(N_2R)(SO_3H)$ [$NH_2:N_2R:SO_3H=1:2:4$], and will give on reduction *o*-naphthylenediaminesulphonic acid, $C_{10}H_5(NH_2)_2(SO_3H)$ [$NH_2:NH_2:SO_3H=1:2:4$]. Of these azo-compounds, the one selected for examination was Congo-red, which is formed by the combination of tetrazodiphenyl with α-naphthylaminesulphonic acid. The aqueous solution of the dyestuff is readily reduced by the addition of ammonia and zinc-dust. On cooling, benzidine crystallises out, and the solution contains *o*-naphthylenediaminesulphonic acid. The latter was not isolated, but was identified as an ortho-diamine by its capability of giving a quinoxaline with phenanthraquinone. The aqueous solution obtained as above was acidified with acetic acid, and mixed hot with a solution of phenanthraquinone dissolved in aqueous sodium bisulphite with addition of sodium acetate. A crystalline precipitate of the sodium salt of diphenylene-β-naphthaquinoxalinesulphonic acid—

quickly separates. This sodium salt forms fine yellow needles, tolerably soluble in hot *pure* water to a yellow solution with a green fluorescence, but precipitated by the slightest trace of sodium hydrate or any salt. On heating it is decomposed, and diphenylenenaphthaquinoxaline sublimes. The free acid forms orange-red flocks, which become crystalline on boiling, and dissolve with a violet colour in strong sulphuric acid. Hence, Congo-red has the constitution—

On Fisetin, the Colouring Matter of Fustic-wood. Jakob Schmid. *Ber.* 19, 1734—1749.

ALTHOUGH the dyestuff of young fustic has been examined at various times by several investigators, very little light has as yet been thrown upon its constitution, the usual opinion being that it consists of quercetin contaminated with a red dyestuff. The author shows that this is not the case, for the wood contains a yellow dyestuff only—viz., *fisetin*, which is quite distinct from quercetin; the red colouring matter previously observed being formed by the oxidation of the *fisetin* in the process of isolation. The yellow colouring matter occurs in the wood as a tannic acid compound of the glucoside of *fisetin* (named by the author *fustin tannide*).

Fustin Tannide.—To obtain this body the wood is extracted with boiling water, the solution treated with lead acetate and acetic acid to precipitate impurities, the excess of lead removed by H_2S , the filtrate concentrated and saturated with salt, which precipitates the greater part of the tannic acid, and finally the *fustin tannide* extracted from the solution by acetic ether, from which it crystallises on evaporation. It forms long yellowish-white needles, easily soluble in water, alcohol and ether. With lead acetate and stannous chloride, it gives white precipitates, soluble in acetic acid. By warming with acetic acid it is resolved into *fisetin-glucoside* (*fustin*) and tannic acid (probably the tannic acid of sumac). By warming with alkalis or mineral acids, it is resolved into *fisetin*, a glucose, and tannic acid.

Fustin (Fisetin Glucoside), $(C_6H_{11}O_6)(C_{23}H_{12}O_5)_2 \cdot O$, $(C_{23}H_{12}O_5)(C_6H_{11}O_6)$.—This body crystallises from hot water in fine silvery needles, easily soluble in alcohol and dilute alkalis, sparingly in ether. It melts at $218-219^\circ$ with decomposition. With lead acetate and stannous chloride, it gives yellow precipitates soluble in acetic acid. Ferric chloride gives a beautiful green colouration, which, on adding dilute sodium carbonate, passes through bluish-violet into red. On heating, the glucoside reduces silver nitrate and Fehling's solution. By warming with dilute H_2SO_4 , it is split up into *fisetin* and a glucose (probably isodulcite).

Fisetin, $C_{23}H_{10}O_5(OH)_6$.—The dyestuff is most conveniently prepared in a pure state from the extract of the dyewood, which comes into commerce in a solid form under the name of "cotinin." The product is extracted with alcohol, and the impurities precipitated by careful addition of acetic acid and lead acetate; after removing the excess of lead by H_2S , the dyestuff is precipitated by the addition of hot water. By recrystallisation from dilute alcohol or acetic acid, it forms fine yellow needles, or yellow prisms ($+6H_2O$). It is very slightly soluble in hot water, easily soluble in alcohol and acetic ether, sparingly in ether and benzene. It melts at a high temperature, and sublimes in microscopic needles. With lead acetate and stannous chloride it gives orange precipitates soluble in acetic acid, with ferric chloride it gives a dark-green colouration. It reduces silver nitrate and Fehling's solution on heating. Fuming HNO_3 oxidises it to picric and oxalic acids. By fusion with KOH, or by reduction with sodium-amalgam in alkaline solution, it yields phloroglucinol and protocatechuic acid. On the other hand, by reduction with sodium-amalgam in acid solution, a red colouring matter is formed, which is readily reoxidised to *fisetin*, and gives a beautiful green colouration with KOH. The sodium and potassium salts of *fisetin* crystallise in yellow needles, and have the composition $C_{23}H_3O_5Na_2$ and $C_{23}H_4O_5K_2$. By heating *fisetin* with acetic anhydride and sodium acetate, it yields a hexacetyl-*fisetin*, $C_{23}H_4O_5(C_2H_5O_2)_6$, which crystallises from alcohol, in which it is sparingly soluble, in fine white needles, of melting-point $200-201^\circ$. The hexabenzoyl-*fisetin*, $C_{23}H_{10}O_5(OC_6H_5)_6$, forms white felted needles, sparingly soluble in alcohol, melting at $184-185^\circ$. By heating *fisetin* with ethyl iodide and alcoholic potash, the hexa-ethyl ether, $C_{23}H_{16}O_5(OC_2H_5)_6$, is formed, which crystallises in long yellow needles, of melting-point $106-107^\circ$, easily

soluble in alcohol, ether, etc. The hexamethyl ether, $C_{23}H_{16}O_5(OC_2H_5)_6$, forms yellow needles, melting at $152-153^\circ$.—A. G. G.

Preparation of o- and p-Nitraniline from the Corresponding Nitrophenols. V. Merz and C. Riz. *Ber.* 19, 1749—1754.

THE best method at present known for the preparation of *o*-nitraniline is that given by Nietzki and Benkiser (*Ber.* 18, 2296), which consists in sulphonating acetanilide, nitrating the acetylsulphanilic acid, and finally removing the SO_3H group by heating with HCl. As the last stage of this operation is somewhat troublesome if the substance is required in quantity, the following method of preparation will probably prove more convenient. The author finds that if *o*-nitrophenol is heated with aqueous ammonia under pressure, the OH group is replaced by NH_2 . Twelve parts of *o*-nitrophenol are heated with 20 parts of aqueous NH_3 (35%) for 16 hours at $160-170^\circ$; the product is crystallised from water. The yield of *o*-nitraniline is about 60 per cent. of the *o*-nitrophenol employed. On the large scale the operation could probably be carried out in an iron autoclave.

p-Nitraniline is also formed in the same way by heating *p*-nitrophenol with aqueous NH_3 at $190-200^\circ$; the yield being likewise about 60 per cent.—A. G. G.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Improvements in obtaining and treating Fibres from the Barks of Plants of the Urtica Family and the like. G. W. H. Brogden and E. Casper, London. From E. Fremy and V. Urbain, Paris. Eng. Pat. 2817, February 26, 1886. 6d.

THIS invention relates to the treatment of rhea fibres for effecting the separation of their epidermis from their inner integument. Various methods of treatment with alkalis are described, also a method of treatment with oleate of soda instead of caustic soda. The object of these various processes is in each case the elimination of pectose, cutose and vasculose.—H. A. R.

VII.—ACIDS, ALKALIS, AND SALTS.

Solubility of Calcium Oxide, with some Remarks on Lime Water. A. Goldammer. *Pharm. Centralb.* 26 442—446, 455—457.

THE author has again confirmed the known fact that the solubility of lime decreases with rise of temperature, and that at the boiling point of water scarcely one-half of the amount of lime which water takes up at 0° is dissolved. He also confirms Lamy's statement that the longer the lime and water remain in contact, the less calcium oxide is dissolved. The slaking of the lime has a great influence on its solubility, and the strength of the solution varies according as more or less water has been used to slake the lime, especially at the beginning. A large number of experiments show that while calcium oxide possesses in a marked degree the property of forming supersaturated solutions, calcium hydroxide does not. Solutions supersaturated at a low temperature contain about 2.4 grms. per litre (about double the quantity in ordinary lime water). At temperatures above 12° Goldammer found an average of 1.8 grm. CaO per litre. It is difficult to give an exact ratio for the solubility of calcium oxide in water, but 1:800 expresses as nearly as possible the proportion for an average temperature. In order to obtain a strong and equal lime water it is necessary to thoroughly shake the mixture of lime and water at the beginning. The caustic lime used should be as free as possible from calcium carbonate. The author gives the following method for the preparation of lime-water:—1 part of calcium oxide prepared from marble is slaked with 0.5 part distilled water, and the powder obtained added to 100 parts

distilled water, and the mixture well shaken. The lime-water is clear and colourless, and 100cc. should require at least 4cc. normal acid for neutralisation.

—G. H. M.

Improvements in the Manufacture of Chlorine from By-products of the Ammonia Soda Process, or similar Chemicals obtained from other Sources. W. P. Thompson, Liverpool. From Solvay & Co., Brussels. Eng. Pat. 8724, July 20, 1885. 6d.

THIS invention is a supplement to previous patents granted to Solvay in 1880 (No. 838) and 1884 (No. 7258). The process patented is the decomposition of calcium chloride with silica and alumina in presence of air. In practice this operation is carried out in a cupola furnace, but the heating of the cupola being a difficult problem, the inventors propose the addition of a certain proportion of inert material to the matter to be decomposed, in order to absorb the heat of the issuing gases, and to impart this heat to the air necessary for the decomposition. Formerly it was intended to use the residue from this process for making cement. It is now proposed to mix the residue, which consists of calcium oxide, alumina and silica, with solid ammonium chloride, and heat the dry mixture to 350° C., when all the ammonia is liberated, the chlorine combining with calcium to calcium chloride, which is thus most intimately mixed with alumina and silica, and well adapted to produce chlorine under the influence of air and heat. The same silica and alumina may thus be used over and over again to decompose successively an indefinite quantity of ammonium chloride.—S. H.

A New or Improved Process for treating Galvanised Iron or Steel. H. Grimshaw, Manchester. Eng. Pat. 9993, August 24, 1885. 6d.

THIS invention relates to a process intended principally for treating waste galvanised sheet iron or steel, so as to separate metallic zinc from iron, and utilise the same. The waste galvanised iron is treated either with dilute sulphuric, hydrochloric or nitric acids, or with a boiling solution of zinc chloride or sulphate which dissolves the zinc, leaving the iron or steel undissolved.—S. H.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Improvements in Drying and Evaporating Apparatus for use in the Manufacture or Treatment of Cement and other Materials. C. Kingsford, Middlesex. Eng. Pat. 6813, June 4, 1885. 8d.

THE inventor refers to a former specification (12,379, September 13, 1884), describing an apparatus for drying, evaporating, or calcining various materials, by the waste heat from a coke oven or other furnace, with which the said apparatus can be combined or connected. His present invention provides for the more economical and advantageous utilisation of the waste heat of coke ovens, by combining therewith a steam boiler or generator, such as was described in a former specification of the inventor's (1078, March 6, 1882), together with means for drying, etc., somewhat similar to those particularised in Eng. Pat. 12,379, September 13, 1884. An important application of the improved apparatus is the drying of slurry in the manufacture of cement.—E. G. C.

Improvements in the Manufacture of Plaster, and in the Machinery and Apparatus used in connection therewith. R. Stone, London. Eng. Pat. 8096, July 3, 1885. 6d.

THE raw materials, such as chalk, limestone, etc., are first treated with sulphuric acid, then burned in furnaces or kilns at an intense heat, and lastly ground, direct from the furnaces or kilns, by machinery described in detail in the specification. When the plaster is required to set very hard "a proportion of alumina, such as that

derived from river mud, unmanufactured, as obtained direct from the river bank," is burned with the materials soaked in vitriol.—E. G. C.

Improvements in the Manufacture of Artificial Stone. W. P. Thompson, Liverpool and London. From G. Lilienthal, Victoria. Eng. Pat. 9780, August 18, 1885. 4d.

KEENE'S marble cement (alum-gypsum), slaked lime, and curdled milk, are intimately mixed together, with or without addition of colouring matter, and worked to a very stiff paste. The mass thus obtained is cut off while coming through the opening of the mixer, and pressed into moulds of a suitable size and shape. The blocks harden without artificial heat, and can be employed as mosaic pavement and model stones.—E. G. C.

Improvements in the Treatment of Sewage Water by the Lime Process for the Production of Cement. G. R. Redgrave, London. Eng. Pat. 6520, May 15, 1886. 4d.

THE specification describes improvements upon the various patents granted to Major-General Scott for a like purpose. Finely-divided, washed clay is added to the undefecated sewage, which is then allowed to settle in a tank in the usual way. The effluent from this tank is divided into two portions—one containing five-sixths of the whole; this portion is treated with caustic lime, 20 to 24 grains per gallon being used. The effluent from the settlement of this is mixed with the one-sixth portion remaining from the first treatment, which is treated only with from 6 to 9 grains per gallon. The final effluent is clear, and not so highly alkaline, as is usual in the ordinary lime treatment. The sludge from the first tank is dried and used as manure, that from the second and third calcined into cement in the usual way.

—C. C. H.

X.—METALLURGY, Etc.

Cupola with Steam Blast. Beekert. Stahl. u. Eisen, 1886, 6, 399.

THE cupola designed by F. A. Herbertz, Cologne, is said to be economical in fuel, at least for small and moderate-sized foundries. The throat of the cupola is closed by means of doors, beneath which is placed a double tube within the wall ascending obliquely, and into which steam is blown. The hearth hangs beneath the shaft by means of bolts, and an adjustable slit is thus formed, which completely surrounds the furnace through which air is admitted to the cupola, instead of by the usual tuyères. The whole of the carbon of the fuel is said to be converted into carbonic anhydride, resulting in decided economy in fuel. The iron melted is said to be less changed than in other cupolas, the loss being 2.4 to 2.6 per cent., as against 6 per cent. in other furnaces.

—J. T.

Iron Phosphide in Basic Bessemer Slag. E. Jensch. Chem. Zeit. 10, 820.

THE author combats the idea that a considerable proportion of phosphorus occurs in the slag as phosphide. His experiments lead to the results obtained by J. Klein (Chem. Zeit. 10, 721)—namely, that the amount of phosphide present is almost a vanishing quantity. Thus, in eight samples of slag, the average amount of phosphoric acid obtained by the action of the powerful oxidising agents, alkaline carbonates with potassium chlorate, nitro-hydrochloric acid, and nitric acid, was 18.83 per cent., whilst solution in hydrochloric acid gave 18.54 per cent., showing a difference of 0.29 per cent. of phosphoric acid, or 1.54 per cent. of the phosphoric acid which may be supposed to be derived from phosphide. The maximum given by the slags was 3.79 per cent. Since the phosphate dust is largely employed in agriculture it was sought to ascertain whether this small amount of phosphide is readily decomposed so as to

become available for the plants. Slags showing the greatest amounts of phosphide were extracted repeatedly with hydrochloric acid, and the residue thus obtained was mixed with (a) garden soil, and (b) sandy loam, in which oats were sown. The plants grew excellently. The only liquid supplied to them was a titrated solution of sodium nitrate. At the end of three months the phosphide was almost completely converted into ferrous phosphate.—J. T.

Improvements in the Process of and Means for Zincing or Coating Sheet Metal with Zinc. F. W. Kofler and E. Zwierzina, Vienna. Eng. Pat. 12,485, October 19, 1885. 8d.

IN the hot process of zinc coating, the same mechanism which effects the withdrawal of the plate from the metal bath, causes the application of rotating steel wire brushes to the surface of the plate, whereby the excess of zinc is removed, and a better and more serviceable sheet is obtained.—W. G. M.

A New or Improved Treatment of Blast Furnace or other Slags for subsequently obtaining Useful Products therefrom. G. Craig, Lugar, N.B. Eng. Pat. 6128, May 6, 1886. 4d.

SLAGS in the compact state in which they usually occur, are almost unaffected by acids. It is proposed to obtain porous slags by means of the following machinery:—The molten slag direct from the furnace is run into a horizontal iron pipe, which is partly submerged in a trough of water. Through the centre of the pipe works an archimedean screw which drives the slag towards the end of the trough, thus permitting the liquid slag always to fall into clear water. The slag may be removed from the trough by means of a Jacob's ladder. A certain proportion of the sulphur existing in the slag is evolved as sulphuretted hydrogen, and may be utilised in the usual way. The slag, without further preparation, may then be treated with acids, when it is quickly decomposed.—S. H.

Improvements in Metallic Alloys. P. A. Newton, London. From C. A. Paillard, Geneva. Eng. Pat. 6367, May 11, 1886. 6d.

IT is sought to substitute for the use of steel in the mechanism of chronometers and watches, that of a non-magnetic and inoxidisable, but hard and elastic metal of small expansibility. For this purpose a series of nine alloys is described, consisting essentially of palladium (65 to 72 per cent.), copper (25 to 14.5 per cent.), and silver (5 to 10 per cent.), with smaller and variable proportions of nickel, steel, gold, platinum, or rhodium (singly or together) which may be used for hair springs and compensation balances. A harder metal for rollers, escapement wheels, and the like, contains 45 per cent. palladium, 25 silver, 15 copper, with 5 gold, 5 nickel, 3 steel, and 2 platinum. These alloys may be hardened by slow cooling from a red heat. They are best made by fusing half the palladium with all the other constituents under borax and charcoal, then re-fusing with the remainder of the palladium, and pouring into ingot moulds of the shape dictated by subsequent requirements.—W. G. M.

Improvements in the Process for Coating the Surface of Iron or other Metals with Tin, Lead, or Zinc. A. Gutensohn, London. Eng. Pat. 6404, May 12, 1886. 4d.

AFTER pickling, and before plunging into the bath of coating metal, the plates are dipped in a fluxing solution of chloride of tin, borax and ammonium chloride, containing from two to five per cent. of glycerine and a very slight excess of free hydrochloric acid. By increasing the quantity of acid, the necessity for the preliminary stage of "white pickling" is obviated.—W. G. M.

XL.—FATS OILS, AND SOAP MANUFACTURE.

Action of Sulphuric Acid on Oleic Acid. A. Szabanczew. Russ. Phys. chem. Ges. 18, 35 and 57.

PURE oleic acid cooled to 6° was treated with sulphuric acid (sp. gr. 1.8405) in the proportion of their molecular weights. The reddish-brown substance thus obtained was dissolved in ether and the solution agitated with water. The portion soluble in water was found to consist of *sulphohydroxystearic acid*, $C_{17}H_{33}O_2H(SO_3H)(CO_2H)$. The insoluble portion was again treated with ether and thereby separated into a solid and liquid part. The solid was *hydroxystearic acid*, whilst the liquid product consisted of a mixture of *hydroxystearic anhydride*, *hydroxystearic acid* and unaltered oleic acid. The author is of opinion that the action of sulphuric acid on oleic acid cannot be expressed in one equation, as illustrated by Müller-Jacobs, Liechti and Suida and Lukjanow, but supposes that several reactions occur simultaneously.—D. B.

Improvements in Liquid Soap. R. Livesey. From Dr. Duncan, St. Petersburg. Eng. Pat. 12,305, October 15, 1885. 4d.

THE soap is made from 50 parts cocoa oil or oleine, 20 alcohol, 20 glycerine, and 10 potash (K. H. D. F. in F.), and the ingredients required for scenting and colouring, or for sanitary and medical purposes, are then introduced. No further details are given.—W. L. C.

Extracting Oils from certain Waste Products. A. T. Hall. Eng. Pat. 12,492, October 19, 1885. 6d.

IN "tinning" iron plates, baths of hot grease or oil are employed in the finishing operation, and bran is employed to remove the grease adhering to the plates. Under this patent, the oily bran is treated with a solvent, such as light petroleum oil, by well-known methods, for the recovery of the grease and the cleansing of the bran.—W. L. C.

Improvements in Refining Vegetable Oils. A. T. Hall. Eng. Pat. 13,361, November 4, 1885. 4d.

CRUDE OIL is mixed with an equal quantity of petroleum spirit or of carbon disulphide, and to the mixture is added in thread-like streams, from $\frac{1}{2}$ to 5 per cent. of sulphuric acid. After agitation and subsidence, the oil solution is filtered through animal charcoal, and the solvent is then recovered by distillation.—W. L. C.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

A New or Improved Method of Preparing Elastic Leather and Elastic Material (suitable for Moulding) from Animal Textures or Leather containing Gelatin. Lorentz Albert Groth, London. From Friederich Wilhelm Grüne, Berlin. Eng. Pat. 9603, August 12, 1885. 4d.

ANIMAL textures containing gelatin, such as leather, parchment, etc., are steeped in an aqueous solution of glycerine or sugar and then dried. The material is then exposed to steam at a low pressure or direct heat. There is thus produced a thick, elastic mass which may be moulded by suitable means, etc.—B. H.

Improved Compound for application to Wood, Metal, or other Substance as a Paint or Varnish to prevent Decay, Rust, or other Injury by Atmospheric Action. Henry Gardner, London. From David Lublinski, Schwet, Germany. Eng. Pat. 10,409, September 2, 1885. 6d.

THE compound is made by melting together 25,000 parts linseed oil, 31,250 colophony, 18,250 doubly-rectified American petroleum, 1,250 levigated litharge, 500 pulverised zinc sulphate, 1000 pulverised potash-alum, and 250 parts carbolic acid of 15–20 per cent. The mixture is then boiled for two hours, and allowed to stand for two days.

The clear fluid, called by the inventor "ceralin," can be used without other addition for the impregnation of wood, etc. Mixed with colour it forms a preservative paint for iron.—B. II.

XV.—SUGAR, GUMS, STARCHES, Etc.

Preparation of Calcium Saccharate. Sueretic Indigène, 27, 488.

THE lime used as precipitant in Steffen's defecation process may be substituted by ammonia, the trisaccharate being insoluble in highly-ammoniacal solutions. The ammonia employed is recovered from the liquors.—D. B.

Percentage of Juice in the Sugar Cane. Spencer. Jour. Fabr. Sucre, 27, 15.

ACCORDING to Delteil, the sugar cane contains 85–92 per cent. of juice, whilst Pellet obtained from 88–90 per cent. and MacCulloch 85 per cent. The author gives 90.5 per cent. as the average number of a series of trials. Beet contains from 94 to 95 per cent. of juice.—D. B.

Improvements in the Manufacture of Crystallised Grape-sugar. Alfred Seyberlich, Riga; and Alexander Trampedach, Mitau, Russia. Eng. Pat. 8000, July 1, 1885. 6d.

CONSISTS of a process for the manufacture of crystallised grape-sugar in which the employment of alcohol, bone-charcoal, or permanganate of potash for the purification and cleaning of the liquid grape-sugar is rendered unnecessary.

The saccharification of the starch is accomplished by the exclusive or predominant use of dilute nitric acid, and the sugar liquor prior to inspissation in a vacuum is made strongly alkaline by means of carbonate of soda. It is found that on evaporation of the strongly alkaline syrup to about 33° to 36° Baumé, and on then leaving to cool, the grape-sugar separates out in fine bold crystals, which can be easily separated from the mother-liquor. On the other hand, if the acid syrup be merely neutralised and not made strongly alkaline, the grape-sugar only separates with difficulty and in the form of fine needles, which cannot easily be freed from the mother-liquor.

—A. J. K.

A Honey Substitute. Charles Lyle and J. J. Eastick, London. Eng. Pat. 8863, July 22, 1885. 4d.

THIS article is produced by mixing dextrose, levulose, and cane-sugar in the proportions found in real honey, with in some cases the addition of other matters, such as fruit and flower essences, to give it the flavour of real honey.

It is usual to add 35 parts dextrose to 40 parts of levulose, and then to this mixture add cane-sugar until a 10 per cent. solution of the whole mixture reads 1° on the scale of a Soleil-Weutze polariscope.—A. J. K.

The Improved Utilisation of Sugar Cane. A. G. Wass, Bermondsey. Eng. Pat. 9249, August 1, 1885. 6d.

THIS consists of a process by which the cane or residue of sugar boiling is dried, pressed, and then heated for some time in order to cause carbonisation. The carbonised material can then be used for the body of paint or ink, as a disinfectant and as a fertiliser, or it is suitable for filtering purposes.—G. H. M.

An Improved Process of Manufacturing Sugar from Amylaceous and Cellulose Matters. A. C. Henderson, London. Eng. Pat. 10,110, August 26, 1885. 4d.

NO acid is used in this process. Twenty-five per cent. of the amylaceous or cellulose matter (preferably potatoes) are mixed with 75 per cent. of water and boiled in a digester at a pressure of four atmospheres and temperature of 125° C. The boiled mass is afterwards removed, cooled down to 45° C., and 10 per cent. of brown

kiln-dried malt is then added. The whole is well stirred and allowed to rest about two hours. The syrup is finally evaporated down in a vacuum pan at 70° C. and allowed to crystallise.—A. J. K.

Improvements relating to the Refining of Sugar, and to Apparatus therefor. H. H. Lake, London. Eng. Pat. 3727, March 16, 1886. 11d.

THE object of this invention is the saving of labour in connection with the manufacture of loaf sugar in moulds. By an elaborate arrangement of trucks and rails extending over the whole works, the sugar, after it is once filled into the moulds arranged on one of the trucks or carriages, is not removed again from that carriage until all the refining operations have been completed. Full description with diagrams of the necessary plant is given.

—A. J. K.

Improvements in Apparatus for the Manufacture of Refined Sugar. Peter Jensen. From M. C. P. Barbe, Amsterdam. Eng. Pat. 4516, March 31, 1886. 6d.

THIS relates to an improvement in the construction of the partition wedges and centrifugal drum described in a previous patent (Eng. Pat. 10,172, August 27, 1885). According to the present invention, these wedges are simplified in construction, and so modified as to serve also for lifting out the slabs of sugar from the centrifugal hydro-extractor.—A. J. K.

XVI.—BREWING, WINES, SPIRITS, Etc.

New Process for Preserving and Saving Hops in Brewing. L. Boulé. Compt. Rend. 102, 833.

THE process consists in (1) mechanically separating the lupulin situated at the base of the hop cones, (2) extracting the hops freed from lupulin with boiling distilled water, and drying the extract at a low temperature in a vacuum, and (3) intimately mixing the lupulin with the dried powdered extract.—D. B.

Improvements in the Manufacture of Syrup and Beer from Maize, or Indian Corn and Rice. H. H. Lake. From A. E. Feroe, Poughkeepsie, U.S.A. Eng. Pat. 9950, August 21, 1885. 5d.

THIS is to provide an economical method of separating the insoluble matter in a malt and maize mash from the soluble portions. The chief features are the method in which the starch of the maize is prepared for conversion, thus requiring only a small quantity of malt; the presence of a comparatively small quantity of fine insoluble matter owing to the use of granulated maize with granulated malt instead of ground meal and malt; and an easier way of separating the fine insoluble matter after conversion by means of gelatine and a gas. Detailed description of the method employed, together with illustrations of the plant employed, are given.—G. H. M.

Improvements in treating Wines and Liquors with Electricity, and an Apparatus for the purpose of carrying out the same. E. J. Fraser, San Francisco, U.S.A. Eng. Pat. 11,153, September 19, 1885. 5d.

THIS consists of improvements in the application of electricity to alcoholic liquids for the purpose of "ageing" them. This is done by the "induction process," placing a coil or helix, formed like the helix of an electro-magnet, in the wine or other liquid, and connecting the coil with a battery. Full descriptions of apparatus employed are given.—G. H. M.

Improvements in the Production of Non-alcoholic and Unfermented Wines, Drinks, and the like. H. N. Eckel, London. Eng. Pat. 16, January 1, 1886. 6d.

THE preparation of wines and drinks from fresh grape juice, or from the juice of other fruits of an unferment-

able character and entirely free from alcohol, is apparently effected by sterilisation of the must, subsequent addition of antiseptics, and aëration with carbonic acid under pressure.—G. H. M.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

Pepsin. C. Sundberg. *Zeits. f. Physiol. Chem.* 9, 319–322.

THE author prepared in Hammarsten's laboratory the purest possible pepsin-solution. The outer layer of the coating of a calf's stomach was cut into shreds, finely ground with sodium chloride and then mixed with sufficient water to dissolve the salt; after two or three days it was filtered, and the sodium chloride removed by dialysis in acidified water; the protein bodies separated in the dialyser were filtered off, and the solution heated for some time to 40° in order to destroy the rennet ferment, and also to peptonise the still unchanged albuminoids. (It often requires one to two weeks before the solution gives no reaction with acetic acid and potassium ferrocyanide, and until no ring is formed after 8–9 minutes with Hellet's test.) The still acid liquid was now mixed with calcium chloride and sodium diphosphate solutions neutralised with dilute ammonia; this treatment repeated two or three times, the calcium phosphate solution containing pepsin collected on a filter, washed, and dissolved in a little 5 per cent. hydrochloric acid. When this solution is purified by dialysis, a very active pepsin solution is obtained; and since it gives no reactions for albumen—it differs in this respect from Briicke's pepsin solution, which reacts with platinum chloride, neutral and basic lead acetate, and is only precipitated by alcohol—Sundberg concludes that pepsin does not belong to the albuminoids.—G. H. M.

(B) SANITARY CHEMISTRY.

A New or Improved Treatment of Chemical Agents, and the Employment of the Resultant for the Precipitation, Clarification, and Defecation of Sewage Matters. G. W. Bremner, London. Eng. Pat. 13,761, November 11, 1885. 6d.

NATURAL phosphate of alumina—e.g., Redonda and Alta Vela phosphates—is calcined in a reverberatory furnace with sodium, potassium, or calcium salts. The resultant is then treated with water, with or without the addition of caustic soda or potash, at a temperature of 180° F. An acid extract may be similarly obtained by the use of mineral acids. The two solutions so obtained are added to the sewage in such proportions that “the products held in solution are liberated” and “the sewage matter is oxygenised.” The resultant sludge is filter-pressed, dried, ground and mixed with bone refuse. The claims are (1) the preparation of the extracts of phosphate of alumina as above described; (2) their use in the treatment of sewage.—C. C. H.

(C) DISINFECTANTS.

Improvements in the Manufacture of Carbon-alum, and Application of the same to Useful Purposes. T. H. Cobley, Dunstable. Eng. Pat. 9853, August 19, 1885. 6d.

CARBON-ALUM is an intimate combination of alumina with carbon, and is to be applied for treating sewage matter or such like purposes. Equal parts of coke-dust and clay are ground with water to a stiff paste, and then heated in a retort furnace or other contrivance, where the air can be excluded. The mass is then treated with one-third of its weight of sulphuric acid, 120° Tw., and allowed to digest by spreading it on a tile hearth heated at a low temperature. In order to use carbon-alum, thus prepared, for rendering innocuous, sewage matter or polluted water, the deodorising agent is exposed in

troughs or beds provided with perforations through which the sewage matter is made to pass. Or it may be ground up into a thin liquid state with water, and run into the polluted water kept in brisk agitation.—S. H.

The Manufacture of an Improved Antiseptic. H. H. Lake, London. From C. Collins & Co., Antwerp. Eng. Pat. 10,130, August 26, 1885. 4d.

THE patentee claims the production of an antiseptic having all the reactions and characteristics of salicylic acid by heating two volumes of phenic acid with one volume of Nordhausen acid. The substance produced is a mixture of ortho-, meta-, and para-oxyphenyl-sulphurous acid.—C. C. H.

Improvements in preventing and removing Incrustation in Boilers and Heaters. A. Roberts, Tipton. Eng. Pat. 10,423, September 3, 1885. 6d.

VEGETABLE MATTERS, such as hay ensilage, tan, oak bark, or Irish moss, are suspended in a cage in the interior of the boiler, the infusion of which accomplishes the object aimed at; or the infusion may be made in a separate small boiler and injected into the main boiler.—C. C. H.

XVIII.—ELECTRO-CHEMISTRY.

Improvements in the Manufacture of Carbon for Electric Lamps and other Electrical Apparatus. From La Société à Chertemps et Cie., Paris. Eng. Pat. 7222, June 13, 1885. 4d.

IN this invention, fluoride of boron and its derivatives are employed for dehydrating organic matter containing the elements of water in chemical combination, with the object of obtaining carbon suitable for use in the construction of lamps. After treating the organic matter with fluoride, it is subjected to an elevated temperature without access of air or oxygen, to remove excess of fluoride. The carbon is now impregnated with some carbo-hydrate, as sugar, glucose, etc., and the operations of exposure to fluoride, and submission to elevated temperature are repeated until the desired degree of density and conducting capacity in the carbon are attained.—B. T.

Improvements in Secondary Batteries, part of which is applicable to Primary Batteries. From Edmund Julien, Brussels. Eng. Pat. 8881, June 23, 1885. 8d.

THE scope of this invention is indicated by the claims:—The combination of parts forming an improved accumulator or secondary battery, the plates being composed of an alloy of lead, antimony, and quicksilver supporting the active materials of metallic salts contained in a bath, hold a suitable proportion of peroxide of hydrogen. The production of the alloy in the proportions indicated. In secondary batteries, the use of plates composed as above and coated with active material. The use in the conducting liquid of a variable proportion of peroxide of hydrogen for the purpose of counteracting the polarisation. In secondary batteries the use of corrugated plates and the use of perforated plates designed to replace sharp angles opposite each other by plane or curved surfaces. The improved mode of joining plates together by means of flexible conductors covered with gutta-percha, and joined at a common terminus.—E. T.

An Improved Process and Apparatus for treating Metals, Alloys, and especially Auriferous Ores by Electrolysis. Henry R. Cassel, London. Eng. Pat. 8574, July 15, 1885. 8d.

THIS patent is based on the action of nascent chlorine on gold and certain other metals, and its generation by the electrolysis of common salt. Gold is deposited at the cathode (see 4879, October, 1883). The apparatus consists of a drum containing carbons forming the positive pole, mounted upon a hollow shaft, the ends of

which pass into tanks forming the cathode, the drum revolving, and the portion of the shaft within the drum perforated, and its outer surface insulated and covered with asbestos. The hollow shaft has an archimedean screw for causing the solution to circulate, and for the removal of the slimes. The shaft passes through stuffing boxes into standards, which serve as tanks. The revolving apparatus contains carbons connected by metallic rods, and these are connected with one pole of the source of electricity by means of brushes or rollers, while the shaft on which the drum is mounted is connected with the other pole. There are twelve claims in the patent.—B. T.

Improvements in Galvanic Batteries. William Hy. Quarterman, London. Eng. Pat. 8733, July 20, 1885. 8d.

THE object of the invention is to simplify the charging and discharging of galvanic batteries so as to be readily used for domestic electric lighting. The construction is simply that of a series of glazed cells, each with an opening in the bottom capable of being stopped at will, and containing the carbon electrodes, which are hollow and closed at the top, the end projecting so as to be fitted to a cap or hollow cork. The zinc electrodes are tubular, and are made to fit tightly into the covers of the jars. The series of cells is contained in an outer vessel fitted with taps so that the liquids can be drawn off conveniently.—B. T.

Improvements in Electric Batteries. From A. W. Desruelles, Paris. Eng. Pat. 9415, August 7, 1885. 8d.

THIS invention relates to a battery, the exciting liquid in which is composed of sulphuric acid macerated with peroxide of manganese and mixed with mercury bisulphate, oil, glycerine and water. Also a depolarising liquid which has in addition to sulphuric acid and manganese peroxide, any alkaline bichromate and nitric acid and water. The carbon plates, or electrodes, are treated with a solution of sugar, which is subsequently carbonised; these plates are grooved so as to increase the depolarising surface. There are patented arrangements for hermetically closing the external and porous vessels of the battery, and contrivances for ensuring steadiness in the plates and securing them from injury by the action of the liquids. Also arrangements for protecting the suspending rods.—E. T.

Improvements in Electrical Accumulators or Storage Batteries. C. P. Elieson. Eng. Pat. 9522, August 10, 1885. 8d.

THE inventor employs spirals or cylinders of sheet lead separated superficially by insulating and acid-proof material. The cylinders are placed in frames of lead or other suitable material. The advantages claimed are—that no oxides of lead are required; that the spiral or cylinder affords a very large acting surface for electrical storage; that the cells so constructed increase in capacity so long as disintegration of the frames is avoided.—E. T.

Improvements in the Preparation and Production of Insulating Compounds for Electrical Purposes. Alexander Muirhead and C. R. A. Wright, London. Eng. Pat. 9580, August 12, 1885. 6d.

THIS patent is an extension of Eng. Pat. 5835 of 1883 and 8077 of 1884, and its object is to produce elastic materials from suitable oils more perfectly, and to purify such elastic materials, especially from unaltered oily matters which depreciate the insulating power, or facilitate decay. The use of chloride of sulphur is entirely obviated, and the polymerisation, which is often accompanied by partial dehydration, is effected by metallic salts having powerful affinity for water, such as zinc bromide and chloride or anhydrous copper sulphate. Castor oil is specifically referred to by the patentees, who classify their claims under four heads.—B. T.

An Improved Galvanic Element or Battery. From Karl Pollak and G. Wehr, Berlin, Germany. Eng. Pat. 9896, August 20, 1885. 8d.

THIS invention relates to a galvanic element in which the depolarising substances are always regenerated. Zinc and "metal" elements—i.e., Zn and Cu—are used by setting the "metal;" that is to say, in the case of a zinc-copper element, the copper in conducting connection with the carbon, which only dips partly in the exciting liquid, which will be different according to the nature of the element. The construction of the elements is by suspending a cylindrical glass vessel in a clay vessel provided with many openings. The clay cell is filled with small pieces of metallic lead or silver, mixed with pieces of carbon, and a suitable carbon plate dipping into this carbon and lead mixture serves to conduct the current to the terminal. Through the middle of the clay passes an insulated copper wire to the zinc plate placed below the perforated clay cell. The cylinder is so far filled with, for instance, a solution of common salt, that the clay cells dip but a little into the liquid. It is needed that the metal situated in the clay cell should be oxidisable. Drawings accompany the patent.—B. T.

Improvements in Compound Galvanic Batteries, and in the Method of working the same. S. H. Emmens, London. Eng. Pat. 10,011, August 24, 1885. 4d.

THE inventor proposes to simplify the construction of compound galvanic batteries, and to diminish the cost of charging the secondary elements. First, by employing as electrodes in each cell one or more peroxidised lead plates, which are so mounted as to be easily replaced. The electrolyte is dilute sulphuric acid by preference. The oxidation of the exhausted plates is effected by using them as anodes in a bath capable of yielding oxygen from the solution when electrolysed. The inventor uses copper sulphate as an electrolyte in the bath, because he can charge the lead plates by means of a current of lower electromotive force than that evolved by their discharge in the battery.—E. T.

Improvements in Galvanic Batteries. Leon Napoleon Loeb, London. From abroad. Eng. Pat. 2647, Feb. 23, 1886. 8d.

THE invention consists in the production of a new depolarising fluid, and of a ring or clamping device to hold in position the carbon plates or negative element of the battery, thus enabling the carbon plates to be placed close to the porous cell, and so decrease the internal resistance caused by the electric current having to pass through so large an amount of fluid. The depolarising fluid consists of 4lb. soda bichromate, 12 parts sulphuric acid, and water 6 parts by weight. The surface of the carbon is coated with paraffin, stearine, or wax.—E. T.

Improvements in Galvanic Batteries. Leon Napoleon Loeb, London. Communication from abroad. Eng. Pat. 2648, February 23, 1886. 8d.

THIS invention relates to improvements in the construction of galvanic batteries, specially for incandescent electric lighting. Essentially the construction is an outer box of wood or other non-breakable substance, lined internally with a close-fitting box or cylinder of paraffin, stearin or wax, and a cylinder of zinc, which rests in a groove or cup within the usual porous cylinder. The grooves retain sufficient mercury to keep the zinc amalgamated. The porous cup is properly supplied with sulphuric acid (1 to 5 of water). The outer jar is partially filled with a depolarising solution, consisting of salt, soda bichromate, sulphuric acid and water. The depolarisation is claimed as due to the production of free chlorine. There are seven claims in the patent.—B. T.

Improvements relating to the Conversion of Heat-energy into Electrical Energy, and to Apparatus therefor. From Willard E. Case, New York, U.S.A. Eng. Pat. 4937, April 8, 1886. 8d.

THE invention is based upon the decomposition by heat of chromium chloride, in the presence of tin, into free chlorine and chromium protochloride. The chlorine then combines with powdered metallic tin—to form tin protochloride—and as a consequence of this reaction an electrical current is established through the liquid and between the metallic tin as one electrode, and the carbon plate as the other electrode. The heat is maintained until all the tin is converted into protochloride: the apparatus—which is merely an open tank containing water—in which the decomposing vessel is placed, is now exhausted. The source of heat is removed and artificial cooling resorted to, when the original compound is re-formed, and by the time the normal temperature is reached, the original conditions are resumed, and the operation and the reactions commence on heating as at first. There are twelve claims in the patent.—B. T.

XIX.—PAPER, PASTEBOARD, Etc.

An Improved Method of making Paper Transparent to render it suitable as a Substitute for Glass for Photographic and other Purposes. W. B. Woodbury and F. Vergara, London. Eng. Pat. 9575, August 11, 1885. 6d.

THE paper prepared by this process is to be used in place of glass in photography, one advantage being the reduction in the weight of the plates. Thin and even-textured paper is to be treated in the following baths:—Benzene, 32 ounces; gum dammar, 61 ounces; mix well for 24 hours till gum entirely dissolved. Benzene, 2 ounces; gum elemi, $\frac{1}{2}$ ounce; mix as above. The two solutions are mixed and filtered thoroughly through fine muslin. The paper is to be treated in separate sheets, and dried at about 80° F. The second bath consists of the following:—Gelatine, 2 ounces; water, 40 ounces, after which the paper is allowed to dry. Sheets of paper rendered transparent in this way can be used for coating with emulsion, or for other purposes, such as making tracings or drawings. When used as a substitute for glass for photo-negatives, paper so treated is very light, and has many other advantages over glass for this and many other purposes.—H. A. R.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

On a Constituent of the Root of Paeonia Moutan. W. Will. Ber. 19, 1776—1777.

By distilling the dried root of the Japanese peony (*paeonia moutan*) by means of a current of steam, three or four per cent. of *peonol* passes over. This body, which was discovered by Nagai, has the constitution—

and is thus a mono-methyl ether of dioxyacetophenone. It forms fine colourless needles, of melting point 47°. By fusion with KOH it yields β -resorcylic acid. By demethylation it gives a dioxyacetophenone identical with that obtained from resorcinol.—A. G. G.

On Umbelliferone. W. Will and P. Beck. Ber. 19, 1777—1786.

It has already been shown that two isomerides exist of the dimethylumbelliferic acid, of which the less stable α -isomeride melts at a lower temperature than the stable β -isomeride. A considerable number of derivatives is described possessing no special industrial interest, with the exception, perhaps, of the *p*-methoxycoumarone—

prepared by the dry distillation of the silver salt of *p*-methoxycoumarilic acid—

It is a colourless oil, somewhat heavier than water, and having a powerful odour of flowers. It boils at 178—180°, is very volatile with steam and easily soluble in alcohol and ether.—A. G. G.

Some New Constituents of Atropa Belladonna. H. Kunz. Arch. Pharm. [3], 23, 721—735.

IN addition to the true belladonna and hyoscyamus alkaloids, there occurs also both in the belladonna and hyoscyamus a substance soluble in water, bile-neurine or choline, $C_5H_{15}NO_2$. The quantity of the former amounts in extractum belladonnae to about 1.8 per cent., in extractum hyoscyami to about 0.5 per cent.; of the latter, in belladonna extract, to about 1 per cent., in hyoscyamus extract, to 3 per cent. The fluorescence of an alkaline solution of extractum belladonnae is due to elrysatropic acid, $C_{12}H_{10}O_5$, which occurs in all parts of the plant, together with a smaller quantity of leucotropic acid, $C_{17}H_{22}O_5$. In the extract prepared from belladonna plant, normal succinic acid occurs to the extent of 0.6 per cent.—G. H. M.

On some Menthol Derivatives. G. Arth. Ann. Chem. Phys. 7, 433.

BY the oxidation of menthol with potassium permanganate a mono-basic acid named *hydroxymenthyllic* acid, $C_{10}H_{18}O_5$, is obtained. It forms a viscid liquid, boiling and decomposing at 280°. Distilled under a pressure of 15mm. it boils at 173—175° without decomposition. It is sparingly soluble in water, but dissolves freely in alcohol and ether, and forms very hygroscopic white crystalline salts with alkalis. In addition to this acid the following oxidation products are formed:— β -pimelic acid $C_7H_{12}O_4$, butyric, propionic, formic, oxalic and carbonic acids. When cyanogen and cyanogen chloride act on menthol, *mentholurethane*—

and *menthylcarbonate*, $CO(C_{10}H_{19}O)_2$, are obtained. The former melts at 165°, and is decomposed when heated with water or dilute hydrochloric acid, carbonic anhydride, ammonia and menthol being produced. Menthyl carbonate melts at 105°. To corroborate the alcoholic character of menthol, a series of solid crystallisable ethers was prepared and examined: *Menthylbenzoate*, $C_{11}H_{15}.COOC_6H_5$; *normal and basic menthylsuccinate*, $C_6H_4(COOC_{10}H_{19})_2$, and $COOH-C_2H_4-CO.OC_{10}H_{19}$; and *normal and basic menthylphthalate*, $C_6H_4(COOC_{10}H_{19})_2$; and $COOH-C_6H_4.COOC_{10}H_{19}$.—D. B.

Processes for the Preparation of m-Methoxy-p-nitrobenzaldehyde for use in the Manufacture of Vanillin. Ludwig Landsberg, Offenbach-on-the-Main, Germany. Eng. Pat. 6190, May 7, 1886.

THE inventor claims the preparation of *m*-chloro-*p*-nitrobenzaldehyde by the conversion of *m*-chloro-*p*-nitrotoluene into *m*-chloro-*p*-nitrobenzyl chloride, or into *m*-chloro-*p*-nitrobenzyl bromide, and boiling these products with a solution of nitrate of lead or of copper, substantially as described. Also the preparation of *m*-methoxy-*p*-nitrobenzaldehyde by heating *m*-chloro-*p*-nitrobenzaldehyde with alkali methylate or alkali hydroxides dissolved in methyl alcohol, or by the conversion of *m*-chloro-*p*-nitrobenzaldehyde by heating with an aqueous solution of caustic or carbonated alkalis, into *m*-oxy-*p*-nitrobenzaldehyde, which is finally converted into *m*-oxy-*p*-nitrobenzaldehyde by treatment with methyl.—T.

XXI.—EXPLOSIVES, MATCHES, Etc.

Improvements in the Manufacture of Gunpowder and analogous Explosives. F. B. W. Roberts. From Friedrich Becker, Amtenhaus, Germany. Eng. Pat. 368, January 10, 1885. 2d.

THE object of this invention is to obtain a gunpowder giving increase of velocity and decrease of pressure in the gun. This object is sought to be obtained by employing in place of the ordinary charcoal, the product obtained by charring wood, by preference dogwood, to a yellow or chocolate colour. The proportions of the constituents preferably employed are 80 parts of potassium nitrate, 3 parts of sulphur, and 17 parts of the charred dogwood. What is claimed is, first, in the manufacture of gunpowder or similar explosives, the use of under- or but partially-charred dogwood or other woody matter; second, the manufacture of gunpowder or similar explosives by the combination of saltpetre, sulphur, and under- or but partially-charred dogwood or other woody matter, in the proportions previously mentioned, or thereabouts.

—W. D. B.

An Improved Explosive Compound. H. H. Lake. From Charles Lamm, Stockholm. Eng. Pat. 13,690, November 10, 1885. 6d.

ACCORDING to this invention, an explosive mixture termed "Bellit" is prepared by mixing a nitrate with a nitro-compound, "containing carburetted hydrogen," such as dinitro-benzene, trinitro-naphthalene, or nitro-toluene, and then subjecting the mixture to a temperature of from 50° to 100° C., the object being to effect the fusion of the nitro-compound, and thus coat the particles of the nitrate to protect the same against atmospheric influences. As examples of the proportions employed, the following are given:—1 part of dinitro-benzene with at least 0.96 part of potassium nitrate; 1 part of trinitro-naphthalene with at least 1.41 parts of potassium nitrate, it being calculated that with these proportions the carbon will be oxidised to the monoxide. If deemed advisable, the proportion of nitrate may be increased in order to effect the complete oxidation of the carbon.—W. D. B.

Improvements in Explosive Compounds. C. E. Bichel, Berlin. Eng. Pat. 15,528, December 17, 1885. 4d.

A MIXTURE of 10 parts of a hydrocarbon, with 3 parts of sulphur, is distilled at a temperature of from 90° to 150° C. The distillate, consisting of a muddy liquid, is clarified by washing, and is then mixed with potassium nitrate, in the proportion of 100 parts of the distillate to 30 parts of the nitrate. The "explosive oil" thus produced may be mixed with an absorbent, and formed into cartridges. The "explosive oil" may also be obtained by mixing potassium nitrate with carbon disulphide in the cold, and then adding the liquid hydrocarbon. "The product must be carefully washed."—W. D. B.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

Alpha- or Beta-Naphthol in the Presence of Sulphuric Acid a Test for Nitric and Nitrous Acids, and Free Chlorine. H. Hager. Pharm. Centr. 26. 353—354.

A ONE PER CENT. solution of naphthol in absolute alcohol is used. 3—4cc. of the liquid to be tested is mixed with 2cc. of naphthol solution, and then 15—2cc. pure concentrated sulphuric acid allowed to run down the side of the vessel with great care, and collect at the bottom. According to the quantity of acid or chlorine present the layer of the liquid in contact with the sulphuric acid in a few seconds becomes yellow, brownish-red or brownish-black.—G. H. M.

Valuation of Calcium Acetate. H. Phillips. Chem. News, 53, 181.

1GRAM. of the sample is distilled in a 100cc. retort, with 10cc. of a 40 per cent. solution of phosphoric acid, and

40cc. of water, until the retort contains only about 5cc. of liquid. The residue is allowed to cool, treated with 50cc. of boiling water, and distilled as before. After repeating this operation the whole of the acetic acid will have been carried over. The distillate is then titrated with a standard solution of soda, phenolphthalein being used as indicator. To economise time the author proposes to place the retort with the stem pointing upwards in an inclined direction. The stem is covered with flannel, and has the end curved so as to pass easily into the condenser. The retort is closed by a caoutchouc stopper fitted with a small funnel, through which the water enters. During the distillation the funnel is closed by means of a small-tapered glass rod, covered with indiarubber tubing.

The valuation of calcium acetate is frequently effected by converting the calcium salt into sodium acetate by treatment with sodium sulphate, decomposing the acetate into sodium carbonate by ignition, and titrating the alkali thus produced. The author finds this process to be very liable to error, and consequently does not recommend its adoption.—D. B.

Estimation of Glycerol in Wine and Beer. J. Skalweit. Rep. Anal. Chem. 6, 183.

100cc. of wine or 200cc. of beer are mixed with 10grms. of quartz sand (20grms. in the case of beer), and 3cc. of milk of lime (200grms. calcium hydroxide in 500cc. of water), and evaporated nearly to dryness. The mixture is then boiled out with about 150cc. of alcohol (90 per cent.), and the residue extracted with alcohol (90 per cent.), in Soxhlet's extraction apparatus. After concentrating the mixed extracts to a syrupy consistence, the mass is treated with 10cc. of pure alcohol and 15cc. of ether. The clear solution is distilled in a flask provided with a long neck, 30—40cc. of water being previously added to the liquid. The distillation may be carried on without loss of glycerol until the fluid in the flask has been reduced to from 5—10cc. The residual liquid is then weighed and the glycerol determined with Abbe's refractometer, the results being calculated according to the glycerol table given in *Rep. Anal. Chem.* 5, 18, and *Chem. Zeit.* 9, 433.—D. B.

Estimation of Mineral Oils in Fats. Finkener. Mitth. Techn. Versuchs-Anstalten zu Berlin, 4, 13.

OILS containing less than 10 per cent. of unsaponifiable fat are treated as follows:—10grms. of oil are heated for 15 minutes on a water-bath with 50cc. of an alcoholic solution of soda (35grms. NaHO dissolved in 85cc. of water and 730grms. of boiling alcohol), 5grms. of sodium carbonate are then added, and the solution is heated until the alcoholic odour has disappeared. The liquid is then transferred to a glass cylinder, agitated with 300cc. of light petroleum boiling under 100° and filtered. 150cc. of the petroleum extract (equal to 5grms. of oil) are then distilled to a small bulk. The residue is transferred to a watch-glass, dried and weighed. Commercial fatty oils yield from 0.5 to 3 per cent. of unsaponifiable residue. In the case of oils containing more than 10 per cent. of mineral oils, the estimation may be effected by determining the quantity of alkali required to saponify the fat.—D. B.

New Books.

HANDBOOK OF PATENT LAW OF ALL COUNTRIES. By W. PHILLIPS THOMPSON, C.E., F.I.P.A., etc., of Liverpool. Seventh Edition, Revised, 1886. London: Stevens & Sons, 119, Chancery Lane; New York: D. VAN NOSTRAND, 23, Murray Street. 1886: Entered at Stationers' Hall.

THIS little work has now reached its seventh edition. It is a small octavo volume, bound in cloth, containing 127 pages of subject matter, and a table of contents. The Table of Contents explains

the mode of subdivision of the subject, the subdivisions being well spaced off, and headed in bold type:—**BRITISH PATENTS.** Varieties of Protection. What can be patented. Who can patent. General Rules relating to Patents. First Step in Patenting. Procedure and Cost of obtaining Patent. Subsequent Taxes. Prolongations. Amendments. Revocation of Patents. Infringement of Patents. Legal Proceedings. Licenses and Assignments. **GENERAL HINTS.** What Inventions are Profitable. How to Sell a Patent. Caution to Investors in Patents. How to Safely Invest in Patents. Searching. REGISTRATION. FOREIGN AND COLONIAL PATENTS.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

9562 E. Böhlig and G. O. Heyne, London. An improved apparatus for eliminating air and gases and carbonate of magnesia from feed water for boilers which have been purified by means of caustic magnesia or basic carbonate of magnesia. Complete specification. July 23
 9563 P. A. Newton, London—Communicated by W. Craig, U.S.A. Improvements in condensers. Complete specification. July 27
 9733 A. G. Meeze, Redhill. Improvements in apparatus for heating and cooling fluids. July 28
 9739 E. Jones and A. Beech, Longport. Improvements in filter presses and the mode of charging same. July 29
 9783 N. Evans, Liverpool. Improved means of obtaining artificial draught under the grates of steam generator furnaces. July 29
 9785 S. Smithson, Bradford. An improved method of and apparatus for heating steam boiler and other furnaces by means of ground coal, or coal-dust, and also for consuming smoke. July 29
 9787 P. D. Bywater and M. J. Bywater, London. Filtering and purifying fluids, called "The London filtering tap." Complete specification. July 29
 9838 E. C. Allam, London. Improvements in filters. Complete specification. July 30
 9845 P. A. Newton, London—Communicated by C. H. Peters & Co., Germany. Improvements in fuel-feeding apparatus and appliances for furnaces. July 30
 9911 C. Otto, London. Improvements in working furnaces by means of compressed air. Complete specification. August 3
 10022 J. Whitley, Leeds. Improvements in the manufacture of apparatus for the distillation and condensation of liquid and gaseous substances. Complete specification. August 5
 10037 E. Edwards, London—Communicated by G. Lunge, Switzerland, and L. Rohrmann, Germany. Improvements in apparatus for effecting the absorption of gases by liquids or solids. August 5
 10085 F. M. Lyte, London. Improvements in the preparation of materials for, and in the manufacture of, cupels and tests. August 6
 10086 F. M. Lyte. Improvements in the manufacture of cupels and tests. August 6
 10098 J. Atkinson, London. Improvements in machines for producing cold air or other gases. August 7
 10128 J. Daglish, London. Improvements in kilns for burning lime, and ores, and other substances. August 7
 10161 G. F. Redfern, London—Communicated by J. J. Imbs, and Messrs. Toison and Fradet, jun., France. Improvements in apparatus for utilising the heat which usually passes off with the smoke in chimneys. August 9
 10169 G. A. Hagemann, London. Improvements in furnaces. Complete specification. August 9
 10233 B. Raymond, London. Improvements in apparatus for elevating water and liquids. August 10
 10272 A. Rathbone, Liverpool. Improvements in apparatus for condensing, heating, or cooling liquids and fluids. August 11
 10370 S. Vickers, Liverpool. Improvements in apparatus for filtering liquids. July 8. Previously included in No. 8205
 10378 C. J. Croft and F. Dowling, Stevenage. Apparatus for forcing draught in boiler furnaces. August 13
 10381 E. Edwards, London—Communicated by K. Welser, Germany. An improved fire-grate for furnaces of all kinds. May 22. Previously included in No. 6919
 10469 S. S. Broughhead, London—Communicated by F. J. Anbladet, France. A smoke-consuming apparatus. August 16
 10505 H. J. Gibson and W. Buck, London. A safety attachment for taps or cocks for gases, vapours, or liquids. August 17
 10552 W. R. Lake, London—Communicated by J. Evans and D. H. Burrell, U.S.A. Improvements in centrifugal apparatus for separating liquids of different densities or specific gravities. Complete specification. August 17

10555 A. Flamache and E. Picard, London. Method of, and apparatus for, desiccating wood and other porous substances. August 18
 10641 D. Rylands, B. Stoner, and R. Potter, Barnsley. Improved arrangements for feeding melting furnaces. August 20
 10663 J. Rankin, Glasgow. Improvements in furnace grates. August 20
 10722 F. Foster, London. Improvements in machinery for charging liquids with carbonic acid gas. August 21

COMPLETE SPECIFICATIONS ACCEPTED.*

1885.

10185 F. Maxwell Lyte. Manufacture of cupels in the cupellation of metals, and production of other refractory apparatus. August 20
 10301 J. H. Selwyn. Liquid fuel furnaces and their appliances. August 17
 10657 F. B. Daring. Apparatus for evaporating sea-water, nitrate, or other solutions or liquids. August 10
 10663 E. Edwards—Communicated by E. Foucault and E. Jaques. Regenerative furnaces for heating air. July 30
 10805 J. Murrie. Apparatus for indicating temperature or pressure. August 13
 11016 H. C. Turner. Oven, furnace, and other door fastenings. July 30
 11312 H. Smith and J. E. S. Perkins. Apparatus for washing and drying various substances. August 6
 11329 P. Teague and W. H. Thomas. Means and apparatus for pumping water, or other liquids. July 27
 11507 J. S. Stubbs and S. H. Stubbs. Water-heating apparatus. July 30
 11903 G. F. Redfern—Communicated by A. Lamart. Apparatus for automatically allowing the escape of gases, liquids, or fluids under pressure. August 6
 11905 W. F. Goreham and W. W. Hewitt. Apparatus for generating steam. August 10
 11920 J. G. Walker. An improved purifier or separator. July 27
 13679 M. Pedersen and J. Nielsen. Mounting the container in centrifugal separators. August 3
 14033 J. Lee. Construction of boiler flues for the consumption of smoke. August 6

1886.

8533 H. E. Newton—Communicated by R. A. Cheesbrough. Steam generators and superheaters. July 30
 8548 H. H. Lake—Communicated by G. E. Bonninghoff and C. F. Jewell. Furnaces for combustion of gaseous fuel. July 30
 8616 G. Seagrave. Apparatus for inducing the flow of air, gas, or other fluid, by means of a smaller volume at high velocity. August 3

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

9598 J. H. Johnson, London—Communicated by E. Delamare-Deboutville and L. P. C. Malandin, France. Improvements in apparatus for carburetting air. July 21
 9616 T. Smith, Newcastle-on-Tyne. Improvements in the arrangement for burning liquid fuel for steam-boilers and other purposes. July 26
 9694 T. Mace, London—Communicated by the Vitrite and Luminoid Company, U.S.A. New or improved manufacture of the incandescing portion or luminant of incandescence electric lamps. July 27
 9695 T. Mace—The Vitrite and Luminoid Company. The manufacture of materials for use as the incandescing medium or luminant of electric lamps, for electrical resistances, or for other purposes. July 27
 9696 T. Mace—The Vitrite and Luminoid Company. New or improved treatment or manufacture of materials for use as the incandescing medium or luminant of electric lamps, or for other purposes. July 27
 9737 A. Brin, London. Improvements in apparatus for regulating the flow of, and uniting and burning oxygen and hydrogen, or other gases. July 28
 9805 W. Maxwell, London. Apparatus for carbonising filaments for incandescent electric lamps. July 29
 9806 C. A. von Welsbach, London. Method of obtaining compounds of the rarer metals from their earths for use as incandescence bodies for illuminating purposes. Complete specification. July 29
 9819 F. V. Hadow, Buxted. An improvement in the artificial manufacture of coal so as to render it comparatively smokeless. July 30
 9833 C. S. Bailey, London. A system or mode of, and apparatus for, effecting the more efficient and economical employment of gaseous or explosive fuel in the driving of motive-power engines. July 30

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Specifications thus advertised are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

9866 H. A. Stuart, Bletchley. Improvements in petroleum and other explosive engines. July 31
 9867 J. Thomson King, Liverpool—Communicated by C. Vose, U.S.A. Improvements in extracting paraffin from petroleum distillate. Complete specification. July 31
 9912 A. Gutensohn, London. Improvements in the manufacture of artificial fuel and fire-lighters. August 3
 10088 J. R. Wigham, Dublin. Improvements in the means and apparatus employed in illuminating lighthouses, beacons, bays, and establishments or localities requiring artificial lights, which improvements are also applicable to other purposes. August 6
 10328 W. Boggett, London. Improvements in producing fuel by new combinations of combustible materials. August 12
 10540 P. Comte, A. Desaubean, and E. Delarue, London. A chemical fire-lighter. August 17
 10596 W. J. Williamson, Deptford. A fuel economising and smoke-consuming apparatus. August 18
 10600 J. E. Rogerson, J. G. Statler, and J. S. Stevenson, London. Improvements in or connected with electric furnaces or heating apparatus. August 18
 10635 S. S. Bromhead, London—Communicated by H. C. Gambier, France. Improvements in gas-heating apparatus. August 20
 10698 T. Thorp, Whitefield. Improvements in non-regenerative gas lighting. August 21
 10740 F. V. Hadow, Buxted. An improvement in the artificial manufacture of coal so as to render it comparatively smokeless. August 23

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

9551 W. Gunn—Communicated by The Coal Economising Company. Compound for the prevention of smoke in furnaces and fire-places. August 10
 9720 B. Andrae. Generation of gas for lighting and heating, and apparatus therefor. August 13
 10778 H. E. A. Wallis. Apparatus for conducting gas-flame heat to hydro-carbon containing vessels. August 13
 11520 R. Walker. Compound fuel. July 30
 11679 R. Scott. Application of air, water, or other fluids as a motive power. July 20
 15191 N. P. Bargh and A. Gray. Motors actuated by expansion of gases resulting from combustion of fuel. August 3

1886.

1349 W. von Ruckteschell. A new combustible compound. Previously included in No. 15475, of 1885. August 17
 6349 O. Inray—Communicated by J. B. Archer. Process and apparatus for manufacturing water oil gas. August 6
 6449 J. Horton. Apparatus for burning gas for illuminating, heating and cooking purposes. August 17
 6859 A. M. Clark—Communicated by C. A. Paquelin. Apparatus for automatically generating and burning inflammable vapours. August 10
 7847 W. A. S. Thompson—Communicated by G. R. Davis. Means for using inflammable oils as fuel. August 3
 8357 S. Butler. Machinery for the manufacture of compressed fuel from coal. July 27
 8549 H. H. Lake—Communicated by G. E. Benninghoff. Utilisation of gas or vapours for lighting and heating; and apparatus therefor. August 13
 8625 W. G. Appleford. Gas burners for heating purposes. August 3
 8880 H. J. Haddan—Communicated by H. Welsh. Apparatus for promoting combustion of fuel. August 10

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

APPLICATIONS.

9550 O. Rose, London. Improvements in apparatus for the distillation of coal, shale, and other materials. July 23
 9921 J. Jones, Glasgow. Improvements in the construction and setting of retorts for distilling shale, coal, and other bituminous substances. August 5

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

9713 J. Y. Johnson, London—Communicated by C. Rumpff, and The Farbenfabriken vorm. Bayer & Co., Germany. Improvements in the manufacture of chinolines or chinoline compounds. July 28
 9751 L. Schad, London. A process for the production of a bluish-black colour. Complete specification. July 28
 10134 Dahl & Co., Leeds—Communicated by E. Elsaesser, Prussia. Improvements in the manufacture of blue dyestuffs, or colouring matters. Complete specification. August 9

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

5038 R. Barringer, J. H. Wallis, and W. Barringer. Preparation of blue colouring matters for laundry purposes. August 13
 8528 C. P. Anderson. Dyes and detergents. August 17

V.—TEXTILES, COTTON, WOOL, SILK, ETC.

APPLICATIONS.

9840 G. Harrison, London. An improvement in making fireproof starch and paint for the purpose of rendering all textile fabrics and wood non-inflammable. July 30
 10035 A. Wilkinson, London. Improvements in the treatment and utilisation of plants and shrubs, barks of trees, and various other useful fibres to be used in all kinds of spinning processes, and to be woven in textile and woven fabrics. August 5
 10053 W. Mather, London. Apparatus for treating textile materials with liquids, gases, or vapours. August 5
 10176 H. R. Randall, London. Improvements relating to the treatment of silk cocoons, raw silk, and the like, and to apparatus therefor. August 9
 10250 J. S. Farmer, Manchester. Improved apparatus for testing the purity of raw cotton. August 11
 10542 T. Holliday, London. Improvements in dyeing textile fibres. August 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

9811 M. Raabe, A. C. G. Skynner, and S. Henning. Manufacture of yarns and woven and felted goods from animal and vegetable fibres. August 10
 11561 G. Kassner. Manufacturing caoutchouc, wax, fat, colouring matter, vegetable fibre, fibre wool, etc., from laticiferous plants. August 6

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

9611 G. E. Sutcliffe, Halifax. An improved means, method, or process of dyeing cotton in the sliver for the purpose of producing coloured yarn. July 26
 9776 E. Sutcliffe and G. E. Sutcliffe, Halifax. An improved method of and means for dyeing slivers of woollen, worsted, alpaca, and mohair, for the purpose of making coloured yarn therefrom. July 29
 9777 E. Sutcliffe and G. E. Sutcliffe, Halifax. An improved method of and means for dyeing slivers of silk for the purpose of making coloured yarn therefrom. July 29
 9816 M. Hilton, Prestwich. An improvement in the use and application of materials such as catechu, or catechu, or gambir, combined with animal or vegetable gelatinous matter alone, or in combination with biclornate of potash, alum, or tannic and gallic acids. July 30
 9874 A. M. Clark, London—Communicated by La Compagnie Française du Celluloid, France. An improved process of colouring or producing coloured designs upon celluloid or analogous products. July 31
 10315 H. Renold, Manchester—Communicated by R. Hegnauer, Switzerland. Improvements in the method of and means for dyeing hats and hat materials. August 12
 10718 L. Harmel, J. Harmel, and A. Harmel, London. Rotary apparatus for preparing for dyeing and for dyeing combed wool in bobbins. August 21

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

12159 S. Smithson. Method of and apparatus for dyeing. August 3

1886.

2051 R. H. Ainsworth and E. B. Manby. Apparatus for bleaching by the "Thompson" and other processes, applicable also for dyeing. July 27

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

9556 H. J. Haddan, London—Communicated by J. Roussenu, France. A new or improved process for the extraction of iodine and salts from sea-weed and such like. July 23
 9621 J. H. Galloway and J. W. Galloway, London. Improvements in generators employed in the manufacture of carbonic acid gas. July 26
 9801 The Tyne Alkali Co., Limited, and T. Gibb, London. Improvements in the manufacture of hydrate and salts of baryta and strontia. July 29
 10000 A. W. Gillman and S. Spencer, London. Improvements in means or apparatus employed in the manufacture of sulphites. August 1
 10008 J. S. Kipping and F. Seadder, Manchester. Improvements in obtaining certain solutions of iron and in methods of preserving such solutions. August 4
 10009 H. H. Lake, London—Communicated by Count R. de Montglas, United States. Improved apparatus for the manufacture of chlorine gas. Complete specification. August 4
 10011 H. H. Lake—Communicated by R. de Montglas. Improvements in the manufacture of chloride of aluminium and double chloride of aluminium and sodium. Complete Specification. August 1

10013 H. H. Lake, London—Communicated by R. de Montgela. Improvements in apparatus for the manufacture of chloride of aluminium and double chloride of aluminium and sodium. Complete specification. August 1

10036 A. A. Croll, London. Improvements in the distillation of ammoniacal liquor. August 5

10018 E. Vandenhoff, London. Improvements in the manufacture of vinegar. August 5

10119 G. Jarmay, Liverpool. Improvements in separating the ammonium chloride from liquors obtained in the manufacture of soda by the ammonia soda process. August 14

10191 J. Barrow, London. Improvements in the manufacture of alkali. August 16

10095 E. Jacobsen, London. Improvements relating to the production of sulphurated hydrocarbons, and to the extraction or preparation therefrom of sulphonic acid, and other substances. August 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

11129 G. L. Wigg, M. Steele, and M. J. Wigg. Apparatus for treatment of residuals from copper works and chlorine manufacture to obtain pigments and sulphate of lime. August 13

11178 P. A. Mawdsley and T. Macfarlane. Manufacture of sulphur and ferric oxide from alkali waste by means of metallic chlorides. August 10

1886.

7801 J. V. Johnson—Communicated by F. von Heyden. Manufacture of salicylic acid and its substitution compounds. August 6

8153 J. V. Johnson—Communicated by C. Kolbe and C. Reitsch. Manufacture of alpha- or beta-carbonaphthol acid alkaline salts. August 6

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

9650 J. Armstrong, London. Improved machinery and appliances for the manufacture of rolled glass. July 27

10019 E. Walsh, jun., London. An improved method of and apparatus for rolling plate glass. Complete specification. August 5

10075 A. D. Brogan, Glasgow. Improvements in the manufacture of rippled glass, and in apparatus therefor. August 6

10165 L. de Borlodot and J. Quinet, London. Improvements in the manufacture of cylinder glass. August 9

10271 E. Townsend and T. H. Thompson, Birmingham. Improvements in coloured glass or other ornamental glass screens. August 11

10574 A. Drummond, Glasgow. Improvements in the manufacture of glass and in the application of the same for roof lights and other glazing purposes. August 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

11395 A. D. Brogan, Glasgow. Manufacture of plate glass, and apparatus therefor. July 27

11589 A. M. Clark—Communicated by La Société Appert frères and La Société Geneste-Herschier et Cie. Process and apparatus for manufacturing perforated glass. August 10

11681 W. Jones. Means for drying bricks, porcelain, terracotta, or earthenware, etc. August 3

12011 J. Pratt. Process of gilding glass. August 13

1886.

8695 J. Plant. Machinery for turning pottery ware. Aug. 3

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

9536 E. T. L. Clark, London. An invention to be known as Laxton's improvements in hardening and preserving plaster of Paris (sulphate of lime) casts and moulds, making them impervious to water, and rendering unnecessary the ordinary process of white-washing or painting. July 23

9511 C. Duncombe, London. An improved method of laying asphalt or other kindred substances. July 23

9729 T. Bayley, Birmingham. Improvements in the colouring of marble and other materials composed of calcium carbonate. July 28

9981 J. Davies, Manchester. Improvements in the method of and in apparatus for preparing clay for use in brick and tile making. August 1

10167 P. Jeserich, London. A new or improved artificial asphalt and process for manufacturing the same. Aug. 9

10182 J. W. Breakell and T. Breakell, Manchester. An improved material for decorative purposes. August 10

10329 H. D. Cunningham, London. Improvements in the construction of chambers for drying Portland cement, slurry, bricks, or tiles, etc., by heat. August 12

10514 H. J. Hadden, London—Communicated by H. Deschamps, France. Improvements in tiles. August 17

10693 C. Drake, London. Improvements in artificial stone. August 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

9881 F. Shorten—Communicated by A. Raehner. Manufacture of stucco objects and surfaces. August 3

10331 R. Stone. Manufacture of cement and apparatus therefor. August 17

11684 W. Jones. See Class VIII.

11806 W. T. Timewell. Manufacture of cement. August 10

12390 J. S. Armstrong. Improved forms of building materials. July 30

12405 J. J. Allen. Machinery for manufacture of bricks and tiles. August 3

12814 W. R. Lake—Communicated by J. P. E. Durst and L. Vidrie. Apparatus for impregnating wood with preservative and other fluids. July 30

1886.

7671 H. Mathey. Manufacture of cement. August 10

8331 F. C. A. Meier. Centrifugal apparatus for moulding clay, cement, plaster, etc. August 10

X.—METALLURGY, ETC.

APPLICATIONS.

9630 G. Nurse, London. An improved method of treating or operating upon black plates previous to tinning or tinning. July 26

9661 C. E. Moneriff, Belfast. Improvements in means of raising rock salt from the mine. July 27

9663 M. R. Moore, London. Improvements in machines for making sand moulds for casting metals. Complete specification. July 27

9664 M. R. Moore. Improvements in machines for making sand moulds for casting metals. Complete specification. July 27

9700 H. J. Hadden—Communicated by L. Fleury, France. A new or improved process for annealing copper and its alloys. July 27

9711 A. J. Boulton, London—Communicated by E. Hamélin, France. Improvements in or relating to cupolas and blast furnaces. July 27

9731 A. G. Mecze, Redhill. A process and arrangement of apparatus for the purification of pig-iron and the conversion thereof into steel or homogeneous metal of higher grade. July 28

9815 J. Pinder and B. Woodcock, Bradford. Improvements in the method of hardening and tempering steel wire. July 30

9919 E. W. Parnell and J. Simpson, Liverpool. Improvements in the treatment of ores containing sulphide of antimony, for the purpose of obtaining such sulphide in a concentrated form, with any gold and silver that may be present. August 3

9926 H. J. Allison, London—Communicated by J. Robertson and J. Hardie, United States. Improvements in hydraulic lead presses for coating wire and cable with lead. Complete specification. August 3

10062 W. P. Thompson, Liverpool—Communicated by W. H. Wright, United States. Improvements in the manufacture or working of metals in a cold state into certain forms, and in apparatus therefor. August 6

10085 and 10086 F. Maxwell Lyte. See Class I.

10089 R. Heathfield, London. Improvement in apparatus used for coating sheets of iron and steel with zinc or alloys of zinc or other coating metal or alloy. August 6

10227 H. R. Lewis, C. B. Phillips, and C. J. Sandahl, London. Improvements relating to the extraction of metals from refractory, complex, and other ores. August 10

10241 H. H. Lake, London—Communicated by E. Thomson, United States. Improvements relating to the welding of metals and to apparatus therefor. Complete specification. August 10

10277 H. E. Newton, London—Communicated by A. Nobel, France. An improved mode of disintegrating rock by heat. August 11

10353 P. Barry, London. An improvement in the manufacture of iron for the production of a hardening and tempering metal or steel. August 12

10177 W. A. Thoms, London. Improvements in the deposition of platinum by electricity. August 16

10506 H. Tabor, London. Making moulds for foundry purposes. Complete specification. August 17

10517 J. W. Jones and R. S. Harrison, Blyth. Kirving or cutting coal and other minerals. August 17

10591 J. Clark, London. Improvements in the process of obtaining alloys of aluminium with copper and with other metals. August 18

10605 W. R. Lake, London—Communicated by Count R. de Montgela, United States. An improved process of extracting aluminium from chlorides of the same, and of aluminium and sodium. Complete specification. August 18

10606 W. R. Lake—R. de Montgela. An improved process of extracting aluminium from its chlorides. Complete specification. August 18

10607 W. R. Lake—R. de Montgela. Improvements relating to the electro-deposition of aluminium. Complete specification. August 18

10753 R. Schneider, Berlin. Improvements in separating-funnels or kits used for making perfectly solid and pure castings of iron, steel, or any other metal. August 23

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 10185 F. Maxwell Lyte. See Class I.
10752 E. Dawson, A. T. Harvey, and J. Bow. Mode of and plant for manufacturing wrought-iron or steel sleepers. July 30
11402 B. H. Thwaite. Decarbonising, desilicifying, dephosphorising, and desulphurising fluid iron metal, and apparatus therefor. August 13
11199 J. S. Sellon. Process and means for soldering aluminium. July 27
11538 A. M. Clark—Communicated by C. Cholat and F. Mercier. Treating and purifying cast iron, and apparatus therefor. August 3
11624 E. R. Blundstone. Utilising waste tin, tin plate, lead and terne plate. August 13
11798 O. Inray—Communicated by L. Bondy. Process of extracting wrought iron and steel directly from ores. Aug. 6
11854 B. D. Healey. Method and apparatus for making steel. August 10
12355 W. Edmunds. Blast furnace. July 30
12501 J. W. Summers and T. Sharp. Working light scrap iron, etc., in making steel bars. August 10
12615 G. Allen and T. Turner. Appliances for producing ingots compounded of iron and steel. August 6
12616 G. Allen and T. Turner. Manufacturing variegated metal for twist barrels, etc. July 30
12756 J. Riley. Regenerative steel-making furnaces. August 17
12891 J. E. Sherman. Manufacture of iron and steel. August 3
12909 S. Pitt—Communicated by J. Weirich. Treatment of auriferous and auro-argentiferous minerals. August 3

1886.

- 6690 R. Richards and H. R. Landon. Means and apparatus for boring to great depths for water and minerals by the aid of electricity. July 30
8338 T. Twynam. Refractory linings for metallurgical furnaces, etc. July 27
8833 C. B. Headly. Gold-covered alloy. August 6
8988 T. Fenwick. Treating waste tin cuttings to recover tin and iron fit for remanufacture, and apparatus therefor. August 10

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

- 9553 T. Schofield, Bradford. Reclaiming oil or other lubricants from cleaning cloths, greasy cotton-waste, and the like. July 23
9591 J. Thomson, London. An improved antiseptic soap. Complete specification. July 21
10226 H. H. Lake, London—Communicated by N. J. Clute, P. B. Rose, and J. M. Aubrey, United States. Improvements in the manufacture of soap. Complete specification. Aug. 10
10395 G. W. Bremner, London. A new or improved method of treating materials for the manufacture of washing liquids and cleansing powders. August 13

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11561 G. Kassner. See Class V.
11726 W. Marriott and H. Marriott. Improving the viscosity of oils. August 20

1886.

- 8921 J. Whittle. Apparatus for separating oil or grease from cotton-waste, etc. August 10
8933 J. L. Mott, jun.—Communicated by Dreher & Co. Lubricating compounds. August 13
9115 H. H. Lake—Communicated by W. B. Albright. Bleaching fats and oils. August 20

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

- 9581 J. B. Hannay and E. J. Pape, Glasgow. Improvements in making white paint. July 21
10127 E. Schroder and H. Perner, London. An improved process for giving a non-oxidising, or only slightly oxidising coating to wood and other materials or objects. August 7
10238 F. Maxwell Lyte, London. Improvements in the manufacture of white pigment. August 11
10391 G. W. Bremner, London. A new or improved method of operating on animal and mineral material for the manufacture of a paint suitable for ships' bottoms and other submerged bodies. August 13

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11177 O. Inray—Communicated by E. A. Behrens. Bleaching and refining resins, etc. August 13
11529 E. L. Kitchingman and A. Andrews. Waterproof and anti-corrosive composition for coating ships' bottoms, etc. July 27

- 11543 G. W. Carr and J. Dickinson. Anti-fouling composition for coating ships' bottoms, metal, wood, etc. July 27
12249 S. Banner. Substitute for turpentine. August 13
12723 T. C. Huntington and M. Chiapponi. Treating antimonial ores or compounds to obtain pigment. August 17

1886.

- 7975 A. Buel. Method and apparatus for drying pigments, etc. August 3

XIII.—TANNING, LEATHER, GLUE AND SIZE.

APPLICATIONS.

- 9604 W. Ross, London. Novel application of a material or substance produced by the treatment of waste leather. July 24
9613 T. Laycock, Northampton. An improved method of making leather and other materials flexible to any degree, and of waterproofing the same, so as, when used for the manufacture of boots and shoes or other articles, the same are damp and waterproof, and may be made flexible to any degree required. July 26
9771 J. Vassie, jun., Glasgow. Improvements in operating the tables of leather-dressing and hide-working machines. July 29
10347 G. W. Bremner, London. A new or improved treatment of substances containing phosphoric acid and alumina, for the manufacture of a mineral gum and glue. August 12

XIV.—AGRICULTURE, MANURES, ETC.

APPLICATIONS.

- 9636 L. A. Chevalet, London. A new or improved process for manufacturing neutral phospho-guano. July 26
9847 T. H. Cobley. See Class XVIII.

XV.—SUGAR, GUMS, STARCHES, ETC.

APPLICATIONS.

- 9569 W. Burns. See Class XVII.—B.
9726 C. Tully, Newcastle-on-Tyne. An improvement in the manufacture of indiarubber, gutta-percha, and combined indiarubber and gutta-percha sheets, pipes, washers, etc., by the incorporation of mica with the indiarubber and gutta-percha used in the manufacture of such goods. July 28
9992 A. G. Wass, London. The improved utilisation of lime and other calcareous material impregnated with saccharine matter. Complete specification. August 4
10161 H. J. Haddon, London—Communicated by A. Z. Champy, A. N. Champy, and L. P. Champy, Belgium. Improvement in the treatment of Jerusalem artichoke to prepare it for use in distilling, in the manufacture of glucose, and similar industries. August 9
10257 C. Lyle and J. Lyle, London. Improvements in the manufacture of lump sugar. August 11
10481 M. Strasser, London. A process for the manufacture of artificial gum. August 16

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11561 G. Kassner. See Class V.
11671 J. Bagnall. Dissolving vulcanised indiarubber and indiarubber compounds. July 30

XVI.—BREWING, WINES, SPIRITS, ETC.

APPLICATIONS.

- 9551 A. G. Fraser and G. Epstein, London. Improvements in treating distillers' worts in separating yeast therefrom, and in treating yeast.
9630 L. Béchaux, London. Improvements in the distillation and the rectification of alcoholic and other liquids. Complete specification. July 26
9658 F. Faulkner and W. Adam, London. An improved appliance for use in circulating and aerating malt and raw grain worts when producing ordinary malt liquors, distillers' wash, and vinegar brewers' wash, applicable also to other processes. August 3
10164 H. J. Haddon—Communicated by the Messieurs Champy. See Class XV.
10376 D. W. Hamper and J. H. Howell, London. Improvements in brewers' coppers and other like or analogous vessels. Complete specification. August 13
10722 F. Foster. See Class I.
10761 F. Heyman, London. An improved syphon suitable for storing beer. August 23

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 9956 C. R. Bonne. Apparatus for testing brewing materials. August 10
11935 W. S. Squire. Manufacture of yeast. August 10

- 1208 W. S. Squire, Manufacture of yeast, August 10
12163 W. S. Squire, Manufacture of yeast, August 13

1886.

- 8161 Sir F. Bolton, Process for fining beer, July 27
9131 H. W. Lafferty, Utilisation of the refuse or slops of breweries, distilleries, etc., August 20

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

APPLICATIONS.

A.—CHEMISTRY OF FOODS.

- 9712 E. R. Allen and W. C. Allen, London, Improvements in the manufacture of articles of food made from the kernels of almonds and other fruit, July 27
9738 A. Brin, London, Improvements in treating milk for preserving it, July 28
9865 J. Mackenzie, Cork, Preservation of butter, or other substances, in packages, July 31
10076 A. Dintour, Manchester, A process for making the bones in fishes eatable, August 6
10170 H. J. Haddon, London—Communicated by M. Blumenthal, Germany, Improvements in the manufacture of rennet, Complete specification, August 9
10518 A. H. Reed, London—Communicated by R. Ellin, United States, Certain improvements in the production of evaporated milk, Complete specification, August 17
10772 W. R. Lake, London—Communicated by M. A. B. Mount, United States, An improved substitute for coffee, August 23

B.—SANITARY CHEMISTRY.

- 9569 W. Burns, Leith, Improvements in the manufacture of deparating and decolorising charcoal for purifying sewage and other foul liquids, and for decolorising syrups, July 24
9847 T. H. Cobley, London, Improvements in the treatment of sewage, the manufacture of a precipitant therefrom, and the treatment of the resulting product for the preparation of a manure or fertiliser, July 30
10017 W. Astrop, London, Improvements in the apparatus and process for solidifying and drying sewage sludge and such like articles, August 5
10703 E. Segeant, Bolton, Improved furnaces for treating materials infected with disease, and other refuse, August 21

COMPLETE SPECIFICATIONS ACCEPTED.

A.—CHEMISTRY OF FOODS.

1885.

- 12178 A. G. Brookes—Communicated by T. S. Nowell, Baking powders, August 13

B.—SANITARY CHEMISTRY.

1885.

- 11255 G. R. Keeling, Destroying noxious smells and gases in sewers by the action of flame, etc., August 20
12261 J. Hanson, Process and means for disinfecting, deodorising, and purifying sewage, etc., August 10
16000 J. H. Kidd, Purification of sewage from organic matter, August 13

1886.

- 1792 F. Candy, Preparation of materials for the treatment of sewage, etc., August 13

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

- 9582 J. P. Hall, Manchester, Improvements in dynamo-electric machines, July 21
9594 H. Weymersch and J. Whittall, An improved battery solution, July 21
9635 and 9636 T. Mace—The Vitrite & Luminoid Co. See Class II.
9841 F. E. Elmore, London, Improvements in dynamo-electric machines, July 29
9855 O. March, London, Improvements in primary batteries of the manganese or Leclanche type, July 30
9901 H. Aron, Glasgow, Improvements in electric batteries, August 4
10222 E. Andreoli, London—Communicated by J. V. Warnou, Paris, Improvement in voltaic batteries, August 10
10286 F. H. W. Higgins, London, Improvement in voltaic batteries, August 11
10319 W. Haberlein, Berlin, Improvements in secondary batteries, August 12
10536 E. D. Kendall, London, A new and useful composition of matter to be used as an electric battery excitant, Complete specification, August 17

- 10569 C. H. L. Clarke, Manchester, Improved mechanical means of hermetically sealing electric batteries, August 18
10581 E. M. Gardner, London—Communicated by T. L. Kauffer, United States, An improved galvanic battery, August 18
10641 A. Millar, Glasgow, Improvements in electrodes for secondary batteries, Complete specification, August 20
10765 W. Lowrie and C. J. Hall, London, Improvements in secondary generators for the conversion of electrical energy by induction, August 23

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 10616 H. H. Lake—Communicated by S. F. Van-Choate, Armatures for electric generators and motors, August 3
11307 C. Moseley and T. Parker, Secondary voltaic batteries, July 27
11451 T. J. Jones, Voltaic batteries, July 27
11652 T. J. Jones and W. H. Tasker, Manufacture of plates or elements for voltaic batteries, July 30
12288 H. Thame and J. R. Thame, Secondary batteries, August 17

1886.

- 7541 H. J. Smith, Dynamo-electric machines, August 13
7840 S. F. Thompson, Dynamo-electric machines, Aug. 3
8151 J. G. Tongue—Communicated by J. Kirby, Manufacture of carbons for electrical purposes, August 20
8501 W. L. Gates, Portable galvanic batteries, August 17
9103 A. J. Boulton—Communicated by O. Lago, Galvanic batteries, August 20

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

- 9885 R. Kron, London, Improvements in machinery for grinding, mixing, sizing, dyeing and otherwise preparing materials for the manufacture of paper, July 31
10267 J. B. Scammell, London, Improvements in the manufacture of paper for cigarettes, Complete specification, August 11
10293 C. L. Lawrence, London, A process for rendering paper impervious, August 11
10356 J. Brandt, London, Improvements in pulp and half-stuff machines, August 12

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11876 C. Jackson, Manufacture of hardened asbestos, August 10
13022 F. G. Morton and N. Salamon, Manufacture of pulp or "half-stuff," utilising refuse material, August 6

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

- 10280, J. Y. Johnson, London—Communicated by F. von Heyden, Germany, A process for the manufacture of oxy-chinoline carbonates, Complete specification, August 11
10281 A. Knoll, London, Process for the production of the ethers of morphinecarbonic acid, August 11
10357 A. Knoll, London, Process for producing methyl-morphin (coduin), ethyl-morphin and higher homologues of morphin, August 13

XXI.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

- 9615 J. R. Linsley and J. H. Proctor, Newcastle-on-Tyne, Improvements in cases or canisters for containing or carrying gunpowder or other explosive, July 26
9632 J. Pain, London, Improvements in fireworks, July 27
10330 G. Beattie, Glasgow, Improvements in lucifer matches and in manufacturing the same, August 12
10437 C. D. Abel, London—Communicated by W. Lorenz, Germany, Improvements in percussion fuses for projectiles, August 11
10580 D. Johnson and W. D. Borland, London, Improvements in ammunition, August 18
10728 G. A. Sweetser, London, Improvements in the manufacture of cigar lights, fuses, or vesuvians, August 21

XXII.—GENERAL ANALYTICAL CHEMISTRY.

APPLICATION.

- 10345 L. Brockmann, London, Combinations of gelatine with chloride of cobalt, chloride of copper, and nitrate of nickel oxyd for indicating the moisture of the atmosphere, August 12

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 9. — VOL. V.

SEPTEMBER 29, 1886.

Non-Members 30/- per annum; Members
21/- per Set; Single Copies 2.6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.

COUNCIL FOR YEAR ENDING JULY, 1887.

President: David Howard.

Vice-Presidents:

Sir I. Lowthian Bell, Bart., F.R.S.	Sir H. E. Roscoe, M.P., F.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
Dr. Peter Griess, F.R.S.	E. C. C. Stanford.
Dr. Ferdinand Hurter.	J. C. Stevenson, M.P.
E. K. Muspratt.	John Williams.
Dr. W. H. Perkin, F.R.S.	Philip J. Worsley.

Ordinary Members of Council:

John Calderwood, F.R.S.E.	John Pattinson.
Eustace Carey.	S. A. Sadler.
It. Forbes Carpenter.	Sir Bernhard Samuelson, Bart., M.P.
Henry Doulton.	Sir Chas. Tennant, Bart.
Dr. John Evans, F.R.S.	Lewis T. Wright.
S. H. Johnson.	
Ivan Levinstein.	

With Sixteen Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

THE JOURNAL.

Publication Committee:

The President.

Sir F. A. Abel, F.R.S.	F. Hurter, Ph.D.
Joseph Bernays, M.L.C.E.	Ivan Levinstein.
H. Brunner.	Prof. R. Meldola, F.R.S.
W. Lunt Carpenter.	Ludwig Mond.
Prof. Frank Clowes, D.Sc.	E. K. Muspratt.
George E. Davis.	C. O'Sullivan, F.R.S.
W. Y. Dent.	John Pattinson.
Prof. Dewar, F.R.S.	Dr. W. H. Perkin, F.R.S.
Prof. Chas. Graham, D.Sc.	Sir H. E. Roscoe, M.P., F.R.S.
Peter Griess, Ph.D., F.R.S.	John Spiller.
D. B. Hewitt, M.D.	A. Norman Tate.
J. J. Hummell.	Thomas Tyrer.
Prof. A. K. Huntington.	

Editor: Watson Smith, The Owens College, Manchester.

ASSISTED BY THE FOLLOWING STAFF OF

Abstractors:

G. H. Beckett.	C. F. Cross.
D. Bendix.	A. R. Davis.
E. E. Berry.	A. G. Green.
E. J. Bevan.	S. Hamberger, Ph.D.
W. Dalrymple Borland.	James Hulme.
T. L. Briggs.	Bertram Hunt.
E. G. Clayton.	C. C. Hutchinson.
Julius B. Cohen, Ph.D.	D. E. Jones.

Abstractors:

W. E. Kay.	H. A. Rademacher.
A. J. King, B.Sc.	A. Rée, Ph.D.
D. A. Louis.	F. W. Renaut.
F. Machenhauer.	James Taylor, B.Sc.
Wm. Macnab, Jun.	V. H. Veley, M.A.
W. G. McMillan.	Alex. Watt.
G. Harris Morris, Ph.D.	Sydney Young, D.Sc.
J. M. H. Munro, D.Sc.	

NOTICE.

The supply of copies of the Journal for January, 1882, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of that number, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the number will be reprinted.

CHANGES OF ADDRESS.

CHANGES OF ADDRESS REQUIRED.

A. Macalister, 10 Eastfield Chemical Works, Rutherglen, Glasgow.

W. A. Woods, 10 Johnson's Saccharum Co., Stratford, E.

Death.

Prof. Wm. Ripley Nichols, of the Massachusetts Institute of Technology, Boston, Mass., U.S.A., at Hamburg, July 14.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.
H. E. Armstrong.
W. Lant Carpenter.
W. Crowder.
C. Graham.
S. Hall.
A. K. Huntington.

R. Messel.
B. E. R. Newlands.
B. Redwood.
T. Royle.
John Spiller.
G. C. Trewhy.
J. Williams.

Local Sec. and Treasurer: Thos. Tyrer,
Garden Wharf, Church Road, Battersea, S.W.

The meetings of the London Section will be held on the first Monday in each month.

Prospective Arrangements.

Nov. 1.—Mr. Lewis T. Wright, F.C.S., C.E., "What shall we do with our Tar?"

Dec. 6.—Mr. Tonrehsel, "On Strontium Hydrate." Mr. Fairley, F.C.S., "Comparative Experiments on Various Forms of Sprengel Pumps."

Jan. 3.—Mr. Watson Smith, F.I.C., F.C.S., "On the Explosive, 'Kinetite.'"

Notices of papers and communications for the meetings to be sent to the Local Secretary.

PRESERVING STANDARD TARTAR-EMETIC SOLUTIONS.

BY ARCH. R. MILLER.

HAVING occasion frequently to estimate the tannic acid in samples by means of tartar-emetic, I found it very troublesome to make up a fresh standard solution every time I made the estimation. The inside of the bottle containing the tartar-emetic solution invariably turned white after standing for an hour or two. I discovered that by excluding the air from the solution it would keep for any length of time without decomposition taking place. By placing the solution in a bottle with a well-ground close-fitting glass stopper (which, to ensure a good fit, may be rubbed before insertion with a little lard or vaseline), and after bottling the solution and melting some spermaceti round about the stopper, the solution may be kept without fear of change. It is advisable, however, not to make too large a quantity at one time, or if so it must be kept in different bottles—say, of a capacity of 500cc. each—as each time the stopper is withdrawn a small quantity of air gets in. If the stopper is quickly replaced and sealed after abstracting the required quantity of the solution, any decomposition which may take place is very slight, and by the time 500cc. of solution are used, is very trifling.

Manchester Section.

Chairman: Sir H. E. Roscoe, M.P.

Vice-Chairman: I. Levinstein.

Committee:

Dr. Bowman.
R. F. Carpenter.
C. Esteourt.
H. Grimshaw.
Peter Hart.
Dr. Gerland.

C. Schorlemmer.
Dr. Schunck.
Dr. Watson.
Wm. Thomson.
L. Siebold.
Dr. Hewitt.

Local Secretary:

J. Carter-Bell, Bankfield, The Cliff, Higher Broughton, Manchester.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

ERRATA.—In Mr. Ad. Steiger's paper, in the July number (pages 416—421), where the capacities of Gerson's filters are given, for "hectolitres" read "cubic meters" in every case—namely, on pages 418 and 420.

THOMAS-PHOSPHATE SLAG, OR BASIC CINDER IN THE STATE OF POWDER, AS A HIGHLY ACTIVE PHOSPHATIC MANURE.

BY WATSON SMITH, F.C.S., F.I.C.,

Lecturer in Chemical Technology in the Victoria University, Manchester.

EVERY agriculturist at the present time will be interested in a question which is exciting very great attention in Germany just now—viz., the use of powdered basic cinder as manure. The German experimenters find that a general treatment with sulphuric acid is, in many cases, wholly unnecessary and therefore wasteful, since the conversion into superphosphate designed to render soluble the phosphoric acid of the slag, and the preparation from the slag of precipitated phosphate are processes which are mostly too expensive. It is now known that, especially in the case of certain soils and earths, the phosphate of the basic slag is *gradually*, but quite speedily enough, rendered soluble for assimilation by the vegetation to which it is applied as manure; indeed, to have it more soluble would mean more or less loss by sinking into the earth beyond the zone of usefulness. Anyone doubtful of the statement of the great interest in the utilisation of basic cinder awakened in the German Fatherland among those interested in agriculture, should procure and read the stirring articles which appeared in the *Frankfurter Zeitung* for Sunday, August 22. It is, however, matter for a certain amount of congratulation that the Society of Chemical Industry has not been behind, but fully equal to the occasion, and that one of its members, Dr. J. M. H. Munro, of the Downton College of Agriculture, with Professor J. Wrightson, has for some time past been experimenting in the direction referred to; and that these gentlemen are fully alive to the importance of the question is evident to all who read the valuable report noticed under New Books in our July number, page 437. The writer was informed in Germany that German buyers have been sent over to this country empowered to buy up all the basic slag they can find available, so that what have been unsightly rubbish-heaps and waste ground, will now contribute to the produce and increase of the verdant pastures and of the fruitful plains. It is a fact, that already cargoes of the waste material referred to (the phosphoric basic cinder) have been shipped from Middlesbrough to Germany, Denmark, and Sweden, and the present rate of shipment to the Continent (September 12, 1886) is something like 1200 tons per week.

Messrs. H. & E. Albert, of Biebrich-am-Rhein, manufacturers of manures, etc., and specially interested in the Thomas-basic cinder, have issued a very instructive circular, which, since it contains much useful information, and being a record of observations partly of their own, is well worthy of reproduction. Of course, since the document in question bears the character of a trade circular as well as a record of observations, the writer must give the statements for what they are worth, and without the endorsement that could be accorded after personal experimental verifications. Nevertheless, the names quoted are of fully sufficient authority to warrant not only publication, but a most careful consideration by ironmasters and agriculturists alike.

By the combustion of the phosphorus in phosphoric iron in presence of lime, millions of hundredweights (centners) of fused phosphate of lime are prepared, and as fused slag are run off from the steel formed at the same time. On the average this Thomas-slag or basic cinder contains 16–20 per cent. of phosphoric acid, and 46–54 per cent. of lime and magnesia.

At first a chemical treatment of the slag so as to form superphosphate and precipitated phosphate was attempted, but this was not found to pay owing to the high percentage of lime present; experiments in the field meanwhile, made upon peaty soil and moorland, sour and wet meadowland, have shown excellent results, as Dr. Fleischer, director of the Experimental Station for Moorland Agriculture, near Bremen, has demonstrated by hundreds of experiments carried out on the large scale. Employed on ordinary field and meadowland it was, however, unexpectedly found in the very first harvests, that considerable improvement and increase were the result, equal to what has been obtained with a superphosphate containing an amount of soluble phosphoric acid double that contained in the ground cinder. As in acid soils, so also in those kinds of soils that are poor in lime, specially high results were obtained, because of the large amount of lime in the ground cinder (*Schlackenmehl*), which had contributed to supply the deficiency of lime in the soil.

It was chemically proved that this form of calcium phosphate—i.e., that in the cinder—is very easily soluble, proving quite soluble in waters containing carbonic acid, and in neutral ammonium citrate solution when the latter was employed in sufficient quantity. H. Albert found that 1 part of ground basic cinder with 100 parts of peat and 500 parts of water in two weeks yielded 94 per cent. of its phosphoric acid in a form soluble in water. A humic acid salt of lime, and free phosphoric acid soluble in water, are formed, and at the same time only small quantities of ferrous oxide were rendered soluble. These results prove that all the phosphoric acid that was combined with the lime is soluble in the natural acids of the soil, and is in a form easily taken up by the roots of the plants. The innocent nature of the ferrous oxide of the cinder, which is with difficulty soluble, is clear from the chemical behaviour in the peat, as also from the field experiments in which, when even more than 20 centners of ground basic cinder per $\frac{1}{2}$ hectare were used, showed no injurious action on the seed and crops; it may thus be assumed that these oxides of iron are just as insoluble as those naturally present in the usual soil itself. In a great number of manurial experiments in the field and analytically, it has consequently been proved beyond a doubt that this slag phosphate is a highly active and valuable phosphate manure. Professor Wagner, of the Darmstadt experimental station, has established its action in 235 exact manurial experiments performed upon four different kinds of soil, and further proved that

by fine grinding of the cinder, the action of its phosphoric acid on the average, when used in double the quantity of superphosphate-phosphoric acid, soluble in water, is equally active in the first crop. A complete confirmation of Wagner's results was obtained by Professor Fittbogen, of the experimental station of Dahme, in a series of exact experiments extended to oats and potatoes. In the latter case the ground basic cinder, comparing it with superphosphate and precipitated phosphate, according to the phosphoric acid contained in the substances, was found, weight for weight of phosphoric acid contained, equally effective. Messrs. Albert quote the experiments at Downton, by Dr. Munro, and the high crop results there obtained with ground cinder. For the still further improvement based on the use of mixtures of ground cinder and superphosphate Dr. Munro has taken out a patent (see this Journal, vol. v. page 433; Eng. Pat. 7740, June 25, 1886). The experiments on meadow land by Munro and Wrightson, in England, gave good results, coinciding with those obtained in Germany.

From the thousand-fold experiments tried, the following very important data for agricultural science, have been derived: That the Thomas basic cinder, when reduced by grinding to the finest possible condition, is more quickly effective than ground bones, is to be preferred in clayey and sandy soils poor in lime, in wet meadows of acid character, mossy, and for clover fields. In soil rich in lime, when manured with a three-fold quantity, equally greatly increased results were obtained to begin with, but in addition, the good results were more lasting.

For moorland, wet and sour meadows, two centners per $\frac{1}{2}$ hectare (Morgen) are used, and the land is manured annually; in case of necessity a potash salt manuring is also given, or three centners of ground cinder containing potash are used in the manuring. On sandy and clayey earths poor in lime it is necessary to use four centners for a triennial manuring, in earths rich in lime six centners for four years. If the intention be to enrich the land for from six to eight years in phosphoric acid and lime, then it may be manured with 10 centners and more per $\frac{1}{2}$ hectare. A lucerne field, the crops of which need on the average 26 pounds of phosphoric acid per annum, should be manured with 16 centners of powdered basic cinder if it is to furnish good crops for 10 years; if after from four to five years a falling off takes place, potash is probably deficient in the soil, and then clover can be obtained in full crop by adding in the winter every two years, by means of an after-manuring, 6 centners of kainite.

Since the powdered basic cinder by its content of lime disintegrates still further in the air and soil, and thereby becomes more soluble and active, it is advised to apply it to the soil as early as possible; it can be strewed on the meadows after each hay harvest and let lie over the winter, and when possible be raked into the soil. On fields, it can be strewed and let lie upon the stubble until it is ploughed in, the heavy cinder powder sinks in soon, and a loss is not to be feared. The ploughing into the soil must, however, take place so that the cinder manure may lie where the moisture is mostly retained, and the roots spread themselves. If the basic cinder manure is ploughed in directly before the seed is sown, the plants do not, it is true develop so quickly in the first month as would have been the case with superphosphate, but after six weeks the positions would be the same. It must be assumed that all classes of soil are partially exhausted of phosphate, because an enrichment with it, as a consequence, affords everywhere great in-

crease in the yields of the crops. With powdered cinder and potash salt, the constituents of the ash of the plants are completely given, and consequently that which is understood by the name of the "strength of the soil" ("Bodenkraft"). Various plants, and happily the chief ones used as fodder—butterfly orchis, clover, lucerne, vetches, lupins, peas, beans—need only this mineral nourishment in order to flourish to the full, and to yield large crops of the best hay. The high yields of fodder attained at the same time lead to a class of hay much richer in vegetable albumen, starch-sugar and fat. Besides a well-nourished stock of cattle, a richer stable manure is obtained, whereby the grain, rapeseed, cabbage, potatoes, and beets are caused to yield larger crops, and the landed property is rendered profitable with very small outlay.

It is recommended that every two years gardens be manured with powdered basic cinder, the consequence being that on subsequent treatment with stable or the nitrogenous dung-manures, the latter will be doubly effective. Like the beets and cabbage in the field, all vegetables, flowers, fruit trees, and vines will be found to yield double and fourfold, and also, through strong healthy growth, to be less sensitive to the attacks of insects, etc. One reason, of course, why the powdered basic cinder is so useful, and is superior to the superphosphate for moorland and damp meadowland, is just by reason of its being more insoluble than the latter, which too easily sinks deep into the earth or gets washed away*; but even in drier soils its greater stability and more gradual action is preferable, and the English field experiments referred to show that in the most extreme cases a mixture of the powdered cinder with superphosphate will raise the yields greatly even in the driest summer weather.

It is calculated, as regards price, that at present 1 lb. of phosphoric acid in the form of the Thomas basic slag powder, could be delivered for about 1d. (10 Pfennige); also, by means of a subsidiary dunging with $\frac{1}{2}$ to 1 centner of Chili saltpetre per $\frac{1}{4}$ hectare, ground bones and guano can be replaced, and the best harvests obtained in a far cheaper manner than formerly.

Chili saltpetre (nitrate of soda) and potash salts can of course be mixed with the powdered cinder to begin with, and the whole furnished as a special manure, but not so sulphate of ammonia, which, in the presence of the lime of the basic cinder, would lose ammonia.

The grinding of the basic cinder must be very thorough, so as to yield a very fine powder, and upon this very much depends its usefulness. The firm in question (Messrs. Albert) find it best to furnish a powder of which they guarantee 90 per cent. shall fall through a $\frac{1}{2}$ millimeter sieve.

EXPERIMENTS IN THE PREPARATION OF ULTRAMARINE WITH JAPANESE KAOLINS.

BY K. IWABUCHI.[†]

THE kaolins which the author took for his experiments are those of Gotō, Gairome, Harima, Yamato, Tororoishi, Tonoguchi, Shigaraki, and Shiraye. The analyses of them are given in the table on next page.

No doubt another reason is, that the basic cinder contains excess of lime, which neutralises the excess of acid in such sour lands.

[†] 1 hectare = 10,000 sq. metres = 2.47 imperial acres.

[‡] Abstracted from Graduating Thesis, and communicated by T. Takamatsu, Lecturer in Applied Chemistry, Imperial University, Engineering College, Tokyo, Japan.

1.—GOTŌ KAOLINS (A and B).

These kaolins occur as a fine white powder in the island of Gotō, on the southern coast of Nagasaki. Both qualities, A and B, in the carbonate mixture, yielded a light green mass, shrinking regularly on calcination. This mass, after blueing, was found to be rather dull in colour. This is perhaps due to a large amount of potash in the kaolins, as seen in the above table.

2.—GAIROME KAOLIN.

This is a greyish white powder used for the body of porcelain, at the village of Seto in Owari. Although a green mass was produced on calcination of the carbonate mixture, yet it shrunk irregularly, and the blue produced was not good, perhaps due to the presence of too much iron and potash in the clay.

3.—HARIMA KAOLIN.

A grey stone which, when powdered, has a white colour. It is called Rōseki, in Japan, being used for sculpture purposes. Experiments were tried several times to prepare ultramarine from the kaolin, but without any successful result. This is no doubt due to a great excess of silica present in the clay, the ratio of Al_2O_3 to SiO_2 being 1:3.9. The same is also true for the three following kaolins:—Yamato, Tororoishi, and Tonoguchi, in all of which the ratio of Al_2O_3 to SiO_2 exceeds over 1:3.

4.—YAMATO KAOLIN.

Found at the village of Nakasuji in Yamato. It is a greyish white powder which, on calcination, becomes grey. The carbonate mixture was made with this clay. It gave, on calcination, a semi-fluid mass, but no ultramarine.

5.—TOROROISHI.

This kaolin is found in Amakensa, and is used for porcelain making in Kyōto. Containing too much silica, it is not fitted for the production of ultramarine.

6.—TONOGUCHI KAOLIN.

It is a very white powder, usually employed for making the body of porcelain in Aizu. No ultramarine was formed from this kaolin, as it contains too much silica.

7.—SHIGARAKI KAOLIN.

This is a greyish white clay, and is extensively used for making the body of porcelain in Kyōto. The carbonate mixture on calcination yielded a blue mass, which by a subsequent blueing process gave ultramarine of light reddish shade. The colour, however, was not fine, owing to the presence of too much alkalis and iron.

8.—SHIRAYE KAOLIN.

It is found in Mino, along the river Nasubi, and is used in porcelain works at Seto, in Owari. From the foregoing analysis it will be seen that this kaolin contains very little impurities, and moreover contains Al_2O_3 and SiO_2 in the ratio 1:2. In fact it is a very suitable material for the production of good ultramarine. It was first purified by elutriation, then dried, ignited and pulverised as fine as possible. The carbonate mixture was then prepared in the following proportions, according to Gentile:—

Kaolin	50grms.
Sodium carbonate	50 "
Sulphur	30 "
Charcoal	6 "
	136 "

The mixture, after being calcined for three hours, gave a green mass, which was homogeneous and

fritted regularly. It was washed, ground, and finally treated with sulphur. The ultramarine so obtained had a dark blue colour with some lustre. The weight of the ultramarine was found to be 42grms.—that is, about 30 per cent. of the original mixture.

In order to get ultramarine of lighter shade, the author tried to prepare sulphate ultramarine by taking the following mixtures:—

	I.	II.
Kaolin	50grms.	50grms.
Sodium sulphate	45 ..	50 ..
Charcoal	8.5 ..	8.5 ..
	103.5 ..	108.5 ..

Of these, II. gave a good result, and yielded 44grms. of ultramarine of lighter shades, but without good lustre. The weight of the colouring matter corresponds to about 40 per cent. of the original mixture.

In order to increase the ratio of the Al_2O_3 to SiO_2 , which exist in the Shiraye kaolin, a calculated

ever, the mixed kaolins had been employed to form the sulphate mixture, no ultramarine was obtained on calcination and subsequent treatment.

Experiments were next made with the object of preparing some mixed ultramarines with a view to obtain intermediate shades between the carbonate and sulphate ultramarines, the former being always too deep, while the latter were too light in shades.

The following mixture was then prepared:—

Shiraye kaolin	100grms.
Sodium sulphate	41 ..
Carbonate	11 ..
Charcoal	17 ..
Sulphur	13 ..
	212 ..

This gave on calcination a homogeneous green mass, which, after blueing, became a good ultramarine; but it was not so lustrous as the carbonate ultramarine before mentioned. The weight of the ultra-

	Gotô (A).	Gotô (B).	Gairone.	Harima.	Yamato.	Tororoishi.	Tonoguchi.	Shigaraki.	Shiraye.
SiO_2	48.85	48.42	53.90	65.49	62.41	71.53	76.78	58.42	47.74
Al_2O_3	36.89	37.09	41.95	28.31	24.73	16.75	17.02	28.37	36.68
Fe_2O_346	.50	1.25	.41	2.68	.75	.13	1.20	.42

MgO15	.01	—	—	—	.17	.11	—	—
K_2O	6.80	6.13	1.78	.34	.54	1.88	—	2.53	.24
Na_2O87	.83	.48	1.41	—	1.58	.36	2.65	.21
Loss on ignition ..	5.90	6.16	—	3.16	9.84	3.06	5.22	5.29	13.64
	100.34	99.89	99.92	99.88	100.69	100.36	100.33	99.88	100.03
Ratio of Al_2O_3 to SiO_2	1:2.25	1:2.22	1:2.2	1:3.9	1:4.29	1:7.12	1:7.67	1:3.55	1:2.25

amount of free silica was added to a given amount of the kaolin so as to make the ratio as 1:3, and the following carbonate mixture was prepared:—

Kaolin + silica	50grms.
Sodium carbonate	50 ..
Sulphur	30 ..
Charcoal	6 ..
	136 ..

Proceeding in the same way, the author obtained ultramarine of somewhat reddish shade, which could resist the action of weak acetic acid and a solution of alum better than the one prepared without any addition of silica. The yield of ultramarine, however, was very much less than in the previous case.

Next, experiments were made with a view to prepare sulphate-ultramarine with the kaolin to which a calculated amount of free silica was added so as to make the ratio of Al_2O_3 to SiO_2 as 1:3. The following mixtures were prepared:—

	I.	II.	III.
Kaolin + silica	100	100	100
Sodium sulphate	83	90	100
Charcoal	17	17	17

Proceeding in the usual way with these mixtures no ultramarine was obtained.

Instead of free silica, some kaolin, rich in silver, was then added to the Shiraye kaolin so as to make the ratio of the whole Al_2O_3 to SiO_2 as 1:3. For this purpose, calculated quantities of Tonoguchi and Shiraye kaolins were mixed intimately, and the carbonate mixture was then prepared in the usual proportions. The ultramarine obtained from this mixture was pretty good, and had a reddish shade. When, how-

marine thus obtained was about 25 per cent. of the original mixture.

After a few more experiments, using different proportions of materials, the author deduces the following summary:—

1. Of the Japanese kaolins which were subjected to experiments, Shiraye kaolin is the best, in which the ratio of Al_2O_3 to SiO_2 is 1:2.

2. Carbonate ultramarine prepared with this kaolin in Gentele's proportion is very bright, and has a deep blue colour.

3. Sulphate ultramarine made under the same conditions is inferior in lustre, and has a light blue colour.

4. The same kaolin, with the previous addition of silica or another clay, so as to make the ratio of Al_2O_3 to SiO_2 as 1:3, gives carbonate ultramarine of somewhat reddish shade, but no sulphate ultramarine.

5. Materials, when mixed to form two kinds of ultramarine, give a good product of intermediate shade, but it is not so bright as carbonate ultramarine.

Communication.

NOTE ON THE VOLUMETRIC TEST FOR MANGANESE.

BY R. W. ATKINSON, B.Sc., F.I.C.

I HAVE to thank Mr. Pattinson for calling attention, in the July number of this Journal, to the error in

of a system of small pipes is placed in direct communication with the diaphragm D, which acts upon the stem of a valve V inserted in the pipe H. If the water in vessel G sinks below a certain level, it exposes the chamber A to the heat of the steam, thereby expanding the liquid therein, which, acting upon D, closes the valve V, and thereby re-establishes the water level in G. If desired, a gauge C may be provided as shown for the purpose of externally indicating the action of the apparatus. Reference is made also to previous patents, 15,947 of 1884, and 303 of 1885, by the same inventor.—B.

Improvements in Filter-presses and in Apparatus connected therewith. J. B. Allott, Radford, Nottingham. Eng. Pat. 10,942, September 15, 1885. 11d.

The improvements herein specified are of two kinds—first, to provide a rapid means for drawing back the movable head of the filter-press, and, second, to provide means for preventing the fracture of the plates when operating upon fibrous substances, such as are met with in sewage sludge. A cylinder provided with a piston, and having a connection both for the inlet and outlet of air or steam at each of its ends, may be placed co-axially with the filter-press. When the tightening nuts and distance pieces used for forcing the chambers together are run back, the admission of steam to the cylinder or compressed air causes the follower to be rapidly drawn back. Another modification is shown where the air cylinder is placed below the filter-press, and operates upon the follower by means of a bell crank or bent lever. The fracture of the plates is prevented by staying their surfaces, and this is done by providing faced projections cast upon the plates themselves, or formed upon the collars securing the cloths in position and bearing against each other. The bearing stays may be also made loose, and screwed into the body of the plate through the cloth, and they then assist in maintaining the cloth in position.—C. C. H.

An Improved Mechanical Filter. A. P. Laurie, Dud-dingstone. Eng. Pat. 11,687, October 1, 1885. 8d.

THIS apparatus consists of a tank open or closed at the top, containing the material to be filtered, and at the bottom of which is placed the filtering medium, consisting of a sheet of felt secured between two perforated sheets of iron or steel. The bottom of the tank is connected by four pipes with a direct acting steam pump, which has two cylinders—one the water pump, and the other an air pump. The liquid is drawn through the filtering medium by the suction of the pump at one end of the tank, and coincident with this operation a current of air is forced through the filtering medium at the other end of the tank. Gas or steam may be used instead of the air, and the object of the inventor is to keep the filtering medium open and unclogged by the solid matter removed by the filtration. The patentee claims the general arrangement of combination of the different parts of the apparatus described and shown.—C. C. H.

II.—FUEL, GAS, AND LIGHT.

*Mineral Oil Lamps.** Sir Fredk. A. Abel and Mr. Boverton Redwood.

THE accidents which occur in the use of mineral oil lamps have formed the subject of an inquiry in which we have, for some time past, been engaged. Although the completion of this inquiry has been delayed by official calls upon us, it had progressed far enough a year ago to admit of our making certain practical suggestions, the chief of which were embodied in a circular issued last October and widely distributed by the Metropolitan Board of Works. A copy of this circular is enclosed. A large number of the accidents with mineral oil lamps are not actually due to the occurrence of explosions, but arise from fracture of the oil reservoir, caused by the lamp being dropped or upset, or carelessly

carried about, or by the burner becoming overheated. Many accidents have, however, doubtless resulted from the explosion of the mixture of petroleum vapour and air formed in the upper part of the oil reservoir. They usually occur after the lamp has been burning for some time, and when it is being moved, or is being extinguished by the process of "blowing down the chimney." Such explosions, even if not sufficiently violent to fracture the lamp, may so alarm the person carrying or handling it as to cause the lamp to be dropped or overturned. A careful investigation of many accidents, together with a critical examination of the construction of various lamps, and the results of many experiments, have led us to arrive at several definite conclusions with respect to the immediate causes of lamp explosions, and to certain circumstances which may tend to favour the production of such explosions, of which the following is a summary.

If the lamp of which the reservoir is only partly full of oil be carried or rapidly moved from one place to another so as to agitate the liquid, a mixture of vapour and air may make its escape from the lamp in close vicinity to the flame, and, by becoming ignited, determine the explosion of the mixture existing in the reservoir. This escape may occur through the burner itself if the wick does not fit the holder properly, or through openings which exist in some lamps in the metal work close to the burner of sufficient size to allow flame to pass them readily. A sudden cooling of the lamp by its exposure to a draught or by being blown upon may give rise to an inrush of air, thereby increasing the explosive properties of the mixture of vapour with a little air contained in the reservoir, and the flame of the lamp may at the same time be drawn or forced into the air-space filled with that mixture, especially if the flame has been turned down, as the latter is thereby brought nearer to the reservoir. The sudden cooling of the glass, if it had become heated by the burning of the lamp, may also cause it to crack if it is not well annealed, and this cracking, or fracture, which may allow the oil to escape, may convey the idea that an explosion has taken place. If the evidently common practice is resorted to of blowing down the chimney with a view to extinguish the lamp, the effects above indicated as producible by a sudden cooling may be combined with the sudden forcing of the flame into the air-space, and an explosion is thus pretty certain to ensue, especially if that air-space is considerable. If the flashing point of the oil used be below the minimum (73° Abel) fixed by law, and even if it be about that point or a little above it, vapour will be given off comparatively freely if the oil in the lamp be agitated, by carrying the latter, or moving it carelessly; the escape of a mixture of vapour with a little air from the lamp, and its ignition, will take place more readily, but, on the other hand, it will probably be feebly explosive, because the air will have been expelled in great measure by the generation of the petroleum vapour. If the flashing point of the oil be high, the vapour will be less readily or copiously produced under the conditions above indicated; but as a natural consequence, the mixture of vapour and air existing in the lamp may be more violently explosive, because the proportion of the former to the latter is likely to be lower and nearer that demanded for the production of a powerfully explosive mixture.

If the quantity of oil in the lamp reservoir be but small, and the air space consequently large, the ignition of an explosive mixture produced within the lamp will obviously exert more violent effects than if there be only space for a small quantity of vapour and air, because of the lamp being comparatively full. If the wick be lowered very much, or if for some other reason the flame becomes very low, so that it is burning beneath the metal work which surrounds and projects over the wick holder, the lamp will become much heated at those parts, and the tendency to the production of an explosive mixture within the space of the lamp will be increased, while at the same time, heat will be transmitted to the glass, and it will be correspondingly more susceptible to the effects described as being exerted by its sudden exposure to a draught. Experi-

* The substance of a letter to the *Daily News* of September 22nd, 1886.

ments have demonstrated that a lamp containing an oil of high flashing point is more liable to become heated than if it contained a comparatively light and volatile oil, in consequence of the much higher temperature developed by the combustion, and of the comparative slowness with which the heavy oil is conveyed by the wick to the flame. Safety in the use of mineral oil lamps is therefore not to be secured simply by the employment of oils of very high flashing point (or low volatility), and the use of very heavy oils may even give rise to dangers which are small, if not entirely absent, with oils of comparatively low flashing points.

The character of the wick materially affects not only the burning quality of the lamp, but also its safety. A loosely-plaited wick of long staple cotton draws up the oil to the flame regularly and freely, and so long as the oil be not very heavy or of very high flashing point, and therefore difficultly volatisable or convertible into vapour, the flame will continue to burn brightly and uniformly, and with but little charring effect upon the wick. But if the wick be very tightly plaited and made of a short staple cotton of inferior capillary power, the oil will be less copiously drawn up to the flame. As a consequence, the length of exposed wick will be increased by the user of the lamp, and as the evaporation of the oil will take place more slowly from each portion of the wick which furnishes the flame, the heat to which the cotton is exposed will be greater, and the charring, which is fatal to the proper feeding of the flame by destroying the porosity of the end of the wick, will take place more rapidly and to a much greater extent. If the wick be at all damp when taken into use its power of conveying the oil to the flame will be decidedly diminished, the capillaries of the fibre being more or less filled with moisture, and similarly, if the oil accidentally contain any water, the latter, passing into the wick, will interfere with the proper feeding of the flame. As the oil is very thoroughly filtered or strained during its transmission through the body of the wick to the flame, it is obvious that any impurities suspended in the liquid will be deposited within the wick, and will gradually diminish its porosity. For this reason the same wick should not be used for a great length of time, and it is decidedly objectionable to use a much greater length of wick than is necessary to reach to the bottom of the reservoir, and to continue its use until it has become too greatly shortened by successive trimmings.

It follows therefore that it is undesirable to construct the lamp reservoir of the fragile materials commonly employed; that channels of communication to the reservoir at or near the burner should be protected by fine wire gauze (twenty-eight meshes to the inch), or be packed with wire, or should not be of a greater diameter than 0.04 inch; and that the wick tube should be prolonged so that the lower end is always sealed by the oil, or the wick surrounded by a wire gauze cylinder of the requisite fineness, and closed at the bottom, which would allow the passage of air or vapour through it towards the burner, while it would effectually prevent the transmission of fire from the lamp flame to the air-space of the reservoir. Lamps are now sold to which these safety expedients have been applied.

These remarks may tend to dispel groundless alarm as to the dangerous nature of petroleum—and paraffin—oil as illuminants, and may, on the other hand, serve to convey some useful information respecting the causes which lead to accidents with lamps, and the readiness with which such accidents may be avoided.

The following is the circular referred to above:—

METROPOLITAN BOARD OF WORKS,
SPRING GARDENS, S.W., OCTOBER, 1885.

PETROLEUM ACTS.

In view of the numerous fatal and other accidents caused by petroleum lamps, the Board consider it desirable to make public the following suggestions as to the construction and management of such lamps, which are founded on recommendations made by Sir Frederick Abel, C.B., D.C.L., F.R.S.,

and Mr. Boverton Redwood, F.I.C., F.C.S., Chemist of the Petroleum Association, after investigating the causes of lamp accidents.

SUGGESTIONS AS TO THE CONSTRUCTION AND MANAGEMENT OF PETROLEUM (OR PARAFFIN) LAMPS.

CONSTRUCTION OF LAMPS.

1. That portion of the wick which is in the oil reservoir should be enclosed in a tube of thin sheet metal, open at the bottom; or in a cylinder of fine wire gauze, such as is used in miners' safety lamps (28 meshes to 1 inch).
2. The oil reservoir should be of metal, rather than of china or glass.
3. The oil reservoir should have no feeding place nor opening other than the opening into which the upper part of the lamp is screwed.
4. Every lamp should have a proper extinguishing apparatus.
5. Every lamp should have a broad and heavy base.

WICKS.

6. Wicks should be soft, and not tightly plaited.
7. Wicks should be dried at the fire before being put into lamps.
8. Wicks should be only just long enough to reach the bottom of the oil reservoir.
9. Wicks should be so wide that they quite fill the wick-holder without having to be squeezed into it.
10. Wicks should be soaked with oil before being lit.

MANAGEMENT.

11. The reservoir should be quite filled with oil every time before using the lamp.
12. The lamp should be kept thoroughly clean, all oil should be carefully wiped off, and all charred wick and dirt removed before lighting.
13. When the lamp is lit, the wick should be at first turned down, and then slowly raised.
14. Lamps which have no extinguishing apparatus should be put out as follows:—The wick should be turned down until there is only a small flickering flame, and a sharp puff of breath should then be sent across the top of the chimney, but not down it.
15. Cans or bottles used for oil should be free from water and dirt, and should be kept thoroughly closed.

J. E. WAKEFIELD,

Clerk of the Board.

NOTE.—The suggestions apply to ordinary mineral oil lamps such as are generally used, and not to benzoline or spirit lamps.

The Formation of Ammonium Thiosulphate in Gas Generators. H. Endeman. Amer. Chem. Soc. Journ. 8, 47.

THE author has observed the occurrence of ammonium thiosulphate as a condensation product from a gas generator in which air forced through anthracite coal was converted into a mixture of carbon monoxide and nitrogen, which was to be used for metallurgical operations. As a Körting steam blower was used for the blast, a certain amount of steam entered with the air, and the steam being wet, the under part of the generator was soon blown cold, and the heat developed only in the upper parts. The gases produced passed from the generator through a 30-inch main, and thence through branches to places where the gas was to be utilised, and in the main pipe, as well as in the branches, considerable quantities of liquid condensed, and were drawn off from time to time, and it was observed that where the liquid had a chance of passing through joints, there were formed long stalactites of a pinkish colour, and proving, on examination, to consist mainly of ammonium thiosulphate. The sulphur was evidently derived from the anthracite coal, the nitrogen of the ammonium radicle from the atmospheric air, and the hydrogen from the steam. The author explains the progress of the reaction to be as follows:—The upright generators contain layers of anthracite in different stages of combustion, the lower, hottest layer of coal producing carbon dioxide, which is reduced to the monoxide in the upper layers. The pyrites present in the anthracite is first split up by heat into sulphur and ferrous sulphide. The sulphur passes off with the gaseous products, and the ferrous sulphide in its downward course through the furnace meets with free oxygen, and yields oxide of iron and sulphur dioxide, which latter passes on likewise with the gases. Some of the water is decomposed by the carbon of the anthracite, yielding free hydrogen, a portion of which is found as such in the gaseous products, whilst a further portion

reacts with atmospheric nitrogen to form ammonia. In this way the gaseous products—namely, carbon, hydrogen and nitrogen—are accompanied into the main with a number of condensable substances, amongst which are water, sulphur, sulphur dioxide and ammonia. When condensation takes place, the following reaction occurs:—

That this is a correct expression, may be adduced the well-known fact that alkaline sulphites in solution have the power of dissolving sulphur to form thiosulphates. The formation of ammonia from nitrogen and hydrogen at high temperatures is already conceded, and since in the present case the hydrogen would be in the nascent state, it might be expected to combine more readily with the nitrogen than it has been observed to do in experiments with a mixture of gases. Moreover, the formation of ammonia during the combustion of non-nitrogenous substances in air is also an established fact. Since the above observations were made, the generator has been fitted with an ordinary fan-blast in place of the steam-blast, and the formation of ammonium thiosulphate now no longer takes place.—W. D. B.

A Steam-spray Apparatus for Tar and Inflammable Oils. Chem. Zeit. 10, 676.

THIS apparatus, constructed by Messrs. Korting Brothers in Hanover, consists of a tube from which the tar, which runs in at the top, flows out in a thin stream in the front, where it meets a jet of steam, and is thereby formed into a spray. The peculiar manner in which the steam jet is constructed prevents even the smallest quantity of tar from falling down unburnt. It contains

the sieve which retains impurities in the tar. The sieve may be readily removed and cleansed. A is a nozzle, which regulates the flow of tar. The jacket H may be lowered in case the nozzle gets choked. V may also be cleaned out with the rod R when required. The steam-spray apparatus Z is fixed in the furnace wall, and by means of the steam jet, which passes through D,

sufficient air for combustion is admitted into the hearth. To regulate the combustion a valve is attached to the jet, also a damper M, for the admission of air. The tar is placed in a vessel above the retort furnace where the heat keeps it liquid.—J. B. C.

A Mixture of Coke and Tar as a Fuel for Gas Generators. W. Bäcker. Journ. f. Gasbel. und Wasservers. 29, 338.

THE author states that 40 per cent. of the tar produced may be economically employed as a fuel. It is run in under the coke about 40cm. below the surface, a little steam being introduced with it to prevent the stoppage of the pipe by the ignition of the tar at its mouth. The cost of the plant is said to be small. One kilo. of tar may be added to four kilos. of coke.—S. Y.

Improved Means and Substances for Producing an Explosive Agent, and the Employment thereof for the Working of Engines for Power Purposes. J. Graddon and P. Harding, Catford. Eng. Pat. 11,215, Sept. 21, 1885. 6d.

THE inventors propose the employment of phosphoretted hydrogen as an agent for igniting the mixture of hydrocarbons and air in gas-engines.—S. H.

A Process and Apparatus for Manufacturing Water Oil Gas. O. Inray, London. From J. B. Areher, Washington, U.S.A. Eng. Pat. 6349, May 11, 1886. 6d.

STEAM superheated to about 1000° F. is made to pass through an injector and draw with it a quantity of oil, which becomes mixed with it; the mixture is further heated to about 1300° F., and then receives in admixture with it an additional quantity of oil, and finally this mixture is heated to about 2400° F., whereby it is converted into permanent gas suitable for heating or illumination. The apparatus used consists of three concentric cylindrical casings standing vertically with their pipe connections as follows: The outermost casing is a cylindrical shell of metal in two parts, the lower one a superheater, having within it a helical passage along which steam, led by a pipe from a boiler, is made to pass in order to become superheated, and the upper part or final retort having an internal space in which the gaseous mixture undergoes its final heating. The outermost casing is enclosed in brickwork. The second casing is of metal not extending so high as the outermost casing, and separated from it by an annular flue space. Within the second casing and separated from it by an annular flue space, is the primary retort—a vertical cylinder closed at the bottom, and expanding at the top to give an enlarged space closed by a removable cover. Below the bottom of the primary retort is a gas burner consisting of a circle of jets, directly heating the bottom. Briefly, the pieces of apparatus required may be enumerated as the burner, the steam superheater and injector, the retort with its internal shell and pipe, the mixing vessel, the helical retort and the final retort with their connecting pipes, and regulating cocks or valves.—W. S.

Improvements in Apparatus for Heating Solid Substances out of contact with the Products of the Combustion of the Fuel employed. Walter F. R. Weldon, Burstow. From A. R. Peckiney & Co., Salindres. Eng. Pat. 9225, May 31, 1886. 1s. 3d.

PATENT 9304, of June 23, 1884, describes a method and apparatus for heating solid substances in brickwork chambers or receptacles by previously passing flame and hot products of combustion through a series of the said chambers in succession, till so much heat is absorbed and stored up in the brickwork that the products of combustion may be cut off, and the charge, being introduced, be heated as required. According to the present invention, which is an improvement on the foregoing,

each heating chamber communicates directly with the combustion chamber, and the products of combustion, after leaving the heating chamber, are brought back to the burner to heat the air and gas employed there. The burner is movable, and provided with wheels, so that it may be applied to whichever chamber is to be heated up. The specification is accompanied by full drawings.

—A. R. D.

Meizel and Couffinhale's Gasholder. Dingl. Polyt. J. 261, 126—128.

THE novel feature of this apparatus consists in the employment of hydraulic pressure for balancing the receiver. The latter is by means of the star-shaped frame G, attached to the rod of a piston P, which moves in a long cylinder fixed in the centre of the apparatus and resting on a firm foundation. The frame G also serves for the suspension of a number of rollers, which glide on rails fixed to the cylinder. The latter stands in communication with the vessel C. By the direct pressure of steam (entering by A) the water contained in C is forced into the cylinder and causes the piston and with

than in the case of the old system, and a considerable saving is effected in the plant of a gas-works by the adoption of the arrangement described. The makers of this apparatus are the Société des Forges et Ateliers de la Chalassière, V. Biétrex & Co.—F. M.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

The Petroleum Oil of Baku. C. Engler. Dingl. Polyt. J. 260, 337—353, 433—445, 481—488, and 525—535.

ALTHOUGH a mass of information has already been published on the Russian petroleum industry, and Marvin and Redwood have by their comparatively recent contributions (see *Engineering*, 1884, 171; and this Journal, 1885, 70) almost exhausted the whole of this subject, the author, who visited Baku and its surroundings in the autumn of last year, considered it of sufficient importance to give a supplementary series of sketches of this industry, bringing its record nearly down to the end of 1885. His remarks are divided

it the receiver to rise. A pressure governor regulates the supply of water to the cylinder in such a manner that the speed with which the receiver rises is always in ratio to the amount of gas supplied by the retorts. By the action of a second governor, which controls a valve allowing the water to return to C, the pressure of the gas drawn from the receiver is being kept constant. Exhausters for diminishing the pressure in the retorts are unnecessary where this apparatus is adopted. The cost of working is said to be less, or at least not greater

under the following heads: (1) Historical and statistical accounts; (2) Occurrence, production, collection and transportation of the crude petroleum; (3) Refining; (4) Manufacture of lubricating oil; and (5) Transportation of the products of Baku. As the papers contributed by Marvin and Redwood deal minutely with the subjects under the first and second heads, it is proposed not to discuss them again. The refining of the crude oil is carried on almost exclusively in the so-called Black Town (*Tcherni Gorod*) at Baku, where,

out of a total of 136 refineries, 100 were in operation at the end of 1885. The most important refiners are :—

	Plant capable of producing annually
Nobel Brothers	216,300 tons of kerosene.
Caspian Company	41,400 ..
Pallaschkowsky (Batoum Naphtha Co.) ..	11,100 ..
Tagieff and Sarkisoff (at Bibieybat) ..	32,500 ..
Baku Naphtha Company (Suvakhani) ..	21,600 ..
Schibajeff (formerly V. J. Ragosine) ..	16,700 ..

The crude oil from Balakhani and Sabuntschi, which is refined in the Black Town, has an average sp. gr. of 0·865—0·870, whilst the oil refined at Bibieybat has a sp. gr. of 0·855—0·858. The products of distillation differ with the sp. gr., as is shown in the following table :—

	Balakhani-Sabuntschi.	Bibieybat.
Light petroleum	5—6 per cent.	10·5 per cent.
Burning oil I. (kerosene) ..	27—33 ..	40·0 ..
Burning oil II. (solar oil) ..	5—6 ..	13·5 ..
Residues	50—60 ..	36·0 ..

The distillation of the crude petroleum for the purpose of separating the kerosene therefrom is effected in apparatus of three different forms: (1.) Stationary,

Its ends rest on iron rails *a*, and the sides are supported by angle irons set into the brickwork. *B* is a dome, and *c* the outlet communicating with a pipe leading to the condenser. *C* is the space in which the residues are burnt, the flames returning by way of *C*₁ and *C*₂. The stills are mostly worked in groups or series. *N* is a charging main with branches *n*, and *d* a steam main with branches *d*₁ running along the back of the stills. The residues are discharged at *E*. *m* is a manhole for cleaning purposes. A dephlegmator or separator is frequently placed between the head of the still and the condenser to separate and return to the still any high boiling oils carried over mechanically. Fig. 5 represents a dephlegmator of simple construction. In Figs. 6 and 7, *a* is an iron cylinder, surrounded by a jacket *b*, and divided in two parts by *c*. The vapours enter at *d*, pass through the apparatus in the direction indicated by the arrow, and escape at *d*₁. The oil which accumulates at the bottom of the cylinder is removed by means of a special pipe. For condensing purposes, cooling worms of the usual construction, or cast-iron pipes of the form shown in diagrams 8 and 9, are employed. Four pipes are placed parallel to one another in a horizontal

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

wrought-iron cylindrical stills, with convex bottom and the ordinary construction of still head, heated by petroleum residues. These stills are almost out of use at the present time. (2.) Waggon boilers (see Figs. 1 and 2), made of wrought-iron plates. Dimensions, 7 metres by 4 by 3. *A* is the still, with corrugated bottom and three still heads *a*. *b* is a manhole, and *c* the outlet for the residues. *B*, *B*₁, and *B*₂ represent the brickwork and the arrangement of the flues. *v* is the "residues" burner. This apparatus is capable of refining from 7 to 8 tons of crude petroleum in 24 hours. (3.) Cylindrical wrought-iron stills, illustrated in Figs. 3 and 4. The still *A* is 5—6m. long, and has a diameter of 2—3m.

position, and in sets of six, one above the other, so that the entire system consists of 24 pipes. The vapours which enter at *a*, are distributed in the head-piece *b*, and pass from the uppermost set of pipes to the lowest series, meeting at *b*₁, *b*₂, and *b*₃, and so on until *b*₁₁ is reached, from whence the condensed oil flows into the receiver. The distillate is collected in closed vessels, the separation of the water from the oil being effected in apparatus similar in principle to a Florence flask. An arrangement of this kind, which admits of the simultaneous observation of the colour of the distilled product, is represented in Fig. 10. The oil after leaving the condenser at *a* runs into the receiver *A*.

The water is removed through the pipe *b*, the undecomposable gases escape at *c*, whilst the oil flows over into *d*, and from thence passes through the lantern B to the different receiving vessels by way of pipes 1 to 5.

FIG. 7.

The residues, called *astutki* by the Russians, and *masut* by the Tartars, which are obtained in the refining of crude petroleum, are mainly used for heating purposes, their fuel value being almost double the value of ordinary coal. With burners of ordinary construction, 1 kilo. of residues evaporates about 12 kilos. of water, whilst with

FIG. 9.

special burners it is possible to evaporate from 14 to 15 kilos. To refine 100 parts of crude petroleum, from 3 to 4 parts of residues are required. The principle of the ordinary oil burner (see Figs. 11 to 14) consists essentially of an arrangement for spraying the oil by means of a jet of steam, the size and form of the flame

FIG. 10.

depending on the construction of the pipe D. A burner frequently employed is that known by the name of the Brandt system (Fig. 15). N is the inlet for the residues, and D that for the steam. Both meet between *f* and *i*, which can be adjusted, and project a tongue of flame

into the furnace at *s*. When the burner is in use, the valves *o* and *l* are opened completely, the pressure of steam and flow of residues being regulated by adjusting the cone *f*. The application of this burner to a Cornish steam boiler is represented in Figs. 16 and 17. R is a store tank, and N a pipe which supplies the oil. D is the steam pipe. The air necessary to support the combustion is introduced through holes in the furnace door *t*. Diagrams 18 to 20 illustrate the oil burner devised by Lenz. D and N are the inlet pipes for steam and residues communicating with the tubes *a* any *a*₁. *g* is a mixing chamber, closed at the top and bottom by screw covers *h*. *o* are rods fitted with eccentric terminals working the slides *c* (see Fig. 19). This arrangement serves to regulate the flow of steam and residues. The mouthpiece *s* is a horizontal fissure running round one half of the cylindrical chamber *g*. The burner consumes from 3 to 3.5 kilos. of residues (sp. gr. = 0.91, flashing point = 140°) per hour per horse power. Nobel Brothers employ the Sandgreen burner (see Fig. 21). Oil and steam are introduced through N and D into the chamber A B, which is divided by the partition *f*. The burner is regulated by the plate *k*, which can be adjusted by the lever *h* and bar *l*. The plate *k*, which forms the

FIG. 11.

FIG. 12.

FIG. 13.

FIG. 14.

outlet for the steam, does not admit of adjustment. By withdrawing the plug *m* steam may be passed through *g* into the oil chamber A for cleaning purposes. For locomotives or tubular boilers it is necessary to employ a burner capable of dispersing the flame over a large surface. Figs. 22 to 25 represent an improved Lenz burner suitable for this purpose. It is similar in construction to the above burner (Fig. 20), the only difference being that the mouthpiece *s* runs round the whole of the cylindrical chamber *g*. By this modification the flame of oil projected into the furnace, instead of being pointed, is made to assume the shape of a ring, and consequently the effect upon the plates of the boiler is less prejudicial. The alteration in the construction of the mouthpiece *s* necessitates a modification in the form of the slides *c* and *c*₁, which in this case are cylindrical, their mode of working being shown in Fig. 24. Fig. 25 is a vertical section through diagram 23 at D and N, which are the steam and oil inlets. In order to clean the oil chamber, steam is introduced through the valve *h*. Fig. 22 illustrates a further modification in the construction of the mouthpiece of the burner. Diagrams 26 and 27 represent an oil burner devised by Brandt, suitable for locomotives. The horizontal disc *a* divides the chamber of the burner into two parts, steam being introduced into the lower part at D and the residues into the upper part at N. The openings at *i* are regulated by the disc *o*, a slight revolution of which either increases or diminishes the width of the apertures. *f* is the mouth of the burner. Fig. 28 shows the same burner *l* in the fire-box of a locomotive. The burner is placed in the centre of the hearth *k*. The residues and steam are introduced through pipes N and D, provided with the valves

4. To work a train with twenty loaded trucks about 10 kilos. of residues are required for each kilometer.

Before retining, the crude petroleum is settled in iron tanks for several days. It is then passed through pipes contained in the vessels in which the residues obtained in the process of distillation are cooled. By this means the oil is heated to a temperature varying between 80°

lined with lead. The mixture of oil and acid is agitated by the introduction of compressed air into the bottom of the washing vessel. The oil is washed with acid in two operations, the waste acid from a previous purification being used for the first treatment, and fresh acid for the second washing, the quantity of acid employed being from 0.6 to 0.9 per cent. After the removal of the last

FIG. 15.

FIG. 17.

FIG. 19.

FIG. 18.

FIG. 20.

FIG. 21.

and 130°, and may be transferred to the hot stills almost immediately after the withdrawal of the residues. To facilitate the distillation, superheated steam is introduced into the still. The purification of the kerosene is effected in iron cylindrical vessels having a conically-shaped bottom and holding from 100 to 200 tons of oil. Two such vessels are placed alongside each other, one above the other. The washing with acid is effected in the upper vessel, which for this purpose is

acid the oil is washed with cold water. It is then run into the lower vessel and agitated with a solution of caustic soda, having a sp. gr. of 1.28—1.35. This treatment is repeated with a less concentrated solution of alkali, the total amount used depending upon the quantity of acid contained in the oil; with careful work it does not exceed 0.3 per cent. of Na O. It is best not to wash the oil with water after the treatment with alkali, as, owing to the decomposition of traces of soda soaps in

solution, the oil may assume an opacity which cannot be subsequently removed without difficulty.

For the examination of the refined kerosene the following tests are in vogue: The presence of organic acids is determined by agitating the oil with about 2 per cent. of a solution of caustic soda, having a sp. gr. of 1.2 and

of the oil is effected by employing Stammer's instrument (see Redwood, this Journal, 1885, 77). Good kerosene should be colourless and water-clear. To test the oil photometrically, Bunsen's apparatus is used, the height of the flame of the standard candle being 52mm. The distillation test is made with the aid of Glinsky's frac-

FIG. 22.

FIG. 24.

acidifying the alkaline solution after settling. The intensity of the milkiness produced forms the criterion of the amount of organic acid present in the oil. To ascertain whether the oil has been perfectly washed with

FIG. 26.

FIG. 27.

sulphuric acid it is again agitated with a small quantity of alkali. The formation of a white emulsion indicates sufficient washing; if, however, the emulsion assumes a yellow appearance, it shows that the oil has been insufficiently treated with acid. The colorimetric examination

FIG. 23.

FIG. 25.

tionating apparatus, the distilling flask being filled with 250cc. of oil, and the distillation being completed in about two hours. The flashing point is mostly determined according to Abel's test. For Russia the flashing point

FIG. 28.

of kerosene, which has hitherto been 28–30°, has recently been reduced to 25°.

In discussing the manufacture of lubricating oils from the petroleum residues, the author refers to the paper by

FIG. 29.

Ljutyk which appeared in *Dingl. Polyt. J.* 253, 460 (see this Journal, 1885, 111). The residues obtained by the

rectification of the crude petroleum at Baku represent a thin liquid oil having a sp. gr. of 0.90–0.91. Being almost free from paraffin they are well adapted for the manufacture of lubricating oils, nevertheless only 10 per cent. of the total quantity produced (56 per cent. of the crude oil) is utilised for this purpose, the remainder being employed as fuel. The manufacture of lubricating oil

FIG. 30.

involves the re-distillation of the residues and purification of the product. The distillation is effected in horizontal wrought-iron stills, similar in construction to the stills used for refining the crude oil. In Fig. 29 A represents the still, which is 3.5m. long, 1.3m. deep and 2m. wide; *a* are upright tubes conveying the vapours to B, thence to the smaller pipe B₁, and through the "separator" C, and the pipe *c* to the condenser. The oil condensed in B runs away through the pipe *b*, that in

FIG. 31.

B₁ through *b*₁, and that in C through *c*₁. For cooling purposes condensers of the usual construction are employed. An effective air-cooling arrangement is shown in Fig. 30. The vapours enter at *a*, and pass through the series of bent pipes, which allow of the withdrawal of any condensed oils by the branches *b*, *c* and *d*. These communicate with the coils *b*₁, *c*₁, and *d*₁, which pass through a water-cooling apparatus. Fig. 31 represents an air-cooling system of recent origin. It consists of horizontal iron

FIG. 32.

tubes *a* to *c*, which are 6 to 7m. long. The diameter of the tubes, which is about 20cm. in *a*, is gradually reduced to about 10cm. in the last tube *c*. The vapours enter the system at *a*₁, any oil condensed in *a* being withdrawn at *a*₂. The oils condensed in *b* and *c* run away at *b*₁ and those collected in *d* and *e* are removed through the pipe

e; from *e* the vapours pass through *f* and thence to the condenser. In *a*, *b*, and *c* the cooling is effected by air, and in *d* and *e* by both air and water. As fuel petroleum residues are employed, the distillation being assisted at the end by the introduction of superheated steam the temperature of which should not exceed 300°. The consumption of residues amounts to 20 per cent. of the charge employed. The distillate is generally fractionated in the following manner:—

	Per Cent.	Sp. Gr.
First runnings (solar oil)	10–15	0.870
Spindle oil ..	9	0.896
Engine oil.....	40–42	0.911
Cylinder oil	3–4	0.915

At a large refinery the following products are obtained:—

	Per Cent.	Sp. Gr.
Solar oil.....	10	—
Spindle oil	10	0.897
Engine oil	25	0.908–0.910
Cylinder oil	3	0.915–0.918

The purification of the lubricating oil with sulphuric acid and alkali is effected in iron pots A (Fig. 32) lined with lead. B is a cylindrical frame to which the stirrers *b* are attached. These agitate the mixture in the manner indicated by the arrows in the diagram. The oil is treated with 2 to 3 per cent. of concentrated sulphuric acid at 30°; the waste acid is then withdrawn and the oil agitated with a concentrated solution of caustic soda (20 B.), this treatment being repeated several times with a less concentrated solution after every washing. Finally the oil is washed with water, and dehydrated in shallow pans heated by the aid of steam coils. The author concludes his paper with some remarks relating to the cost and latest modes of transporting the different products manufactured at Baku.—D. B.

*Comparison between Caucasian and American Petroleum.** C. Engler and I. Levin. Dingl. Polyt. J. 261, 29–34.

THE question as to the illuminating value of petroleum oils of different origin, if burned under the most favourable circumstances, is still unanswered. Although there are to be found in technical journals experiments in that direction, the different specimens of oils were examined promiscuously, just as they occurred in the trade, without regard whether they represented the general average of the products of the Caucasian or American petroleum industry. Other investigators examined quite arbitrarily different fractions of an oil, burning them in the same lamp, and not taking into consideration that different fractions require a different construction of the lamp as regards the quality of the wick, the admission of air, and so forth. Photometric tests give, of course, the most trustworthy criterion as to the value of an oil; but, to answer the question fully, an examination of the different fractions, their capillarity, their rapidity of rising in the wick, and their viscosity is equally necessary. It is well known that petroleum-naphtha has a greater illuminating effect than the high-boiling oils; but, on the other hand, a high percentage of naphtha lowers the flashing-point, thereby increasing the probability of explosions. The regulations of the law give a guarantee against the flashing-test being too low, but the amount of high boiling oils

can only be estimated by a fractionated distillation. Table I. shows the amount of different fractions in several specimens of crude petroleum oil. Table II. gives a comparison between Caucasian and American "refined petroleum," as occurring in commerce.

The general average is thus:—

	Below 150°	150—290°	Above 290°
Caucasian petroleum	8	86.6	5.4 vol. per cent.
American petroleum	16.9	57.1	26.0

We also learn from Table II. that Caucasian petroleum possesses a far higher degree of purity than its American competitor. But it must not be overlooked that the illuminating value does not depend upon the purity. On the contrary, it is just possible that the high-boiling oils of the American petroleum influence less the illuminating effect than the corresponding fraction of the Caucasian product. The flashing test of the portion distilling between 150° and 290° is also considerably in favour of the Caucasian petroleum—viz., 45.5° and 29° respectively. The quantity of oils distilling between 150 and 290 is:—

Caucasian petroleum	13.1 vol. per cent.
American petroleum	42.9

The American refining works purposely mix with the normal petroleum, which boils between 150° and 290°, as much as possible of the low and high-boiling oils, not only to increase the yield, but also to make up for the unfavourable effects of these admixtures—viz., a low flashing-point, high specific gravity and great viscosity.

—S. II.

Comparative Experiments on the Properties of Caucasian and American Petroleum. C. Engler and J. Levin. Dingl. Polyt. J. **261**, 77—87.

THE conclusions arrived at may be summarised as follows:—(1) Caucasian petroleum gives at least as much light as American oil; (2) Although at the commencement American petroleum yields a brighter light, there is considerably less diminution in the light afforded by Caucasian oil, so that at the end of the experiment the latter gives more light than American oil; (3) The consumption of oil for a given illuminating effect is approximately the same with both kinds of oil, but, if anything, it is slightly in favour of Caucasian oil; (4) As a rule, less satisfactory results are obtained when Caucasian oil is burnt in lamps adapted for the use of American oil, or *vice versa*; (5) The illuminating power of the low-boiling fractions of all kinds of petroleum oil is greater than that of the higher-boiling portions; in the case of Russian oil, however, a greater difference is observed in this respect; (6) The fraction of Caucasian oil boiling under 150° contributes less to the illuminating power, and the fraction boiling above 300° has a less injurious effect on the illuminating power, than the corresponding fractions of American oil. This difference is mainly due to the fact that American oil yields about 25 per cent. of distillate above 300°, whilst Russian petroleum does not contain more than 5.25 per cent. of oil boiling above this temperature; (7) Although Russian oil is specifically heavier than American oil, it ascends the wick more readily than the latter, a circumstance which the authors attribute to the higher viscosity possessed by American petroleum—1.15, as compared with 1.07, water being 1.0.

From further carefully-conducted experiments, the following general conclusions were drawn:—I. Comparative measurements as to the illuminating qualities of different kinds of oils only possess any value when they are carried out with different burners, each best suited to the nature of the oil experimented on. II. Also with comparative measurements with single fractions of the oils, burners with draughts of different degrees of velocity must be employed. III. Almost all the numerous measurements of illuminating power hitherto carried out with oils of different origin, and with different boiling fractions, if one and the same petroleum, possess value only in the case of the accidental and narrowly limited conditions afforded in the use of one

lamp; for if the heavier kinds of petroleum, or the higher boiling fractions thereof, be tested with lamps of greater draught, then the ratios of comparison turn round in favour of the heavy oils, and these become more powerfully illuminating than the lighter ones. The recently generally-expressed opinion that the lower-boiling fractions of our burning petroleum oils are of more illuminating power than the higher-boiling ones, is a baseless one. IV. Separation of carbon (smoke) at the wick only takes place—(a) When the petroleum is composed of constituents of too extreme a character with regard to the boiling-point; and (b) When the admission of air in the burner is too weak, considering the heaviness of the oil. V. The test by distillation and the determination of the viscosity furnish the most important key for a preliminary judgment as to the applicability of petroleum for burning in certain classes of lamps.—D. B.

A Second Thioxen. R. Demuth. Ber. **19**, 1857—1859.

ALL endeavours to obtain a second thiophendicarboxylic acid having been unsuccessful, the author attempted to prepare an isomeric thioxen in order to determine whether by oxidising the two methyl groups a new dicarboxylic acid could be obtained. For this purpose γ -thiotolene was converted into the iodo-product, and the latter mixed with methyl iodide and sodium contained in an ethereal solution. After allowing the mixture to stand for several days in the cold, the ether was expelled and the product of the reaction subjected to distillation. On fractionating the distillate a new thioxen boiling between 138—140° was obtained, having a sp. gr. of 0.9777 at 21° compared with water at the same temperature. Mesinger's thioxen yields a dicarboxylic acid on oxidation; the new compound is, however, completely decomposed when subjected to a similar treatment.—D. B.

On Benzene containing Thiophen. C. Willgerodt. Journ. Pract. Chem. **33**, 479.

ON passing chlorine into commercial benzene, boiling at 80—85°, without addition of a chlorine carrier, a turbidity appears; but the solution soon becomes clear again, and shortly afterwards a strong evolution of hydrochloric acid proves that a substitution is taking place. This is owing to the thiophen present in the benzene, the former being chlorinated, for no hydrochloric acid is evolved on passing chlorine into pure benzene.

The author has tried to make use of the reaction on a large scale. Chlorine was passed into 4 kgms. of tolerably pure benzene, which contained some thiophen, for four hours; light was partly excluded, and the solution cooled with ice. On redistilling, the chief portion went over at 80—85°. A portion, which was freed of chlorine, contained no more thiophen. There were furthermore obtained: at 85—95°, 42 grms.; at 95—110°, 53 grms.; at 110—120°, 7 grms.; at 120—130°, 18 grms.; at 130—190°, 30 grms.; at 190—210°, 150 grms. From the last fraction benzene hexachloride separated out on cooling. It is as yet undecided whether it will be possible to prepare pure chlorothiophen from commercial benzene. Combination of chlorine with benzene may no doubt be prevented by the better exclusion of light, and by reducing the time for chlorinating to a minimum.—A. R.

IV.—COLOURING MATTERS AND DYES.

The Composition of Magdala Red. P. Julius. Ber. **19**, 1365—1368.

HOFMANN was the first to study the constitution of this body, which he considered to belong to the rosaniline group, having the formula $C_{30}H_{21}N_3HCl.H_2O$. The substance, which is the hydrochloride of a base, was purified by converting it into the sulphate, and re-crystallising from alcohol acidified with H_2SO_4 . The author is led by a series of careful analyses to modify the above formula of Hofmann's to $C_{30}H_{21}N_4Cl$, and from this and its mode of formation, considers it to belong to the salitrines.

—J. B. C.

Synthesis of Orcinol from Acetone Dicarboxylic-ether.
H. Cornelius and H. von Pechmann. Ber. **19**, 1446—1451.

By an analogous reaction to that by which Baeyer prepared phloroglucinol from malonic ether, the authors have succeeded in synthesising orcinol. The reaction proceeds in two stages. In the first place by acting upon acetone dicarboxylic-ether with its sodium compound, condensation follows:—

In the second phase a six carbon ring is formed by union of a methylene carbon and a ketone carbon atom, with elimination of water :—

The condensation occurring in one of the two directions indicated by the dotted lines. In the third phase molecular change occurs, the sodium compound of dioxyphenyl-aceto-dicarboxylic ether being formed.

By saponification of the ether carbonic acid is at the same time eliminated and symmetrical dioxiphenylacetic acid is formed. To obtain orcinol from this body it is only necessary to distil the silver salt in a current of CO_2 . The resulting compound gave the melting point and all the other physical properties of pure orcinol.

—J. B. C.

Thiophenol and the α -Naphthol of the Thiophen Group.
A. Biedermann. Ber. **19**, 1615—1620.

THE author employed the method of Otto in order to obtain the mercaptan of thiophen C_4H_3S-SH .

Thiophen is first converted into the sulphonic acid by shaking thiophen dissolved in petroleum ether with strong sulphuric acid. This is converted into thiophen sulphonic chloride, and then by the usual method into the zinc salt of the sulphinic acid. This on reduction with zinc and hydrochloric acid gives thiophen sulphydrylate, which may be distilled off by steam. It is a yellowish oil boiling at 166°. The yield is very small. It gives the isatin reaction, and with diazo-compounds combines to form colouring matters. As Pittig and Jayne have shown, isophenyl-crotonic acid on heating gives α -naphthol. On heating thiophen aldehyde with sodium succinate and acetic anhydride the mass becomes brown and CO_2 is evolved. After extracting the unaltered aldehyde with ether, and adding caustic soda, a current of CO_2 was passed through the solution, which precipitated the oxythionaphthene as a flocculent mass. This was crystallised from ether. Oxythionaphthene combines with diazo-compounds to form colouring matters. In most of its reactions it closely resembles α -naphthol.—J. B. C.

A New Synthesis of Mixed Azo-colouring Matters from Aromatic Diamines. Martin Lange. Ber. 19, 1697—1700.

O. WALLACH and NIETZKI (*Ber.* **15**, 2825; and **17**, 343) have described the formation of mixed azo-compounds from aromatic diamines, by diazotising the monoacetyl compound of the diamine, combining this with a phenol, removing the acetyl group by boiling hydrochloric acid, again diazotising, and finally combining this diazo-body with either a phenol or an amine. This process has the disadvantage of small yields of the substances, because by continued heating with hydrochloric acid amidoazo-compounds are considerably decomposed. It is also not possible with this method to form diazo-compounds containing as terminals two different amines. From the following, however, it will be seen that this can easily be done, starting from compounds of the tetrazodiphenyl class. In the formation of colouring matters from tetrazo-

diphenyl and sulphonic or carboxylic acids of aromatic amines, the author noticed the regular formation of intermediate insoluble compounds which were converted—apparently simply on standing some time—into the colouring matters. Investigation showed that these insoluble substances are formed when one molecule of tetrazodiphenyl reacts with one molecule of the aromatic amido-acid, and it also proved that when these bodies are brought together with an alkaline solution of a phenol or amine, or their sulphonic acids, the new diazo-colouring matters are at once formed. These new intermediary compounds have the character of anhydrides of diazo-sulphonic acids. That obtained by the action of 1 mol. tetrazo-diphenyl on 1 mol. naphthionic acid has the formula—

It is almost insoluble in water, ammonia, and alkaline carbonate solutions. If boiled with water the diazo-group is replaced. Both substances thus obtained are colouring matters differing in shade. When this diazo-compound is brought into contact with a phenol or amine in alkaline solution, it reacts at once to form colouring matters, according to the following equation, for example, with phenol :-

A number of similar colouring matters have been patented and manufactured by Messrs. Ever & Pick, of Berlin; they dye direct on cotton. As from tetrazodiphenyl, so can similar diazoanhydro-sulphonic acids be obtained from all tetrazo-compounds which contain the two diazo-groups in para-position to each other, or to the junction of the two benzene nuclei.—T. L. B.

β-Naphthylaminesulphonic Acid. S. Forsling. Ber. **19**, 1715—1716.

By the action of strong sulphuric acid on β -naphthylamine at 140° , a sulphonic acid is obtained, which crystallises from water in fine white needles. The potassium salt $C_{10}H_6NH_2SO_3K$ is extremely soluble in water and forms microscopic needles. All the water of crystallisation of the sodium salt $C_{10}H_6NH_2SO_3Na + 4H_2O$ is removed by standing over sulphuric acid. The barium salt forms fine needles. The free acid suspended in a mixture of alcohol and ether, and exposed to a stream of nitrous acid, is converted into the diazo-compound—

This diazo-compound boiled with hydrochloric acid, converted into the potash salt, dried and then heated with phosphorus pentachloride, gave a β -chloronaphthalene-sulphonic chloride, melting at 128–129°. This compound is very probably identical with that described by K. Arnele, melting at 129°, obtained from the β -chloronaphthalene-sulphonic acid derived from β -chloronaphthalene.

- T. L. B.

On the Toluidines. Leo Lewy. Ber. 19, 1717—1719.

ANILINE combines with phosphoric acid to form only two of the three theoretically possible salts—viz., the secondary $(C_6H_7N)_2H_3PO_4$, and the tertiary $(C_6H_7N)_3H_3PO_4$; on drying, the latter loses aniline and is converted into the former. Paratoluidine forms only the secondary phosphate $(C_7H_9N)_2H_3PO_4$, which is very insoluble in cold water; whilst orthotoluidine forms only the more easily soluble primary salt $C_7H_9N.H_3PO_4$, and *never* the secondary or tertiary. When a solution of orthotoluidine phosphate is shaken with aniline or paratoluidine, the orthotoluidine is liberated and secondary aniline or paratoluidine phosphate is formed; upon this fact is

based the following method of separating the toluidines in commercial toluidine. In order to obtain a very pure orthotoluidine it is well to use an excess of acid on the quantity necessary to combine with the paratoluidine present. 100cc. toluidine, containing, for example, 35 per cent. paratoluidine, are well mixed with 68cc. of a 21 per cent. phosphoric acid solution to form the secondary paratoluidine phosphate, and with other 19.3cc. phosphoric acid to form the primary phosphate with five per cent. orthotoluidine; 30cc. water are then added, the whole well shaken together and left over night. The mixture must be cooled during the addition of the acid. The orthotoluidine filtered and pressed from the paratoluidine phosphate crystals, and then rectified, does not contain sufficient paratoluidine for detection by Rosenstiehl's method.—T. L. B.

A New Class of Azo-colouring Matters. C. A. Martins. Ber. 19, 1755—1756.

THIS paper is of a controversial nature, discussing and confirming the results described by Dr. Lange (see abstract on p. 481), at the same time claiming priority of invention for himself and colleagues. The reaction is stated to be a general one in all cases when tetrazo-diphenyl, tetrazo-ditolyl, or tetrazo-dixylyl salts react with amines, phenols, or their sulphonic or carboxylic acids.—T. L. B.

New Synthesis of Triphenylmethane. H. Griepentrog. Ber. 19, 1876.

THE author has investigated the action of benzaldehyde on toluene in the presence of zinc chloride, the object being to ascertain whether it was possible to effect partial condensation of the benzaldehyde with the methyl group of toluene, in which case it was anticipated that stilbene would be formed, $C_6H_5CH=CHC_6H_5$. It was found, however, that the hydrogen atoms of the benzene nucleus only were eliminated, hydrocarbons of the triphenylmethane group being formed. On applying this re-action to benzene, triphenylmethane was obtained in considerable quantity, its formation being expressed by the following equation:—

—D. B.

An Improvement in the Manufacture of α - or β -Carbanaphthol Acid Alkaline Salts. J. Y. Johnson, London. From Dr. C. Kolbe and C. Rentsch, Radebeul, Saxony. Eng. Pat. 8155, June 19, 1886. 4d.

ACCORDING to the present invention the carbonic anhydride is caused to act on the alkaline salts of α - or β -naphthol, not at an ordinary temperature as in Patent 6134, May 19, 1885 (this Journal, 1885, 531), but under pressure in a closed vessel, and at a temperature at from 120—145°, by which means the alkaline salts are in a nascent state converted into the respective naphthol carbonic alkaline salts.—D. B.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

The Fibre of the German Indianrubber Plants. G. Kassir. Archiv. der Pharmacie, 1886, 224, 97.

THE author has determined the amount of caoutchouc contained in the *Asclepias Cornutia* (Decaisne). The fruit shells were found to be filled with long silky hairs (serving for the dissemination of the flat brownish-red seeds), which from their beautiful lustre had already excited the attention of many, and have occasionally been worked up into textile fabrics. In 1760, La Rouvière, of France, used this wool, partly alone, though for the most part mixed with other fibres, for spinning and weaving into beautiful silk-like fabrics. Fries, of Münsterberg, and Schmieder, of Liegnitz, who tried to utilise these silk plants, found that besides the silky wool, the bast of the *Asclepias* deserves special attention, since when properly prepared it is pure white, very lustrous, and well suited for spinning purposes. The

sprouts, still with leaf, gathered in May, August, and September, when dried and tested gave the following results:—

	May.	Aug.	Sept.
Extract	2.17	5.81	7.20
Crude caoutchouc	0.26	1.45	2.37
Pure caoutchouc	0.15	1.13	1.61

—B. H.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

On the Consumption of Acid in Discharging Indigo-blue Prints. F. Langmann. Dingl. Polyt. J. 261, 43—45.

FOR discharging indigo-blue prints, chromic acid is now chiefly used, which, printed in the form of potassium chromate, and set free during the passage of the goods through acids, bleaches the indigo. The acid used for discharging is a mixture of sulphuric and oxalic acids; the latter on account of its reducing power prevents any further action of an excess of chromic acid. The purpose of this investigation is to measure the consumption of these acids. The discharging apparatus used consisted of three vats. The first vat had a capacity of about 300 litres, was lined with lead, and provided with three rollers and a vertical heating pipe. It was charged with fresh acid at the beginning of the experiment, and during the experiment replenished gradually, first with 300 litres of spent acid from the previous day's work, and then with 150 litres of fresh acid of the same composition as that with which the vat was first charged. The goods passed from this vat through the two following vats, in which they were washed. The following analyses show the composition of the acids: *a*, the fresh acid in the discharging vat as used at first and at last; *b*, the spent acid used to replenish; *c*, the composition of the acid in the discharging vat when 150 litres of acid *b* had been used; *d*, the same after the whole 300 litres of acid *b* had been used; *d* shows the composition in the vat after 150 litres of fresh acid (*a*) had been added. Samples *w*₁, *w*₂, *w*₃ show the acidity of the washings at the time samples *c*, *d*, and *e* were taken:—

Samples.	H ₂ SO ₄ .	C ₂ O ₄ H ₂ +2H ₂ O.	Acidity of Washings.
<i>a</i> ,	9.08	7.77	—
<i>b</i> ,	10.23	5.60	—
<i>c</i> ,	7.05	9.53	W ₁ 0.4
<i>d</i> ,	7.00	7.77	W ₂ 0.45
<i>e</i> ,	11.33	5.71	W ₃ 0.76

The final result is represented by the samples *b* and *e*, which show a considerable decrease of oxalic acid as compared with *a*. The series *a*, *b*, *c*, shows the peculiarity that the amount of sulphuric acid decreases from 9 to 7.05 per cent., although the vat was fed with an acid of 10 per cent., and the amount of oxalic acid increases from 7.7 per cent. to 9.53 per cent., in spite of the fact that the vat was fed with an acid containing only 5.60 per cent. of oxalic acid. The relative quantities of sulphuric acid and oxalic acid used are, however, evidently advantageous, the oxalic acid being well utilised, whilst the activity of the mixture remains constant, owing to the increase of the percentage of sulphuric acid.

Action of Aromatic Bases upon Manganese Brown. F. Rettig. Bull. Soc. Ind. Mulhouse, 1886, 174—175.

IF a piece of cloth dyed with manganese be passed through a solution of aniline hydrochloride or sulphate, a beautiful deep black is obtained, which is fast to soap. Naphthylamine forms under similar conditions a puce, β -naphthylamine a maroon shade. The author has experimented with a series of aromatic bases, and has obtained the following results:—4grms. per litre of the sulphate were

employed. The solution was acidified with 0.4gm. sulphuric acid, and the dye-bath raised from the ordinary temperature, gradually, to 55° C., for three-quarters of an hour.

1. Aniline alone gives a deep black.
 2. The presence of the methyl group in the *ortho* position does not modify to any extent the shade. It is, however, slightly bluer and not so intense.
 3. The presence of methyl in the *meta* position changes the shade to violet (meta-toluidine).
 4. The methyl group in the *para* position gives a weak brown shade, not very fast to soap. Other methyl groups have no sensible effect.
 5. Bases which have the methyl groups in *meta* and *ortho* positions, adjacent orthoxylidine, symmetrical meta-xylidine, and paraxylidine; the first two give a maroon, the latter a very pretty grey.
- None of these bases, excepting meta-toluidine, have a practical value. The presence of the hydroxyl group in the *para* position to the amido group, gives a fast and brilliant manganese brown.—J. B. C.

Improvements in and relating to Mordants for Use in Dyeing or Printing Calico and other Fabrics. H. H. Lake, London. From C. N. Waite, Mass., U.S.A. Eng. Pat. 6070, May 4, 1886. 4d.

This invention relates to a improved mordant for fixing aniline or other dyes on cotton yarn or cloth. The mordant consists of antimony dissolved in lactic acid, and is employed in combination with tannin or other suitable materials. Four hundred pounds of lactic acid (25%) are mixed with fifty pounds of strong nitric acid and as much powdered antimony as the acids can dissolve, a small excess being preferred to avoid the formation of antimonious oxide instead of antimonious oxide, the former not being soluble in lactic acid. On completion of the reaction, seventy pounds of dry carbonate of soda are added, which neutralises two-thirds of the lactic acid, and does not precipitate the antimony. In cases where the acid cannot do harm, the soda is not added. The goods or yarn are first run through a suitable tannin bath, slightly washed, and then treated in a bath of the above mordant. For deep shades the inventor uses 4–5 pounds of lactate of antimony per hundred pounds of yarn or cloth. It is claimed that the antimony remains in solution, if the bath be cold, even if all the acid has been neutralised, and that the bath can be completely exhausted. Also, that the above mixture has many advantages over tartar-emetic, double oxalate of antimony and potash, or “oxy-muriate of antimony.” —H. A. R.

VII.—ACIDS, ALKALIS, AND SALTS.

On the Action of Potassium Sulphate on Metallic Phosphates at High Temperatures. H. Grandean. Ann. Chim. Phys. 1886, 8, 193.

THE author has obtained a number of crystalline compounds by the action of excess of potassium sulphate on phosphates, at temperatures of 800° to 1500°. The nature of the product formed depends on the base present as phosphate, and on the temperature. The phosphates studied are divided into three groups, according to the products formed. (1) Phosphates of Ca, Mg, Zn, Cl, Ba and Sr, which form double phosphates of the formula $MKPO_4$. Barium and strontium form also sulphates. (2) The phosphates of Al, Be, Fe, Ni, Co, Cu, Mn, Cr, U yield at low temperatures double phosphates of the type $MKPO_4$; at high temperatures, crystalline oxides. The last three metals also form potassium salts, manganate, chromate and uranate respectively. (3) The third group includes the phosphates of Ce, Di and La, which yield phosphates having the formula MPO_4 at low temperatures, but at the highest temperatures crystalline oxides. A large number of crystalline compounds have thus been prepared, and the author has succeeded in producing the minerals erythrolite and phosphocerite, and also zircon and cassiterite. He believes that it will be possible to prepare spinel, chrysoberyl, and other naturally occurring aluminates.—S. Y.

New Mode of Formation of Pentathionic Acid. T. Salzer. Ber. 19, 1696.

It is known that thiosulphuric acid when liberated from any of its salts is almost immediately resolved into sulphurous acid and sulphur. The author found that on adding a small amount of potassium arsenite the decomposition is prevented more or less completely. The solution after filtration exhibits the reactions of pentathionic acid. The action is ascribed to the probable formation of intermediate product ($As_2O_3S_5$?). —D. B.

On the Dissociation of Calcium Carbonate. H. Le Chatelier. Compt. Rend. 102, 1243.

THE alterations in the tension of dissociation of calcium carbonate produced by a rise of temperature have never been studied up to the present. The author attempted to fill up this deficiency. He employed a thermo-electrical element for measuring the temperature. Calcium carbonate in different states (marble, chalk, or chemically precipitated) showed the same tension at equal temperatures, the equilibrium being produced in less time, if the matter was in a very fine division. The result of experiments was as follows:—

Temperature.	Tension of Dissociation.
517	27mm.
610	16
625	56
710	255
715	289
810	678
812	763
865	1333

The tension of dissociation therefore equals the pressure of the atmosphere at about 812° C. On heating the substance quickly, the temperature even rises to 925°, where it remains constant, probably owing to the rapid decomposition which is going on, and which absorbs much heat. The author observed the same phenomenon with gypsum and slaked lime. (Compare similar investigations by Kahlbaum, Ber. 18, 3146).—S. H.

Improvements in and relating to the Decomposition by means of Magnesia of the Residual Ammonium Chloride of the Ammonia Soda Process. W. F. R. Weldon. From Pechiney & Co., Salindres, France. Eng. Pat. 9227, August 1, 1885. 1s. 1d.

IN the ammonia soda process the mother-liquor from which sodium bicarbonate has been separated is a mixed solution of ammonium chloride, sodium chloride, sodium bicarbonate and ammonium bicarbonate. In order to recover the ammonia from this liquor, it is heated, whereby all the ammonium bicarbonate is driven off, and also a further quantity of ammonium bicarbonate formed by the reaction of sodium bicarbonate on ammonium chloride. The remaining solution only contains sodium and ammonium chloride, from which all the ammonia is liberated by the addition of milk of lime. The chlorine of the ammonium chloride is thus converted into calcium chloride. The latter, however, is a body from which it is not yet possible industrially to separate its chlorine, while means are known to recover chlorine from magnesium chloride. The inventors therefore endeavoured to replace lime by magnesia. But, although lime readily decomposes ammonia compounds, the same cannot be said of magnesia, if the latter be used for that purpose in the same manner as lime. If the conditions of proceeding are altered, magnesia decomposes ammonia salts nearly as readily as lime, and the present invention consists in treating the mother-liquor under conditions securing those objects. Ammonium bicarbonate is first driven off by heating, and a sufficient quantity of magnesia is then added. The mixture of magnesia with solution of ammonium and sodium chloride is then passed through a series of compartments, all the while being so agitated as to keep its magnesia in suspension. Steam is passed through the mixture, but travelling in the opposite direction, and special care is taken to maintain the

temperature of the compartments, that in none of them condensation of the steam may take place. An apparatus upon these principles is illustrated in the annexed drawings, where Fig. 1 is a vertical section along the line A B; Fig. 2 is a horizontal section along the line E F of Fig. 1; Fig. 3 shows the whole apparatus in elevation; Fig. 4 is a horizontal section along the line

centre of them all passes the vertical shaft *n*, working an agitator in each of them. Fig. 5 shows a vertical section of *C*³. The shaft *n* is surrounded by a hood *z*, and outside of it and enclosing it is a somewhat similar hood *x*. The mixture of steam and ammonia which passes off from the vessel *C*² is thereby compelled to pass first into the conical part of *z*, then rises to the

FIG. 1.

K L of Fig. 3. A A are two vertical boilers: *C*¹, *C*², *C*³, *C*⁴, *C*⁵, are a series of vessels superposed one above the other and surrounded by masonry. With the boilers A A they form a distilling column. The products of combustion from the fireplaces B B (Fig. 1) pass only upon the lower part of the two boilers and then pass by the flues G and H through the passages H H H and K K K into the flue L, and thence to the chimney. By thus traversing the spaces between the vessels C and the masonry, the contents of the vessels C are kept at such a temperature that no steam can condense in them. The five vessels, *C*¹ to *C*⁵, are all alike. Through the

cylindrical part of that hood and then passes down into the liquid contained in *C*³ by the annular space between *z* and *x*, finally issuing either from under the rim of the conical part of *x* or through holes near its lower edge. In the bottom of each of the five vessels *C*¹ to *C*⁵ is a kind of slide valve M (Fig. 6), by which from time to time the contents of the vessels *C*⁵ are transferred into *C*⁴, those of *C*⁴ into *C*³ and so forth. The vessel D (Fig. 1) is also furnished with an agitator. Near the bottom is a circular pipe *t*, perforated with holes, which is connected with *C*⁵ by means of pipe *gamma*. Liquid from D can be run into *C*⁵ by a pipe. In work-

ing this apparatus the mixture of steam and ammonia disengaged in A A passes into the perforated circular pipe *c c*, placed near the bottom of *C*¹, and then rises upwards through the liquid which is contained

the further quantity of ammonia which it carries off from *C*¹. In thus traversing the vessels *C*¹ to *C*³ successively, it continually gathers more and more vapour of ammonia without losing any of its steam, so that

FIG. 2.

FIG. 3.

in that vessel. The contents of *C*¹ being maintained at such temperature that steam cannot condense in it, all the steam passes into *C*², accompanied by the vapour of ammonia which passed off with it from A A, and with

the liquid in the different vessels *C* does not become diluted when reaching A A, in which it is concentrated. When the liquor in A A has reached that degree of concentration that sodium chloride commences to salt

FIG. 4.

FIG. 5.

out, all its ammonia has been driven off and the contents of A A is then partially discharged, and that of C¹ run into the boiler A. The contents of C² is then transferred into C¹, the contents of C³ into C² and so forth, whereas the vessel D is re-charged with new

On evaporating, the foreign salts separate out and are fished out, and on allowing the liquor to cool, ammonium bichromate crystallises out. The salts fished out are utilised for fusing fresh batches of chrome ore.

—S. H.

FIG. 6.

mother-liquor, from which ammonium bicarbonate has been previously driven off. A quantity of magnesia equivalent to the amount of ammonium chloride is then added to the liquor in D, and the process of distilling at once continued. The mixture of steam and ammonia passes from D either into a condensation or into a rectification apparatus, as may be preferred in each particular case.—S. H.

Improvements in Mode of Procedure for Decomposing by Magnesia the Mother-liquor of the Ammonia Soda Process. W. F. R. Weldon. From Pechiney & Co., Salindres, France. Eng. Pat. 9831, August 19, 1885. 8d.

A LITERAL REPETITION of the preceding, but under an altered title.—S. H.

Improvements in the Manufacture of Ammonium Bichromate. J. Hood, London. Eng. Pat. 10,700, September 9, 1885. 6d.

CHROME ORE is furnaceed in the customary manner with soda salts for the manufacture of sodium chromate, and the resulting mass lixiviated. To the solution thus obtained two equivalents of acid are added—that is to say, double the amount of acid requisite to convert sodium monochromate into bichromate. Ammoniacal gas is then passed into this solution, until all the free acid is saturated. The solution now contains a bichromate and a sulphate, chloride or nitrate, according as sulphuric, hydrochloric, or nitric acid was the acid used.

Process and Apparatus for Distilling Ammonia. W. C. Wren, New York. Eng. Pat. 6999, May 25, 1886. 8d.

THE object of this invention is to convert the gas produced by the distillation of ammoniacal liquor into pure anhydrous ammonia without the use of compression pumps or similar devices. Ammonia water is heated in a still made of strong boiler plates, and capable of withstanding a very high pressure. The gases evolved are carried away by an upright pipe extending from the top of the still to a height of at least forty feet above the base. The upright pipe is in connection with a coil, which enters the top of a receiving tank and extends nearly to the bottom of it. Cold water is made to trickle over the surface of the coil and the tall upright pipe. In the course of distilling ammonia, gas and steam is driven into the upright pipe, but the latter is soon condensed, owing to the great height to which the upright pipe is carried, as well as by the effect of the water trickling over the outside of the pipe, and falls back into the still, leaving the ammoniacal gas to pass through the cooling worm into the receiver, where it is liquefied by the continuous pressure from the still.—S. H.

Improved Means of or Apparatus for Distributing or Conveying Acids or other Liquors to the Cisterns or Tanks of Chemical Towers, or to Vats or other Receptacles. J. Brock and E. Saye, Widnes. Eng. Pat. 11,492, September 26, 1885. 8d.

A CLOSED BOX A (Fig. 1) lined with a suitable anti-corrosive metal or material is divided into a number of

compartments B, radiating from the centre from a hollow space C to the edge of the box. Pipes D lead from each division to the corresponding cisterns. Through the

G is so arranged that on rotating the shaft, the openings H in the drum G may be brought over any required division B in the distributing box A. A pipe J passes

hollow space C passes a vertical shaft F, extending above the radial divisions B, and carrying a rotating drum G, having openings H in its bottom. The drum G is so arranged that on rotating the shaft, the openings H in the drum G may be brought over any required division B in the distributing box A. A pipe J passes

its end, gearing with another bevel wheel M, carried by a horizontal shaft N proceeding to the engine room, and carrying at its other end another bevel wheel O gearing with a wheel P, on an upright shaft Q, and carrying at its top a pointer S and handles T to move the pointer over a dial U, divided to correspond with the number of divisions B in the box A. A modification of the foregoing apparatus is shown in Figs. 2, 3, 4, 5. In place of the drum an oblong rectangular box G, having an opening H in its bottom, and sliding over a corresponding distributing box A', with divisions B, may be used. The sliding box can be moved by a rack and pinion and attached to a balance weight Y or by cords, ropes or chains passing over pulleys W, and moved by wheel X carrying a pointer. The box is connected with a dial as before described, so as to indicate the numbers of divisions to be supplied, the movement of the handles operating the sliding box.—S. H.

Improvements in the Manufacture of Sulphuric Acid.
H. H. Lake, London. From U. Cummings, New York. Eng. Pat. 7355, June 1, 1886. 4d.

This invention has for its object the manufacture of sulphuric acid from gypsum, obtaining hydraulic cement as a by-product. Gypsum—i.e., calcium sulphate and clay are intimately mixed, and the mixture is moulded into blocks by means of a small quantity of water. The mass is then calcined in a suitable kiln, when silica combines with lime and alumina, producing a hydraulic cement, whereas the sulphuric acid is expelled either in the form of vapour or it is decomposed into sulphurous acid and oxygen. These gases are converted into sulphuric acid by the usual method.—S. H.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

Fire-clay and Fire-clay Wares. Dingl. Polyt. J. 261, 35—43.

C. BISCHOF publishes two analyses of fire-clay from Eisenberg, which had the following composition :—

	I.	II.
Al ₂ O ₃	5'40 %	21'02 %
SiO ₂ , chemically combined	5'11	30'53
SiO ₂ , mechanically mixed	81'59	34'19
MgO	0'09	0'10
CaO	0'20	0'37
Fe ₂ O ₃	0'21	0'87
K ₂ O	0'61	2'10
Loss on igniting	3'74	7'38

No. I. was remarkably fireproof, and goods made of it did not alter their shape, when heated up to the fusing point of platinum. The unctuous clay (No. II.) swelled up at that temperature. Clay from Brissen, dried at 120° C., tested thus : Al₂O₃ 39'93 per cent., SiO₂ 44'88 per cent., MgO 0'08 per cent., CaO 0'21 per cent., Fe₂O₃ 0'99 per cent., K₂O 0'52 per cent., CaO on igniting 13'03 per cent. This clay is also very fireproof. Besides the chemical analysis, it is well worth while to examine clay for its physical properties. If the specific gravity of burnt fire-clay is high, it will resist the action of heat better than the lighter and more porous kind. If moderately burnt clay shrinks considerably at a much increased heat, goods made of it will be of an inferior quality, and such clay is quite useless for arch bricks. The power of absorption is also important. If fire-clay absorbs liquid slags easily it will not resist the heat well.

II. Seger (*Thonindustrie Ztg.* 1886, 170) examined the black clay from Loethain. It is darkish-brown, very plastic, and after burning of a very white colour. It tested thus : SiO₂ 56'09 per cent., Al₂O₃ 30'10 per cent., Fe₂O₃ 0'76 per cent., CaO 0'38 per cent., MgO trace, K₂O 0'69 per cent., H₂O and organic matter 12'22 per cent. It therefore consisted of 80'15 parts clay proper, 19'20 parts quartz, and 0'65 parts felspar. The clay proper is composed of : SiO₂ 45'30 per cent., Al₂O₃ 37'24 per cent., Fe₂O₃ 0'94 per cent., CaO 6'47 per cent., K₂O 0'86 per cent., H₂O 15'18 per cent. The same investigator (*Thonindustrie Ztg.* 1886, 135) prepared standard cones for the determination of high temperatures in the pottery oven. The attainment of a certain heat is estimated by the fusing of a glazing mixture of known composition. The analysis of the materials of which the cones were made was as follows :—

	Rorstrand Felspar.	Kaolin.	Norwegian Quartz.	Carrarian Marble.
SiO ₂	61'32	46'87	98'52	1'00
Al ₂ O ₃	19'41	38'56	1'04	0'12
Fe ₂ O ₃	0'11	0'83	0'01	
CaO	trace	trace	—	51'93
MgO	0'35	trace	—	0'21
K ₂ O	12'90	1'06	0'40	—
Na ₂ O	2'10		—	—
Loss on igniting	0'57	12'73	—	—
CO ₂	—	—	—	43'76

For the sake of computing the formulas, mentioned later on, these minerals were considered as chemically pure. If one equivalent of felspar be mixed with one, two, or three equivalents of calcium carbonate the following formulas represent the mixtures, in which the alkaline flux, potash and lime, is combined under the common heading RO :—

According to our present knowledge we should expect that mixtures containing more flux and less alumina and silica than felspar, would be more easily fusible than felspar. The latter contains one equivalent of alumina and six equivalents of silica, whereas the mixtures mentioned above represent a trisilicate and a one-and-a-half silicate with one-half, one-third, and one-quarter equivalent of alumina. These mixtures, however, proved to be less fusible than felspar, and their fusing point rose with a decreasing percentage of silica and alumina. The addition of kaolin or quartz raises the fusing point of felspar, whereas the simultaneous addition of lime and kaolin diminishes it considerably. For the sake of the following experiments the different glazing mixtures were finely powdered, moulded in the shape of tetrahedron of 5cm. height and 2cm. edge length, fastened to a fire-clay plate, and exposed to a heat equal to that of fusing felspar. Table I. shows the result ; the first group contains felspar and quartz in the proportion of their equivalents as 1 to 6 ; the amount of kaolin is varied and rises half an equivalent every time. In the three following groups the proportion between felspar, quartz, and kaolin remains the same, but an addition of one, two, and three equivalents of calcium carbonate is made. The groups 5 to 8 contain 12 equivalents of silica.

TABLE 1.

(The mark * denotes the most easily fusible mixture of each group.)

No.	FUSING MIXTURE CONSISTS OF				CORRESPONDING WITH				REMARKS.
	Felspar equivalent to 2735.	Quartz equivalent to 30.	Kaolin equivalent to 1295.	Marble equivalent to 50.	K ₂ O.	CaO.	Al ₂ O ₃ .	SiO ₂ .

8a	1	12	0.5	3	0.25	0.75	0.38	4.75	
*8b	1	12	1.0	3	0.25	0.75	0.50	5.0	
8c	1	12	1.5	3	0.25	0.75	0.63	5.25	

We learn from these experiments that a glazing mixture will fuse easily, if there be a certain and definite proportion of alumina and alkaline flux present. This fact becomes still more evident in Table II. of experiments, where mixtures were prepared with a constant quantity of flux ($0.2K_2O$ and $0.8CaO$) and uniformly increasing percentage of silica and alumina:—

TABLE II.

(The mark * denotes the most easily fusing mixture of each group.)

No.	($RO=0.2K_2O+0.8CaO$)	REMARKS.
8	$RO, 0.2 Al_2O_3, 2 SiO_2$	This group is less fusible than the corresponding members of the next group.

12a	$RO, 0.3 Al_2O_3, 5 SiO_2$	This group is still less fusible than the preceding group. No. 13c and 13d fused at the same time.
12b	$RO, 0.4 Al_2O_3, 5 SiO_2$	
*12c	$RO, 0.5 Al_2O_3, 5 SiO_2$	
12d	$RO, 0.6 Al_2O_3, 5 SiO_2$	
13	$RO, 0.2 Al_2O_3, 6 SiO_2$	
13a	$RO, 0.3 Al_2O_3, 6 SiO_2$	
13b	$RO, 0.4 Al_2O_3, 6 SiO_2$	
*13c	$RO, 0.5 Al_2O_3, 6 SiO_2$	
*13d	$RO, 0.6 Al_2O_3, 6 SiO_2$	

It was then tried to make glazing mixtures still more easily fusible by partly replacing alumina by iron peroxide. The result is, indeed, a more easily fusible mass, as long as no more than $0.2 Fe_2O_3$ is added. A greater amount of iron peroxide causes devitrification. On the other hand, the glaze becomes less fusible by an addition of alumina and silica. Starting from these facts and keeping in view the results of the previous experiments, the standard cones which were to serve as a scale of heat were prepared from the mixtures given on next column, and ranging in their chemical composition between $0.3 K_2O, 0.7 CaO, 0.2 Fe_2O_3, 0.3 Al_2O_3, 4 SiO_2$ and $0.3 K_2O, 0.7 CaO, 3.9 Al_2O_3, 39 SiO_2$.

By the fusion of these cones the temperature between $1145^{\circ}C.$, and the highest heat of the pottery oven can be measured. Taking this difference of temperature as $600^{\circ}C.$, the fusion of each successive cone indicates a rise of $30^{\circ}C.$ The Royal Porcelain Works of Berlin—Königl. Porzellanmanufaktur—sells one hundred of these cones at 4s. 6d.

No.	Chemical Formula: $0.3 K_2O, 0.7 CaO,$ and—	Corresponding to 33.55 parts Fe spar, 53 parts Marble, and—

—S. II.

A New or Improved Method of Glazing China, Porcelain, Earthenware, and Parian. Henry Venables, Linthorpe, Middlesbro'. Eng. Pat. 11,084, September 18, 1885. 6d.

AFTER describing the character of the "soft" glaze appropriate to the detailed operations, the object and claim of the inventor is to glaze ceramic articles by immersing them while in a heated state in heated molten or liquid glaze.—T.

Improvements in the Manufacture of Glass and Articles therefrom. Fred. Stacey Shirley, New Bedford, Massachusetts, U.S.A. Eng. Pat. 8023, June 16, 1886. 8d.

THE patentee relies upon the power which gold, under the influence of varying degrees of heat, has, in combination with certain metallic oxides and salts, such, and principally as, uranium oxide, chromium oxide, copper carbonate, etc., to produce various and remarkable shades of colour. Opalescence, complete or partial, is

produced in the usual way, but gradations of shade, lines, streaks, etc., are produced by partial surface and local heating. The presence of alumina seems to be a necessary element in the production, in the presence of gold, of the translucent and peculiarly coloured glass, which, together with its ornamental treatment, are the subject of this patent.—T.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Hardening of Cements. L. C. Levoir. Rec. des Trav. Chim. 5, 59.

HAVING previously shown (*Chem. Zeit.* 9, 818) that aluminates cannot be the cause of the hardening of cements, further researches lead the author to assume that the hardening is caused by crystallisation. He believes that after Portland cement has been ground and burnt, each grain is split in the air, attracts moisture to a small extent, and is covered with carbonate of lime and gelatinous silicic acid, which after about a month becomes crystalline, the change taking place more rapidly in summer. This explanation of the hardening of Portland cement will also account for the same phenomena in the case of hydraulic lime. The volcanic tufts (trass) contain only half a per cent. of silicic acid, soluble in hydrochloric acid, but corresponding hydrated silicic acids yield, with lime, a hydrated calcium silicate from which the carbonic acid of the air eliminates silicic acid, first in the gelatinous, but finally changing to the crystalline state.—A. R.

On the Influence of Frost on Portland Cement mixed with Slag. Bohme. Mittheil. a. d. Kgl. Techn. Versuchsanstalten zu Berlin, 4, 50.

THE experiments described were undertaken at the request of the Minister of Public Works. It was found that unmixed cements of normal specific gravity (3.099, 3.106, 3.115, 3.125, 3.115) withstood the action of frost, while those of low specific gravity (3.030, 2.617, 3.058, 3.077, 3.030, 3.086) did not. Only one cement of low specific gravity (3.040) unmixed with slag withstood the test. Of those cements which, when prepared from the ordinary materials, withstood the action of frost, only one—of specific gravity 3.099—was improved in this respect by the addition of 30 per cent. of slag. All the rest, and especially those of low specific gravity, were weakened thereby.—S. Y.

On the Influence of Magnesia in Portland Cement. G. Lechartier. Compt. Rend. 102, 1223.

THE author has had a great many opportunities for observing the changes which a certain cement underwent that had been employed for reservoirs, foundation walls, etc. The cement was a well-burnt Portland cement of apparently good quality, and the work was executed perfectly. Though very hard and solid at first, after one or more years the cement was disintegrated, the volume increasing at the same time. The latter was accompanied by a great development of force; the individual pieces retained considerable hardness. Several specimens of cements used for the above purposes were analysed. One gave—

SiO_2 17.42%, Al_2O_3 + Fe_2O_3 9.82%, CaO 43.56%, MgO 29.18%.

In all cases the percentage of magnesia exceeded twelve, while most Portland cements usually only contain very small quantities of magnesia. As St. Claire-Deville has shown, free magnesia can unite with water to form a hard hydrate, an increase of volume taking place simultaneously. This hydration only occurs after prolonged action of the water, in case the magnesia has been burnt at high temperatures. Thus, the phenomena observed by the author are readily explained, for the Portland cements above referred to had been obtained from dolomitic marl, and therefore naturally contained magnesia which was gradually hydrated, and as this also means an increase in volume, the buildings, etc.,

were destroyed. A corroboration of the fact that this is indeed the probable cause, may be gathered from the observation, that the cement was changed the more rapidly the better the water had access to the mass, and that the quantity of the water contained in the cement increased the further this disintegration proceeded.

—A. R.

Notes on the Nature of the Hardening Process in Cement. E. Michel. Journ. Prakt. Chem. 33, 548.

THE author describes experiments undertaken with the object of ascertaining the influence of the lime, silica, and alumina respectively on the hardening of cement. Mixtures of gelatinous silica and pure lime hardened in all cases, but the hardness depended on the amount of lime, on the thoroughness of the mixture, and on the quantity of water present. A moistened mixture of gelatinous silica dried at 110° and of finely divided calcium hydrate became very hard after fourteen days. A mixture of alumina, dried at 110°, with lime forms a cement, but gelatinous or ignited alumina gave negative results unless the mixture was placed in a filter-paper cartridge and immersed in water, when hardening rapidly took place in all cases; the reaction took place more rapidly than with silica, but the cements were not so hard. Mixtures of silica and alumina do not form cements. The lime plays a double part in the hardening of cement; it combines with the silica and alumina, and by the formation of calcium carbonate it forms a protective layer. It was found that the amount of lime which enters into combination is very small, and greater hardness was obtained by employing smaller quantities of lime than are generally present in Portland cements. In a hardened lime-silica cement the amount of combination was ascertained by dissolving the calcium carbonate and free lime in ammonium chloride, and then the calcium silicate in hydrochloric acid. In the case of lime-alumina cements the aluminate was present in the residue from the ammonium chloride. It was found that lime-silica cement contained about 5 per cent. of silicate, lime-alumina cements about 2.5 per cent. of aluminate, and Portland cements about 7.5 per cent. of silicate and aluminate. The compounds appear to be formed only on the surface of the particles of cement, which are thus held together. Alkalis do not produce hardening.

—S. Y.

Improvements in Apparatus for Impregnating Wood with Preservative and other Fluids. W. R. Lake, Middlesex. From J. Plister. E. Durst, and Dr. L. Vidrie, Agram. Eng. Pat. 12,844, October 26, 1885. 5d.

THIS apparatus is chiefly designed for impregnating freshly-felled or dried trunks of trees, of any size, with a preservative fluid. It consists of a hollow cap, provided with a sharp cutting edge and a nozzle for the attachment of a hydraulic force pump; it is fixed on the larger end of the log by means of a cross bar held in position by two bolts, the other ends of which are cramped into the log. The liquid is forced into the cap under pressure by means of a pump until the trunk is thoroughly impregnated or saturated.—C. C. H.

X.—METALLURGY, Etc.

Treatment and Utilisation of Slag. Dingl. Polyt. J. 260, 471—473.

ACCORDING to Hoyermann (*Sitzungsberichte des Vereins zur Beförderung des Gewerbefleisses*, 1885, 234) the slag obtained at Peine in dephosphorising the pig iron contains—

P_2O_5	MgO.	Fe.	Mn.	SiO_2	CaO.	Si.
20	5	11	2	6	50	1

The phosphoric acid is combined with the lime as tricalcium phosphate. This slag is very suitable for manuring purposes, owing to the fact that the calcium phosphate is in intimate combination with substances which are readily decomposed by water. This explains

the circumstance that the slag (even the largest pieces) is gradually reduced to powder on exposure to the air.

Referring to the difficulty experienced in removing the particles of iron contained in basic slag (Thomas' slag) before grinding it, Horn (*Berg. und Hüttenm. Zeit.* 1886, 40) suggests the following mode of procedure. The slag is first broken up in stamping mills or by means of stone hammers. The large pieces of iron are then picked out, and the remainder is subjected to the action of powerful rolling or crushing mills. By this means the metal remaining in the slag is flattened without damaging the surface of the rollers. In order to separate the iron from the pulverised slag, the mass may be passed through a sloping sieve similar in construction to that devised by Nagel and Kaemp.

According to Hohlleiss (*Zeitschr. des Landwirthschaftlichen Vereins der Provinz Sachsen*, 1885, 264) phosphatic meal from Peine contains—

	I.	II.
Phosphoric acid soluble in		
citrate	274 per cent.	381 per cent.
Total phosphoric acid ..	17.65	19.37

It is recommended for soils rich in humus.—D. B.

Some New Investigations and Theories on the State of Carbon in Iron and Steel. A. Ledebur. *Stahl und Eisen*, 6, 374, 380.

THE author reviews the theories of Sir Frederick Abel, and of Osmund and Werth, and describes his own researches on this subject. Abel states that when steel is treated with potassium permanganate and dilute sulphuric acid, a carbide Fe_3C is left behind, and concludes that in strongly heated and in cold rolled steel the carbon is almost entirely present in the form of this carbide, that it is not present in red-hot or fused steel, and that its formation is prevented by rapid cooling. Osmund and Werth have examined steel, and also the residue left after solution, microscopically, and arrive at practically the same conclusions as regards slowly and rapidly cooled steel. They state that if the quantity of carbon set free by the dissociation of the carbide when steel or iron is heated, is too great to allow of its complete solution in the iron, it is found to be present as graphite. They have observed the presence of graphite in steel as well as in grey iron. The author's researches confirm those of Forquignon as regards the elimination of carbon from pig-iron by long-continued ignition in absence of air, the iron being surrounded by some indifferent body, such as sand, or even wood charcoal. In one experiment a piece of white cast-iron and of wrought-iron were heated together in wood charcoal. After heating, the former contained less, and the latter more carbon than at first. That the loss of carbon is not due to oxidation was proved by the absence of carbon monoxide or dioxide in the liberated gases, and the author considers that it is due to the formation of volatile hydrocarbons. This view is supported by the fact observed by Forquignon, that pig-iron loses a large quantity of carbon when heated in a current of hydrogen. It appears that at first the other forms of carbon are converted into graphite, and that this is afterwards eliminated. The presence of manganese retards the decomposition of the carbide or iron-carbon alloy, and therefore the formation of graphite. Silicon, if not present in sufficient quantity to cause the conversion of white into grey iron, appears to be favourable to the elimination of carbon.—S. Y.

Durability of Steel Rails. Ch. P. Sandberg. *Revue Industrielle*, 19, 160.

BESIDES depending on their section, the durability of steel rails is greatly influenced by their chemical composition. A specimen containing 0.3 per cent. of carbon is too soft, if only small quantities of sulphur and phosphorus are present. In case the amount of phosphorus reaches 0.1 per cent., the percentage of carbon should not exceed 0.3 per cent., especially in cold regions. Dr. Dudley recommends a limit of 0.4 per cent. of silicon, but steel containing 0.1 per cent. is good enough to resist most actions which the rails are exposed to, assuming

phosphorus to be present in small quantity. Hard steel is preferable to soft steel, and it may be taken for granted that steel free from sulphur and phosphorus, but containing 0.5 per cent. of carbon, is the best for rails. As compared with iron rails, it was found that steel rails may be used nine times longer than the latter, but for calculations the durability of steel rails may be assumed to be three times that of iron rails.—A. R.

Thallium in Commercial Zinc. Dr. Kosmann. *Chem. Zeit.* 10, 762.

IN some commercial zinc obtained by melting up refuse zinc, the author found comparatively large quantities of thallium, while that rare metal has been hitherto only found in very small quantities in zinc ores. The fracture of the zinc was somewhat uneven, and in the leafy and silvery part short streaks of a grey colour and granular structure were embedded. It was found to contain a large quantity of lead and arsenic, some cadmium, iron, manganese, alumina, and as much as 1.4 per cent. of thallium.—A. R.

Action of Milk of Lime on certain Metals and Alloys. T. Schmelzer, jun. *Chem. Zeit.* 10, 763.

THE author has examined the extent to which different metals are attacked by milk of lime. Pure soft lead is attacked considerably, regulus of antimony remains entirely unchanged, lead tubing containing 25 per cent. of "hard lead" (Hart-blei) is slightly changed, lead plate or brass is fairly attacked, pure pig-iron being strongly corroded; on phosphor-bronze no action could be observed, and it was only very slight in the case of tin. It therefore appears that pumps which are to resist the action of milk of lime should be made of phosphor-bronze, or of an alloy of tin and antimony.—A. R.

Improvements relating to the Separation of Tin from Tinplate, and to the Production of Protochloride of Tin. H. H. Lake, Southampton Buildings. *Eng. Pat.* 10,018, August 24, 1885. 4d.

THE scrap is heated to 400° C., in hydrochloric acid gas, the resulting stannous chloride being afterwards condensed and utilised as desired.—W. G. M.

Improvements in Machinery for the Reduction of Tin Stuff and other partially-pulverised Ores, to extract the Metal therefrom, as well as for Grinding Paint, Cement, and other Hard Substances. S. H. Stephens and S. Rodda, Illogan, Cornwall. *Eng. Pat.* 10,119 August 26, 1885. 5d.

A RECTANGULAR and inclined rubbing bed is used, having medially from end to end a series of transverse rectangular troughs, each extending one-third of the total width of the bed; between each pair are perforations. On either side of this central band are placed parallel troughs, similar, but fixed at an angle with the others; these serve to direct the material under treatment to the centre of the bed. The rubber consists of several transversely placed plates, the right and left wings of which form an angle corresponding to that of the troughs: these plates are fixed to an iron strap, by means of which the necessary reciprocating motion is communicated; the front edge of the plates is bevelled inwards. The ore is fed by means of a launder placed at one end, the crushed material being delivered at the other.—W. G. M.

Recovering Tin from Waste Tinned Iron. W. Beatson, Rotherham. *Eng. Pat.* 11,067, Sept. 18, 1885. 6d.

THE scrap, cut into small pieces, is placed in a cylinder of iron-wire gauze with sheet iron ends, and mounted on an iron axle, or into iron gauze boxes of rectangular shape, and is therein made the anode to a galvanic current passing through a bath of boiling caustic soda and potassium cyanide. The cathode, upon which the dis-

solved tin is redeposited, may consist of iron plates in motion or at rest, of slowly-revolving wheels which will compress the loose deposit, or of the walls of the containing tank itself.—W. G. M.

Improvements in Means or Apparatus employed in Coating Metal Plates with Tin, Ferroc, or other Metals or Alloys. D. Davis, Morriston, Glamorgan. Eng. Pat. 11,280, September 22, 1885. 8d.

THIS patent deals with the passage of the tinned plates through rollers working in grease. Each plate is placed in a cradle and brought mechanically into position beneath a double pair of rollers; the cradle is then raised by a lever until the plate is gripped by the rolls. Two pairs of these double rolls are employed, the mechanism for raising the cradle being actuated in each alternately.—W. G. M.

Process and Means for Soldering Aluminium. J. S. Sellon, Hatton Garden. Eng. Pat. 11,499, Sept. 26, 1885. 6d.

THE aluminium surfaces, cleaned by scraping, are covered with a layer of paraffin wax as a flux, and are then coated by fusion with a layer of a zinc-tin-lead alloy (preferably in the proportion of 5:2:1). The metal so prepared may be soldered in the usual way.—W. G. M.

Improvements in Machinery or Apparatus for use in Pickling and Swilling Metal Plates. R. Evans, Landore. Eng. Pat. 11,753, October 2, 1885. 8d.

THE cradles containing the plates are suspended by rods attached by double rocking bearings to the arms of the supporting cylinder, so that when immersed in the pickling or washing vat an oscillating motion is imparted to them with the aid of a V-lever, actuated by suitable machinery.—W. G. M.

An Improvement in the Process of Extracting Wrought-Iron and Steel directly from Ores. O. Imray, Southampton Buildings. Eng. Pat. 11,798, October 3, 1885. 8d.

THE ore, if necessary buddled and roasted, is mixed with suitable fluxes and heated on the hearth of a regenerative gas furnace to the reduction temperature of oxide of iron; all air is then carefully excluded, and the charge heated to complete reduction in the combustible gases alone; this end attained, air is again admitted, and the temperature raised to the fusing-point of the metal and slag. Carburisation to the required degree is effected by the addition of pig-iron, or of carbonaceous material immediately before tapping. The gas regenerator should be of greater capacity than that used for the air.—W. G. M.

Improvements in the Treatment of Auriferous and Antioargentiferous Minerals. S. Pitt, Sutton. Eng. Pat. 12,909, October 27, 1885. 8d.

IN a semi-cylindrical horizontal trough is a long open framework agitator, to which motion is imparted by an axial spindle actuated by an external handle; this heater, arranged so as to almost touch the bottom of the tank at any point, is kept slowly oscillating to and fro, and thus serves to maintain the contents of the latter in constant but gentle agitation. The ore must be uniformly crushed, and, if necessary, roasted; it is then introduced, with much water and a little mercury, into the trough, where it is kept in constant slow movement for from three to six hours, during which time the heavier particles will sink to the bottom, and there become amalgamated. The contents of the trough are removed carefully through a sliding door at the end of the vessel, the tailings being allowed to run to waste, the heavier portions being washed, and the amalgam distilled. The depth of water in the cylinder will vary from 60cm. to 1m.—W. G. M.

An Improved Metallic Alloy. J. Webster, Birmingham. Eng. Pat. 8320, June 23, 1886. 4d.

A NON-OXIDISABLE ALLOY, of high tenacity, durability, and capacity for vibration, and susceptible of polish, is made by alloying copper 200lb., tin 80lb., aluminium and bismuth, each 10lb., and adding the ingots so produced in the proportion of 4½lb. to copper 164lb., nickel 70lb., and zinc 61½lb. With this is to be used the flux described in Eng. Pat. 12,344, 1885.—W. G. M.

Improvements in and connected with Refractory Linings, particularly adapted for Metallurgical Furnaces, but applicable also for other Purposes. T. Twynam, Kensington. Eng. Pat. 8358, June 24, 1886. 4d.

TO prevent the crumbling of the chrome iron ore lining which occurs if it be prepared with water, oil, or tar alone, it is mixed with 5 per cent. of chromate or bichromate of an alkali or alkaline earth previously dissolved in the water used to render the mass plastic, and made into bricks, or rammed as usual.—W. G. M.

XI.—FATS OILS, AND SOAP MANUFACTURE.

Examination of Oil. T. Morawski. Dingl. Polyt. J. 260, 512–514.

FINKENER (*Ibid.* 260, 431) has recently described a method of estimating mineral oils in fatty oils, which is based on the assumption that the amount of unsaponifiable fat may be determined by the quantity of alkali required to saponify the oil. It is supposed that fatty oils require 19 per cent. of potassium hydrate to completely saponify them. According to the view entertained by the author, this assumption is perfectly erroneous, and the method suggested by Finkener without utility, Kottstoefer (*Ibid.* 232, 286). Allen (*Chem. News*, 43, 267), and Valenta (*Ibid.* 249, 270), having shown that different oils require different quantities of alkali for saponification. The simplest and most accurate methods for estimating oils containing unsaponifiable fats are those of Nitsche (this Journal, 1884, 322), and Morawski and Demski (this Journal, 1886, 179).—D. B.

On the Oxidation of Oils. Ach. Livache. Compt. Rend. 102, 1167.

ACCORDING to a previous communication of the author (*Chem. Zeit.* 9, 1695), the drying up of oils, which is due to a rapid absorption of oxygen, may be accelerated by introducing certain metals, particularly lead and manganese. The best way is to treat the oil with a mixture of finely-divided lead and manganese nitrate, the latter being readily soluble in oil. After decanting, some lead oxide is added to decompose excess of manganese nitrate. Thin layers of linseed oil which have been treated thus dry in less than four hours. A number of other oils, both drying and non-drying, were subjected to the same treatment, and the changes which they underwent when exposed to the air were observed for two years. It was found that oxygen, which converts the drying oils into hard products and turns the non-drying oils rancid, converts a portion of the insoluble fatty acids into soluble ones, the acids with higher molecular weight finally decomposing and forming homologous acids with a lower molecular weight. After two years, the non-drying oils resemble, both in appearance and composition, the products obtained by the hardening of certain drying oils during one year. This relatively slow change which is brought about in the drying oils probably takes place more speedily if a large amount of oxygen can be provided.—A. R.

Refining of Heavy Lubricating Oils. Fr. Recl. Chem. Zeit. 10, 760.

THE chemical composition of certain naphtha oils found in Roumania is identical with that of the oils from Baku, and the residues from both contain the same amount of

fatty matter, and are, moreover, of similar consistency; but the lubricating oil from the former has the higher specific gravity, and the heavy fractions contain a comparatively larger quantity of the saponifiable products than are found in the Baku oils. The author says the safest way of preventing saponification is to prevent agitation during the neutralising period, and he gives a detailed description of the apparatus and method used. If the oil is washed entirely free from acid, it is saponified even before adding caustic soda. Aluminium hydrate is recommended for freeing the oil of finely-divided and suspended charcoal. This hydrate, especially when prepared from bauxite, is excellent for bleaching or clearing mineral oils, but its high price excludes its employment on a very large scale, and it will therefore hardly replace the cheap "bleaching powder" of the prussiate of potash works. The method of saponification used in kerosin works the author has found to be most disadvantageous.—A. R.

Preparation of Soap. F. Eichbaum. Seifenfabrikant, 1886, 102.

IN order to make a soap from strongly-smelling fish fats, the author takes 400kilos. of the fat, 25kilos. raw palm oil, 250kilos. lye, 12° B., and warms up. A further similar amount of lye of 15° B. is added, and the thoroughly-mixed mass allowed to boil till clear and free from scum, more lye being added, as much as necessary. The mass is then poured in a thin stream through 20-degree lye, 50kilos. powdered rosin are added by degrees, and then 40kilos. 20-degree lye, and the mass boiled. When ready the soap is salted out in the ordinary way. The addition of the rosin causes the fishy smell to be remarkably lessened.—B. H.

XII.—PAINTS, VARNISHES, AND RESINS.

An Improved Waterproof and Anti-corrosive Composition suitable for Coating Ships' Bottoms, and such like Purposes. Edwin Lewis Kitchingman, Collingwood, Victoria; and Arthur Andrews, Albury, N.S.W. Eng. Pat. 11,529, September 28, 1885. 6d.

THE composition is made by heating tar (2½lb.) in a suitable vessel to just the boiling point, then gradually adding oxide of iron (2lb.). Rosin (1oz.) is then added, and when the rosin is dissolved sugar of lead (2oz.) is added. The composition can be used hot or cold. If used cold it must be dissolved in a suitable quantity of shellac varnish.—B. H.

An Anti-fouling Composition for Protecting and Preserving Ships' Bottoms and other Submerged Surfaces, applicable also for Coating Metal, Wood and other Underground Surfaces. George Washington Carr and James Dickinson, both of Fleetwood. Eng. Pat. 11,543, September 28, 1885. 4d.

THE composition consists of 100 parts resin, 31 parts bisulphide of carbon, 3 parts powdered lime, 19 parts paint, or other colouring matter, and 18 parts naphtha. The patentees state in their final specification that in practice they prefer to omit the powdered lime.—B. H.

Improvements in the Process or Manner of Manufacturing Caoutchouc, Wax, Fat, Colouring Matter, Vegetable Fibre, Fibre Wool, and Cattle Food, from Lactucarious Plants, or from Plants bearing Milky Juice, or from their Extracts, such as Opium, Lacina, and their likes. George Kassner, Breslau, Germany. Eng. Pat. 11,561, September 29, 1885. 6d.

MOST of the plants with a milky juice contain caoutchouc. By the inventor's process the respective green plants or parts of plants, or extracts from them, are dried thoroughly and reduced to powder. If the plants contain valuable fibres, these are separated from the powder. The dry powder is extracted in a suitable extractor with benzine, "sulphite of carbon" (*sic*, probably for bisulphide of carbon), chloroform or such

mixtures with alcohol. The solution is then run off and the solvent evaporated. The caoutchouc with fat, wax, and colouring matter thus obtained, is then treated with boiling alcohol, and then with alcoholic potash or soda. The raw caoutchouc thus separated from the fat, wax, and colouring matter is purified by resolution in chloroform, etc. The plant powder, after the extraction with benzine, etc., is freed from the remainder of the solvent and pressed into cakes by suitable means, forming a cattle food. If the plant powder contain valuable matters, such as alkaloid, resins, etc., or poisonous matters, these are extracted by alcohol before the treatment of the plant with benzine, etc., and worked up from the alcoholic extract.—B. H.

Improved Means of Dissolving Vulcanised Indiarubber and Indiarubber Compounds. John Bagnall, Manchester. Eng. Pat. 11,671, October 1, 1885. 6d.

THIS invention consists in utilising ercosote oils either alone or in conjunction with other oils, or the ordinary solvents of raw indiarubber.—B. H.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

The Examination of Tannin Extracts. F. Simand and E. Weiss. Dingl. Polyt. J. 260, 564—568.

HIDE POWDER, essential to the estimation of tannin by this process, is prepared by taking fresh skin, washing, unhairing, treating with dilute hydrochloric acid, stretching and drying; the skin is then planed fine, dried, and worked through a fine sieve. The watery residue from 5grms. of this powder gives only 36mgrms. dry residue, containing 5mgrms. ash. The amount of water in extracts is determined, on 2—3grms., by drying in a platinum dish in a water-bath. The ash is estimated by incinerating the residue. 12—16grms. in the case of solid, 22—28grms. in the case of fluid extracts, are dissolved, and the solution made up to 1 litre and filtered clear; 100cc. of the clear solution are evaporated, dried, and weighed, giving the total soluble matter. It is not advisable to determine the insoluble matter directly. To estimate the non-tannin matter, 250cc. of the tannin solution are put into a dry flask with 1grm. of the hide powder and shaken for several hours and then filtered into another flask. The treatment of the solution with 1grm. hide powder is twice repeated. The fourth time, 2grms. hide powder are taken. This quantity (5grms.) is in most cases quite sufficient to extract all tanning matter, 100cc. of the filtrate are evaporated to dryness and dried, the residue being the non-tannin matter. The authors state this process is more exact than Löwenthal's.

The authors give a table of results. They also state that bark extracts contain more ash than wood extracts, the ash, in the case of bark, containing a distinct quantity of manganese, wood extracts only a trace.—B. H.

Remarks on the Orpiment of Commerce and the Removal of Hair from Hides. Terreil. Bull. Soc. Chim. 484—487.

ARSENIC SULPHIDE of the trade contains 0.2 to 3 per cent. non-volatile constituents, such as calcium and iron sulphide, clay or quartz. Samples of Spanish origin sometimes contain small quantities of mercury sulphide. Arsenic trioxide is always present. If, after the removal of the hair, black spots appear on the skin, they are caused by the contact of the skin with rusty iron.—S. H.

The Manufacture of an Improved Material to be used as a Substitute for Leather, and for other Purposes. George Frederick Redfern, London. From Alfred Buckingham, Brussels. Eng. Pat. 8626, July 16, 1885. 4d.

THIS invention relates to the manufacture of a waterproof material (called by the inventor "Cuirette") from leather boards by treatment of them with forms or dies, presses or sawing machinery, and subsequent varnishing,

lacquering or colouring with alcoholic or other suitable varnishes or colours. The improved material can be used for decorative purposes and in the manufacture of trunks, cases, etc.—B. II.

An Improved Process for the Manufacture of Waterproof Material capable of being used as a Substitute for Binders' Leather or Cloth, and for Decorative and other Purposes. William Loyd Wise, London. From Julius Hofmeier, Vienna. Eng. Pat. 12,023, October 9, 1885. 6d.

CELLULAR MATTER, such as fibres of linen, cotton, jute, wool, silk, etc., wood cellulose and the waste from the treatment of such fibres or cellulose, in the form of paper or of woven material, is treated with a solution of albumen. The solution is prepared by making a concentrated solution of equal parts of albumen and glycerine with the necessary amount of water, and adding 10 per cent. of nitrate or sulphate of magnesia and 5 per cent. of basic borate of soda. The albumen solution is either applied superficially or the material is impregnated. The treated material is then passed over a drying cylinder, moistened on the back and pressed between heated rollers, or between the plates of a book-press. If cellulose or other fibres are mixed with the albumen solution, and the stiff but plastic substance pressed in heated moulds, a coagulum is obtained having the elasticity of leather.—B. II.

A Substitute for "Urine" or "Sig" for use in preparing Leather and Skins for Dyeing. Frederick Richard Maggs, of Yeovil, Somerset. Eng. Pat. 6041, May 4, 1886. 4d.

Two parts borate of soda, four of "subcarbonate of potash," six of powdered soap, and eight of carbonate of soda are mixed together. For use, 1lb. of "the preparation" is dissolved in 6galls. water and the leather or skin is immersed in or brushed over with the solution.—B. II.

XIV.—AGRICULTURE, MANURES, Etc.

On the Presence of Copper in Different Organs of Vines Treated with Lime and Sulphate of Copper to Protect them against Mildew. A. Millardet and U. Gayon. Bied. Centr. 15, 336.

THE authors have sought to determine whether copper is taken up by vines treated with a mixture of caustic lime and sulphate of copper, and, if so, to what extent by different parts of the plant. By incinerating the organs and the solid residues of the must and wine, separating the copper by electrolysis, and finally determining colorimetrically, it was found that the leaves at the time of harvest are richest in copper, the amounts fluctuating in different varieties, from 19 to 95mgrms. of copper per kilogramme of undried leaves; next are the pedicles, then the skins and seeds, then the stock. As regards the must, in no case was more than 2.2mgrms. of copper per litre found, and the wine contained still less, the maximum being 0.1mgrm. in 1000 litres. Experiments were also made to determine how long the copper is retained by the plant. A vine was treated with the copper mixture on July 15, and uprooted for the purpose of analysis on October 8. It was then found that the plant contained only 5 per cent. of the copper originally applied, and of this the leaves contained 3 per cent. or 20mgrms. per kilo. of undried leaves. The rainfall in September being very considerable, it would appear that the copper was washed from the leaves, for the mildew attacked the plants so vigorously that in a few days a large proportion of the leaves were cast. The authors therefore hold that if wet weather sets in from the end of July to the middle of August the vines should be treated a second time with the copper mixture, since the presence of 20mgrms. of copper per kilo. of undried leaves is not sufficient to protect the plants until the time of harvest.—W. D. B.

Destruction of the Ova of Phylloxera Bied. Centr. 15, 357.

BALEIANI recommends painting the stocks with a mixture of naphthalene, heavy oil, quicklime and water. Rouanet uses a mixture of heavy oil, tar, naphthalene, and quicklime, in the state of fine powder, applied by means of bellows to all parts of the stock. It penetrates the fissures of the bark, and destroys both the ova and young insects, should any of the latter be developed. Fandrin advises a solution of one part of ferrous sulphate in two of water, or one of cupric sulphate in five of water, the former being preferable. These attack not only the ova, but also insects upon or within the bark.

—W. D. B.

Improved Process for Converting the Waste Liquids of Rendering and like Establishments, technically termed Tank Waters, into Fertilisers and other Useful Products. J. van Ruynebeke, Chicago. Eng. Pat. 6857, May 21, 1886. 6d.

THE inventor manufactures from the waste liquids known as "tank waters," a concentrated antiseptic fertiliser free from the deliquescent and viscid properties which characterise the products generally recovered from these waste liquids. The process consists in subjecting the liquids, after evaporation, to a decomposing temperature not exceeding 260°, a brittle, easily-pulverised substance being obtained, having phenol uniformly distributed throughout its mass, while the volatile products are collected in suitable apparatus as ammonia compounds, amines, illuminating gases, aniline and carbolic tars.—D. B.

XV.—SUGAR, GUMS, STARCHES, Etc.

The Influence of Heat on the Absorbent Power of Animal Charcoal. Otto Moszeick. Arch. f. Anat. u. Physiol. 1885, 275—283.

FILHOL was the first who observed that animal charcoal absorbs more organic matter at higher temperatures than in the cold. The author found that this phenomenon can be readily shown with glucose, picrocarmine and sodium indigo-sulphonate. The circulation which is caused by the heat only partially explains this result, for the same difference in the absorption appears with samples which are shaken in the cold, or treated with animal charcoal at higher temperatures. The absorbed matter only dissolves in traces in boiling water.—S. II.

XVI.—BREWING, WINES, SPIRITS, Etc.

Method for Determining Fusel Oil in Alcohol. J. Traube. Chem. News, 53, 302—303; and Zeit. f. Spiritus Ind. 1886 [36].

AFTER reviewing the present methods for determining fusel oil in brandies, etc., all of which the author pronounces unreliable, the following method is found to give very good results. The author has demonstrated in various chemico-physical researches that the height to which aqueous solutions of organic bodies of one and the same series ascend in capillary tubes (the percentage remaining the same), often decreases very considerably with an increasing molecular weight of the dissolved body. This fact rendered it probable that even a very small percentage of fusel in brandies would betray itself by a reduction of the capillary ascent. It was known to the author from previous researches that the substances present in fusel in estimable proportions, such as the propylic and butyric alcohols, and the various aldehydes, including furfural, reduced the capillary ascent more than ethylic alcohol, but less than amyllic alcohol. It was to be expected that any differences in the composition of the fusels, or of the brandies, would have only a vanishing influence upon this method—an assumption which has been fully confirmed by experience. The apparatus and method of observation is given by the author in *Journal für Prakt. Chem.* New Series, vol. xxxi. 177, 178. A thin-walled capillary tube, as narrow as possible, is fastened to a very fine scale, divided into

half millimetres. The scale terminates at its zero in two points, which are set exactly at the surface of the liquid by means of a stand movable upon screws. The capillary tube can easily be kept clean if it is washed after every experiment with water and alcohol, and afterwards dried by forcing through it a current of air dried and purified over sulphuric acid. The liquid is sucked up in the capillary tube two or three times, and the bottom of the meniscus is read off a few seconds after the liquid has come to rest. With a little practice and observation of all precautions, it becomes readily possible to read off to $\frac{1}{10}$ mm. even without a lens. With this apparatus the author has examined a number of solutions containing from 1 to 1 per cent. by volume both of crude fusel and of pure isoamyl alcohol, dissolved in an alcohol, the specific gravity of which always corresponded to that of a 20 per cent. by volume. This is a degree of concentration very suitable for the examination of brandies. In the table compiled by the author, the capillary heights are given in millimetres. From this table it appears that the solutions of pure isoamyl alcohol, according to expectation, show a rather lower capillary ascent than the corresponding solutions of the crude fusel oils. It appears that generally $\frac{n-1}{10}$ per cent. of amyl alcohol corresponds to $\frac{n}{10}$ per cent. of crude fusel. If the proportion of fusel, as in most cases, is less than 1 per cent., it becomes possible, by reading off to $\frac{1}{10}$ mm., to determine $\frac{1}{10}$, or, in very dilute alcoholic solutions, even $\frac{1}{100}$ per cent. of fusel. The values above 0.5 per cent. fluctuate slightly for the different solutions of fusel; but these values are of no practical importance, since a brandy which contains more than about 3 per cent. of fusel is regarded as dangerous to health. In the examination of brandies by the above method, a preliminary distillation is only required when, as in the case of liqueurs, the specific gravity of the distillate differs essentially from that of the original liquid. The specific gravity is then determined by means of a Mohr's balance, and the brandy is let down to 20 per cent. (volume) by the aid of a dilution table. The capillary height, compared with that of pure 20 per cent. ethylic alcohol, shows at once the proportion of the fusel in the diluted brandy on a scale which is empirically constructed. The firm of C. Gerhardt, glass manufacturers, of Bonn, supply capillaries tested by the author, and showing directly for different temperatures the proportion of fusel in brandies diluted to 20 per cent.

—J. B. C.

Criticism of the Direct Method for the Determination of Tartaric Acid in Wine Lees and Argol. 1st Part. A. Borntrager. Zeit. Anal. Chem. 25, 327—359.

THE author investigates chiefly the method proposed by Warington, and modified by Grosjean and Klein. He shows by numerous experiments the influence of the reagents used on the solubility of acid potassium tartrate. The chief results of his investigation lead to the following procedure:—The preliminary determination of tartaric acid in the sample recommended by Warington may be, and is, omitted. Of wine lees 7.5 grms., of argols and other tartrates 3.75 grms. are taken for analysis, treated as recommended by Warington, with neutral potassium oxalate, of which an excess of from 1.5 to 3 grms. is taken, the solution neutralised with potassium hydrate, filtered, the precipitate washed, and the solution reduced to 50cc. To this solution 5 grms. potassium chloride and 3 grms. citric acid are added, precipitation started by stirring five minutes, then allowed to stand 12 hours. The precipitate of acid potassium tartrate, filtered by means of a vacuum filter, is washed with a 10 per cent. solution of potassium chloride previously saturated with acid potassium tartrate. The ordinary variations of the temperature of the laboratory at time of filtration are of little consequence. The precipitated acid potassium tartrate is then titrated with a normal solution of sodium hydrate, perfectly neutral litmus paper serving as indicator. Results, 99.5 per cent. found for 100 employed. For the numerous tables of solubility of acid potassium tartrate the original must be consulted.

Analyses of Pure 1884 Alsation Wine. C. Anthor. Zeit. Anal. Chem. 25, 359—361.

THE following results were obtained in a series of analyses of the above wines. The numbers represent grams per 100cc:—

	Free Acid.	Volatile Acid.	Tartaric Acid.	Potassium Tartrate.	Ash.	Phosphoric Acid.	Nitrogen.	Amount of Ash in Glycerol.	Pure Glycerol.

The proportion of alcohol to glycerol varies between 100:9.6 and 100:7.

After deducting the total acid the extract gives a maximum of 2.155 and a minimum of 1.232, after deducting the fixed acid 2.235 and 1.295.

The ratio of ash to extract varies from 1:8.5 to 1:13.1; the phosphoric acid to the ash from 1:4 to 1:8.1.—G. H. M.

On the Estimation of Fusel Oil in Brandy and other Spirits. A. Stutzer and O. Reitmaier. Rep. Anal. Chem. 6, 335.

THE author recommends a modification of Röse's method (*Chem. Zeit.* 8, 1879; 9, 1156), which depends on the alteration of solubility of fifty per cent. alcohol in chloroform by the presence of fusel oil. A few drops of caustic potash are added to 200cc. of brandy; 160cc. of this are distilled off, and the volume of the distillate made up to 200cc. 50cc. of this are placed in a 100cc. flask, and sufficient water added from a burette to make a 30 (not 50) per cent. solution (the amount required may be found in Brix's tables), and the flask is then filled to the mark with pure thirty per cent. alcohol. Exactly 20cc. of chloroform are placed in the carefully-dried apparatus in which the solubility is to be determined, and then the 100cc. of diluted alcohol and 1cc. of sulphuric acid of specific gravity 1.286. The mixture is well shaken and allowed to settle. The apparatus is inclined so that the chloroform is transferred two or three times into the bulb and back again into the graduated tube. After a few minutes the temperature and volume of the chloroform are read, and the amount of fusel oil calculated from the following table, which gives the percentage volume of fusel oil in 50cc. of the diluted alcohol (that is to say, in the 100cc. of 30 per cent. alcohol), the temperature being 15°. The number found must be doubled in order to get the percentage volume of fusel oil in the brandy. With pure thirty per cent. alcohol at 15° the volume of chloroform is 21.4cc.

Volume increase of Chloroform.	Percentage volume of Fusel Oil.	0.01cc. increase of volume of Chloroform corresponds to volume per cent.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

On Pasteurised Milk. J. Van Geuns. Bied. Centr. 15, 338.

THE author has made experiments with milk heated for a short time at 60° C. in Thiel's pasteurising apparatus, with a view of determining in what degree such milk differs from the non-pasteurised in respect of lactic acid formation, alteration of casein, and the development and number of micro-organisms present. The samples of pasteurised and non-pasteurised milk were kept in sterilised tubes closed with cotton wool at temperatures from 10–12° C., and determinations of lactic acid made

daily. The following table gives the lactic acid in grms. per 100 cubic centimetres of milk:—

Day.	Ordinary Milk.	Pasteurised Milk.
1	—	—
2	—	—
3	—	—
4	0.046	—
5	0.136	—
6	0.186	0.145
7	0.112	0.279
8	0.151	0.340
9	0.201	0.280

From these figures, it is apparent that pasteurising in the apparatus in question cannot prevent the lactic acid fermentation, but certainly slightly retards that change. Kept at 35–37° C. for 24 hours, both the pasteurised and ordinary milk were found to have curdled; the former in flocculi, the latter in lumps. As regards the alteration of casein and soluble albumenoids, the difference between pasteurised and natural milk does not appear to be appreciable. As regards the influence of pasteurisation upon the development of lower organisms, the author found by Koch's gelatin cultivation method that a sample of milk which contained 2½ millions of organisms capable of forming colonies per cubic centimetre previous to being passed through Thiel's apparatus, only contained 5000–9000 after pasteurisation. A small sample of milk pasteurised by the author in reagent glasses with cotton plugs, appeared when subjected to cultivation to be thoroughly sterilised, whilst the same milk (about 10 hours old) gave 10½ millions of organisms per cubic centimetre. The working of the apparatus in question would not appear to be quite satisfactory in respect of total removal of micro-organisms, hence the lactic acid fermentation is only retarded. The author throws out a suggestion as to the removal of pathogenic organisms by pasteurising instead of by actual cooking, whereby the taste of the milk is altered. On this head further experiments are being made.—W. D. B.

Comparative Experiments on the Rapid Determination of Butter in Milk by various Methods. G. Sartori. Ann. di Chimica, 1886, 158.

THE author concludes that for rapid and exact determinations Soxhlet's areometrical method gives the best results, and he recommends its use in the research laboratories; Marchand's lactobutyrometer is recommended for the use of cheese-makers, and Adam's modified method for the town authorities. The areometer gave quite trustworthy results.—S. Y.

Apple Chips containing Zinc. J. Stinde. Industrieblätter, 1886, 116.

DRIED American apple chips frequently contain zinc, the presence of which is attributed to the treatment with salt water in zinc wire buckets and the subsequent process of drying on hurdles made of zinc wire. The object of this treatment is to prevent the chips from assuming a yellow or brown colour. The whiter the colour the more essential it is to test the chips for zinc.

—D. B.

(B) SANITARY CHEMISTRY.

Contribution to the Question of the Preservation of the Purity of Water-courses. Chem. Zeit. 10, 792.

THIS paper deals with the cause of the pollution of the river Werra and the consequent injury to the town of Herford. The Corporation of Herford laid the blame on the rice starch manufactory of E. Hofmann & Co. in Salzdahlun; the proprietors of the works, however, held that the injury was caused by the damming of the river lower down by the owners of a water mill, the water being thereby rendered stagnant. The case has come before the various courts, and after further improvements in the method of purification of the water from the starch works had been adopted by the owners, and approved by

the commission appointed to consider the question, it has been decided in favour of Messrs. Hofmann & Co. The water as it leaves the works is first treated with chemical reagents, the nature of which is not stated, by which the organic matter is separated in the form of a flocculent precipitate. A large quantity separates at once, and the remainder is deposited in tanks, divided into partitions to make the course longer. There are a double set of tanks, one of which may be cleaned while the other is in use. The water when it finally leaves the tanks is perfectly clear, and it was found by the commissioners that when allowed to stand for several weeks it underwent no alteration; the purification is therefore complete.

—S. Y.

Improvements in the Treatment and Utilisation of Sewage. C. T. Kingzett, Stamford Hill. Eng. Pat. 10,879, September 14, 1885. 6d.

THE sewage is either filtered through finely-powdered coke or is defecated by the addition of finely-powdered coke in conjunction with the use of clay, lime, or compounds of iron and alumina. The sludge may be pressed, used as a manure, or else air-dried and used as an ordinary fuel in boilers and furnaces.—C. C. H.

Improvements in the Treatment and Utilisation of Sewage. C. T. Kingzett, Stamford Hill. Eng. Pat. 11,436, September 25, 1885. 6d.

IN this specification it is proposed to defecate sewage by means of soot used in conjunction with clay or lime or with the saline deposit, or the chalybeate water found at Southborn-on-Sea, which contains large quantities of sulphate of iron and alumina. The soot may be substituted by powdered coke with or without clay or lime, used with the chalybeate water or with similar saline substances.—C. C. H.

(C) DISINFECTANTS.

A New or Improved Antiseptic, Deodorant, and Disinfectant Compound. P. Ockenden, London. From H. Roche and H. T. Tomsitt, Melbourne. Eng. Pat. 10,212, August 28, 1885. 6d.

ORDINARY linseed meal of commerce, by weight about 94 parts, is mixed with dried and pulverised leaves of the eucalyptus 3.5 parts, dried and pulverised seed of the eucalyptus 1.25 parts, oil of eucalyptus 1.25 parts. An alternative method of preparation is the addition to the linseed meal of an alcoholic extract of the seeds and leaves of the eucalyptus. The object of the patentee is the preparation of a crushed linseed possessing septic qualities and specially adapted for the well-known use of linseed in surgical treatment.—C. C. H.

Improvement in the Preparation of Hygienic and Disinfecting Substances, and use of the same as Candles, Night-lights, and such like. E. B. Watson and H. B. Fulton, London. Eng. Pat. 10,576, Sept. 14, 1885. 6d.

THIS is an improvement upon a former patent by the same authors, No. 9341, 1885. In that patent the use of iodine in combination with a hydrocarbon wax or oil made into candles, which when burned acted as a disinfectant, was claimed and the patentees have now discovered that if a small quantity of sulphur be mixed with the iodised wax, instead of hydriodic acid being given off, iodine and finely-divided sulphur are dispersed through the atmosphere, which is attended with a considerable increase in the disinfecting qualities.

—C. C. H.

Improvements in the Manufacture of Vitriolised Ash, and Application of same to the Deodorisation and Purification of Polluted Water and Refuse Matters. T. H. Cobley, Dunstable. Eng. Pat. 11,542, Sept. 28, 1885. 6d.

ASHES or clinkers from boiler furnaces, etc., are furnished with a material containing sulphur, such as spent oxide

of iron: they are then ground with about five per cent. of common salt and 16 per cent. of sulphuric acid of 120° T.; the whole is removed from the mill and allowed to dry. The patentee states he aims at the production of "a chloro-sulphate or chloro-sulphite of iron and alumina." The compound so prepared is used for the defecation of sewage. Where much colouring matter proceeding from dyeworks is present in the sewage, the treatment by the vitriolised ash is to be followed by the addition of a milk of carbonate of lime, ground chalk, or waste lime from soap works.—C. C. H.

XVIII.—ELECTRO-CHEMISTRY.

On Mercurous Sulphate. G. Buchner. Chem. Zeit. 10, 759.

AS mercurous sulphate is frequently used for electro-technical purposes, and particularly in telegraphy for filling batteries, it is of interest to know that the salt is not by any means so liable to oxidation as is generally supposed. Several experiments, which in some cases extend over a period of three years, go to prove that in no case was the change which the mercurous salt underwent very great. Thus, when exposed for two years to the most unfavourable conditions, not more than 10 per cent. were found to have been oxidised. This, however, is of no consequence whatsoever in using the salt for the above-mentioned purposes, as the mercury which must necessarily be formed by the decomposition of the mercurous salt unites with the mercuric sulphate in presence of water, reproducing the mercurous derivative.

—A. R.

New Forms of Apparatus for Electro-Chemical Investigations. Nic. v. Klobukow. Chem. Zeit. 10, 792—793.

Universal Stand for Electrolysis.—The platinum basin S, Fig. 1, which forms the negative electrode, is supported by the ring R, to which are soldered three platinum projections. The electrode E fits the bottom of the basin

FIG. 1.

exactly (Fig. 2), and is perforated with a hole near the centre to allow of the circulation of the liquid. The cross piece T T is made of non-conducting material. The arrangement of the wires is obvious from the diagram. The basin is warmed if necessary by the small

burner B. The metallic deposit is washed by the liquid in the bottle F; when the clip h_2 is closed and h open, the liquid flows from the bottle into the basin; when h is closed and h_2 open, it is siphoned from the basin into the breaker G. The carrier d is graduated so that the distance between the electrodes may be regulated.

Elbow Apparatus for Electrolysis.—The apparatus Fig. 3 is intended for the estimation of the gaseous products of electrolysis, when evolved in small quantity, or for the investigation of liquids which are acted on by the air. Two wide glass tubes are fused together at an angle of 90° , and are provided with narrow tubes a and a' , through which the evolved gases pass into the eudiometer

FIG. 3.

FIG. 4.

tubes. The platinum electrodes c and c' may be of various forms, flat or corrugated discs, spirals of wire, and so on. Their distance is regulated by the stout wires which pass through the corks. The arrangement shown in Fig. 4 is adopted when it is desired to keep the products of decomposition separate. This is accomplished by means of a membrane of parchment or bladder fixed between the armatures A and A' , which are connected by a hinge h , and are firmly closed by the screw s which passes through the slit t .—S. Y.

Improvements in Secondary Voltaic Batteries. Chas. Moseley and Thos. Parker. Eng. Pat. 11,307, September 23, 1885. 6d.

THE positive plates are made of sheet, strip or any convenient form of lead, with the surface perforated, corrugated or roughened. These plates are then subjected to the action of nitric acid, or of a solution of nitric and sulphuric acids, or to the vapours of the solution or solutions, and are then ready for use in the construction of the battery. The negative plates are constructed as above, but instead of the acid treatment the interstices of the plate are packed with oxide of lead or with spongy lead. The positive and negative plates are then immersed in dilute sulphuric acid, and are separated from each other in the usual way. Batteries thus formed are claimed to have a greater storage capacity, and the plates are said to be less liable to disintegration.—B. T.

Improvements in Voltaic Batteries. Thomas John Jones. Eng. Pat. 11,454, September 25, 1885. 8d.

CONSISTS in the use of elastic metal clips and distance-pieces of various forms, drawings of some of which are given, to hold the elements of a cell in position. The clips and distance-pieces are coated with celluloid, and algin or alginate acid.—B. T.

Improvements in the Manufacture of Plates or Elements for Voltaic Batteries. T. J. Jones and W. H. Tasker. London. Eng. Pat. 11,652, September 30, 1885. 6d.

A DRY MIXTURE, composed of definite proportions of an oxide of lead, preferably litharge, an inert porous material as pumice stone, and about 5 per cent. by weight of the lead oxide of one of certain specified salts (ammonium sulphate preferably, but also ammonium chloride, carbonate, chromate or phosphate, or again, sodium or potassium chloride, sulphate or chromate). Such mixture is composed in a mould and steamed. The salt is dissolved, combines with the oxide, and causes the mass

to set, the latter object being ensured by afterwards thoroughly impregnating with a solution of ammonia. A dense coherent, and yet porous plate, is produced. A little glycerine, mixed with the steam, renders the plate harder. It is converted by electrolysis into spongy lead or lead peroxide. Oxidation is helped by a previous immersion in a hot solution of chloride of lime, or by the admixture of a certain proportion of peroxide of lead instead of the inert porous material. The part at which contact is to be made is rendered more conducting by facing with a mixture of the oxide of lead and the salt, without any inert material.—E. T.

Improvements in Galvanic Batteries, and in the Preparation of Liquid to be used in such Batteries. Alexander Schanschliel. Eng. Pat. 12,378, October 16, 1885. 8d.

CONSISTS of elements of zinc and carbon immersed in a liquid prepared as follows:—To basic sulphate of mercury add three times its weight of water, then add strong sulphuric acid, drop by drop. The basic sulphate will be dissolved. Stop the process when the drop falling in produces a precipitate. When filtered and cool, the liquid is ready for use. In the working of the battery the mercury is recovered in a metallic state, and also as a grey powder.—B. T.

Improvements in the Manufacture of Filaments for Incandescent Electrical Lamps. O. R. Swete and W. C. Main, Battersea. Eng. Pat. 6167, May 6, 1886. 4d.

THE authors claim the use of any suitable vegetable fibre, preferably that known as Mexican fibre, thickened to the desired extent by repeated immersions in pyroxiline, such as gun cotton dissolved in ether, the latter being rapidly absorbed, by suitable means, after each immersion. The fibre is then reduced to a uniform cross section, by means of a draw-plate, and carbonised. It is claimed that such filaments are very efficient, free from brittleness, and lasting.—E. T.

Process for the Production of the Ferrieyanides of Potassium, Sodium and Ammonium, by Electrolysis. C. Petri, Alsace, Germany. Eng. Pat. 7426, June 2, 1886. 4d.

THE electrodes are placed in cells separated by porous partitions. The cell of the negative electrode is filled with water, while that of the positive electrode is filled with a solution of potassium ferrocyanide. On passing an electric current of an electro-motive force of 1.4 to 5.4 Volt, the potassium ferrocyanide at the positive electrode is converted into ferrieyanide, while in the cell of the negative electrode potassium hydrate is separated, under formation of hydrogen, and the water of the cell is converted into potash lye. The current is passed through until all ferrocyanide is converted into ferrieyanide. Both solutions are then drawn off and treated separately, for obtaining potassium ferrieyanide and caustic potash. The process can be carried on continuously by causing the ferrocyanide solution and the water to flow continuously into one part of the respective cells, while the ferrieyanide solution and potash lye flow off continuously from another part of the cells. If the negative cell be filled with mercury, the potassium ferrocyanide is converted into ferrieyanide and potassium. The latter is taken up by the mercury, forming potassium amalgam. The above-described process is equally applicable for the production of sodium and ammonium ferrieyanide.—S. H.

Improvements in Clark Standards of Electro-motive Force and other Galvanic Cells having Mercury Electrodes. A. Muirhead, London. Eng. Pat. 8376, June 25, 1886. 6d.

To render portable cells containing mercury as an electrode, the mercury is enclosed in a cage of platinum or platinum-iridium wire, or in a small cell covered with platinum wire gauze, or perforated platinum sheet. The mercury adheres to the platinum, and does not readily separate from it when shaken.—E. T.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Iodoform Powder. G. Vulpins. Chem. Zeit. 10, 791.

IT has been the object of manufacturers to prepare iodoform in the finest possible powder. It is sold in a finely-powdered state, as a still finer precipitate, and in the form of extremely thin scales. The finely-powdered or precipitated product is well suited for mixing with other bodies in the preparation of ointments, but when dusted over wounds with a hair pencil it is apt to cake together in lumps. If not sufficiently fine, or when in the form of scales, it is not thoroughly taken up by the brush. A product is now prepared in the form of a moderately fine powder, which does not cake together and which adheres perfectly to the brush, and this is recommended when iodoform is to be used alone.—S. Y.

On the Njimo Wood. Hugo Schulz. Pharm. Zeit. 31, 350.

THIS wood is obtained from the interior of the Cameroons, and contains a principle which is said to act like pepsin. The drug is found in commerce partly in billets with but little bark, partly as thick circular sections of the root uniformly covered with bark. The wood of both stem and root possesses a beautiful yellow colour, that of the former being dashed with red. It is easily reduced to powder with a rasp, and possesses an odour like musk. It contains numberless circular pores which contain yellow resin. The alcoholic extract of the drug is yellow by transmitted light, but exhibits a green fluorescence resembling manium glass. It appears to contain no alkaloid. The resin contains a bitter substance with a faint aromatic smell. The plant itself is not known, and it is even unknown to what family it belongs.—S. Y.

On Salol. E. Ghillany. Zeit. Oesterr. Apoth. Ver. 24, 229.

PHENOLSALICYLATE, to which the name "Salol" has been given, is now employed as a medicine. It is a white crystalline powder which possesses an aromatic odour, is scarcely soluble in water, but dissolves easily in alcohol and ether, and melts at 45°. The alcoholic solution is coloured red-brown by ferric chloride. According to Dr. Sahli, it acts at least as powerfully as sodium salicylate, and it is also recommended as an antipyretic and antiseptic.—S. Y.

On the various Digitalins of Commerce. Lafon. Journ. Pharm. Chim. 6 Sér. 13, 548.

THE author has examined the digitalins of Nativelle, Homolle and Quevenne, Duquesnel, Mialhe, and Merck, and also Merck's digitoxin. The French brands exhibit the reactions given in the French Pharmacopœia: they dissolve easily in chloroform, and slightly in ether, but are insoluble in benzene, and they are coloured green by concentrated hydrochloric acid. The German digitalin is insoluble in chloroform and gives no reaction with hydrochloric acid. Merck's amorphous and crystallised digitalins do not exhibit the reaction recently described by the author (a blue green colouration on addition of equal parts of sulphuric acid and alcohol and a drop of ferric chloride): but the digitoxin gives all the reactions. The author therefore considers that Merck's digitoxin is identical with the digitalin of Nativelle, notwithstanding that it is yellow and amorphous.—S. Y.

On the Lobelia Alkaloids. Prof. Dragendorff. Pharm. Zeit. Russl. 25, 353.

IN addition to the alkaloid lobelline which is prepared from *Lobelia inflata*, the author has obtained a second alkaloid both from this plant and from *Lobelia nicotianifolia*, which grows in the East Indies. The lobelline is extracted from the ammoniacal aqueous extract by agitation with petroleum spirit, the second alkaloid by agitation with chloroform. Both compounds are poisonous. The composition will be given shortly.—S. Y.

Concissine. K. Polstorff. Ber. 19, 1682—1685.

IN a previous communication (*Ibid.* 19, 78) the author, in conjunction with Schirmer, described the preparation of an alkaloid from the bark of *Holarrhena Africana*, which was considered to be identical with concissine, a base isolated by Haies from the bark of *Wrightia antidysenterica*. The author has extracted the same alkaloid from the seeds of the East-Indian *Holarrhena*. This plant, however, yields less concissine than the African species (5kilos. of seeds gave about 4grms. of pure alkaloid). The base $C_{12}H_{20}N$ forms colourless needles, melting at 121.5°. Its hydrochloride $C_{12}H_{20}N.HCl$ crystallises in groups of needles, and the aurichloride $C_{12}H_{20}N.AuCl_4$ in golden-yellow needles. As a further proof of the identity of the base with concissine, the author prepared and analysed the nitrate and the picrate. The former crystallises in anhydrous small needles, and the latter in lustrous gold-coloured needles.—D. B.

Notes on Quinine Hydrate. Flückiger and O. Hesse. Pharm. J. 16, 3, 897 and 937.

IN reference to Fletscher's statement that quinine hydrate contains only 1 mol. H_2O (*Ibid.* 385), Flückiger communicates experiments from which it is deduced that quinine crystallised from a cold aqueous solution, and dried at 10°, contains 3mols. H_2O . On the other hand, quinine precipitated by ammonia from concentrated solutions, has the composition of a hydrate containing 2 mols. H_2O . Hesse, on the whole, agrees with Flückiger, but is of opinion that precipitated quinine is at first amorphous and free from water, but at the moment of crystallisation, it takes up water to the extent of 3mols. Moreover, the tri-hydrate, even at 20°, loses about 1mol., and at 40—60° the remaining molecules of water. This tendency to effloresce explains why quinine of commerce contains water only equivalent to about 2mols. Hesse has not succeeded in preparing a definite mono-hydrate of quinine.—D. A. L.

Note on Quinine Sulphate. O. Hesse. Pharm. J. 16, 3, 1025—1026.

QUININE SULPHATE of commerce contains as impurity hydroquinine sulphate, from which it cannot be separated by crystallisation, unless it is first converted into acid sulphate. The rotatory power of hydroquinine lies between that of quinine and cinchonidine:—quinine tartrate $[\alpha]_D = -212.5^\circ$; hydroquinine tartrate, $= -176.9^\circ$; cinchonidine tartrate, $= -132.0^\circ$. For this reason the composition of commercial quinine sulphate cannot be determined by the optical method, for the diminished rotation can as well be due to the presence of hydroquinine as to that of cinchonidine. This notice is a reply to De Vrij, who found cinchonidine in all commercial samples of quinine sulphate.—D. A. L.

Improvements in the Manufacture of Salicylic Acid and of the Substitution Compounds and Homologues thereof. J. Y. Johnson, London. From Dr. F. von Heyden, Dresden. Eng. Pat. 7801, June 10, 1886. 4d.

THIS specification relates to improvements in the process described in inventor's patent of July 15, 1884, No. 10,167 (this Journal, 1885, 551). It has been found that the manufacture of salicylic acid can be simplified by causing the carbonic anhydride under pressure, in place of being introduced into the vessel in which the materials are kept at a low or atmospheric temperature, to act on the materials whilst they are maintained at a temperature of from 120 to 145 degrees. Special care must be taken not to allow the heat to exceed these limits, otherwise phenol would be separated and the process would have to be completed as described by Kolbe in Patent 595, February 17, 1874, which the present improvements are intended to obviate. Corresponding results are obtained by the treatment of the homologues and substitution compounds of phenol.—D. B.

XXI.—EXPLOSIVES, MATCHES, Etc.

Improvements in the Manufacture of Explosives. Dingl. Polyt. J. 261, 25–29.

MARKGRAF of Neunkirchen published some experiments on two new explosive substances introduced into commerce by Hellhof of Berlin, and termed Hellhoffite and Carbonite. The Hellhoffite consists of 1 part dinitrobenzene and 1.5 parts nitric acid, or 1 part nitrobenzene and 2.5 parts nitric acid; the latter mixture is preferable. It does not explode by a sudden blow, but it gives off unpleasant vapours on burning, and on being stored eats away the paper-cases of cartridges. Owing to these disadvantages the carbonite was prepared, which is said to consist of nitrobenzene, potassium nitrate, sulphur, and kieselguhr. It has a neutral reaction, is also proof against explosions due to sudden blows, but its explosive force only equals that of dynamite. Tranzl, of Vienna, criticises adversely the use of these explosives. According to him, Hellhoffite is simply an imitation of Sprengel's explosive compounds, the applicability of which the latter inventor himself declared as scarcely probable. The pretended advantage that the explosives may be prepared in the mine shortly before use is really a disadvantage, since it would increase enormously the number of accidents. Furthermore, their preparation is expensive; the paper-cases of the cartridges must be often renewed and the action of the nitric acid on the percussion cap may cause a premature explosion. F. Holzner reports on the use of Hellhoffite for filling shells. The front part of the shell contains a closed glass vessel filled with nitric acid, whereas the back is filled with finely-crystallised metadinitrobenzene. On firing, an intimate mixture of both takes place, which is exploded by the fuse. Experiments in different countries gave contradictory results. General Abbot, of New York, publishes the composition of some new American explosive compounds. Atlas-powder (Repauno Chemical Company, Philadelphia) consists of:—

	A.	B.
NaNO ₃	2	31
Cellulose	21	11
MgCO ₃	2	2
Nitroglycerin	75	50

Judson-powder (Judson-powder Company, Rustie):—64% NaNO₃, 16% S, 15% C, 5% C₂H₅(O.N)₂ (Nitroglycerin). Judson-powder is prepared by grinding nitre, sulphur, and carbon, each separately, mixing them in a drum and heating them with steam to 177° until the sulphur melts and coats the nitre and carbon. After cooling the mass forms grains, which are sieved and coated with nitroglycerin. The fine division of the latter compound is said to produce a more powerful explosion. M. v. Foerster, of Walsrode, issued a pamphlet on experiments with gun-cotton, and the application of compressed gun-cotton for military purposes. From it we learn that wet gun-cotton (25% H₂O) acts more powerfully than dry cotton. A greater specific gravity increases the action of open charges. If there is a space between the charge and the body to be attacked, the effect decreases rapidly. Closed charges show at the percussion cap a power six times as great as at a point which is most distant from the cap. That is to say, that the transmission of the explosive force of gun-cotton is very small. This explains why gun-cotton is not applicable for mining purposes.—S. II.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

The Precipitation of Ammonium Magnesium Phosphate in presence of Ammonium Citrate. C. Mohr. Chem. Zeit. 10, 675.

THE author shows by a series of experiments that the Belgian and French method of determining phosphoric acid in superphosphates, by precipitation of the ammonium magnesium salt in presence of ammonium citrate, gives results which are very much too low. This he estimates at 5.5 per cent. The chief sources of error of this method are due to the fact that the soluble and the dibasic phosphoric acid are determined in one operation. The two operations may be readily separated, as the

soluble phosphoric acid may be much better determined without ammonium citrate. The addition of ammonium citrate is only necessary for dissolving the dibasic salt. The author recommends the following modification: 2grms. superphosphate are rubbed in a mortar with warm water and an excess of sodium acetate added. The precipitated iron and alumina phosphates remain in the residue. The mass is filtered and washed, and made up to 200cc. Of this 50cc. may be used for the determination of the soluble phosphoric acid. The residue is digested with 15cc. of an alkaline solution of ammonium citrate for one hour at 40° to 50°, filtered and precipitated with magnesia mixture. The loss does not exceed 0.3 per cent. The two amounts are then added.—J. B. C.

Determination of Silicon in Iron. L. Blum. Chem. Zeit. 10, 702.

THE author gives data of the method, previously described (*Chem. Zeit.* 9, 1373), for determining the amount of silicon in iron, by employing a solution of bromine in hydrochloric acid. He compares it with the method in general use now—viz., dissolving the substance which has been weighed off, in 200ccm. of water, 100ccm. hydrochloric acid and 20grms. of potassium chlorate, evaporating, filtering, washing with hydrochloric acid and water, igniting and weighing. The author endeavours to account for the fact that this latter method gives somewhat lower figures than his, by assuming that some silicon chloride or silicon hydrochloride is formed and escapes when the reaction is at its height, whereas no loss occurs with his method, as the corresponding bromine compounds are more readily decomposed before they can escape. The latter method also is much preferable, for the solution filters very well, this not being the case when the iron has been treated with potassium chlorate.

It is advisable to dissolve the iron in an evaporating dish. This saves time, and the results are not influenced in the least.

In order to obtain the silica perfectly white after ignition, the precipitate should be very thoroughly washed with the solution of bromine in hydrochloric acid.—A. R.

Determination of Phosphoric Acid in Thomas-Slag. Dr. T. Klein. Chem. Zeit., 10, 721.

IN all the methods at present in use for determining the amount of phosphoric acid in Thomas-slag, oxidising agents are employed. Assuming this slag to contain iron phosphide, it might be supposed that the amount of phosphoric acid found by analysis would somewhat exceed the quantity originally contained in the substance owing to the oxidation of the phosphorus. This, however, does not appear to be the case.

While the use of sulphuric acid gave no good result, it was found possible to decompose the slag by heating it with ordinary hydrochloric acid for more than an hour. The amount of phosphoric acid found in several experiments agreed with the quantity obtained by fusion with soda and nitre, thus proving that the quantity of iron phosphide contained in the slag is either exceedingly small or that it is not decomposed by fusion.—A. R.

A New Method for the Determination of Zinc. G. Löse-kann and Dr. Th. Meyer. Chem. Zeit. 10, 729.

ON adding to a solution of zinc in hydrochloric or sulphuric acid, which has been neutralised with ammonia, a sufficient quantity of disodium phosphate, a voluminous white precipitate, Zn(NH₄)PO₄, is obtained, which becomes crystalline on boiling the solution, and exactly resembles the corresponding magnesium compound. On heating over the blow-pipe, it melts to a transparent fluid, which, however, solidifies again in a Bunsen burner. The weight of the pyrophosphate thus formed very soon becomes constant when heated over the blow-pipe. The analytical data given would show that the method is an excellent one. It is best to precipitate the phosphate by mixing the zinc solution with excess of

ammonia and disodium phosphate, and then adding hydrochloric or sulphuric acid, drop by drop, until the reaction is neutral. Slight excess of alkali or acid is, however, of no consequence if a sufficiently large amount of disodium phosphate has been added. The solution in which the precipitate is suspended is then boiled, filtered after standing a few hours, and washed with hot water until no more phosphoric acid can be detected in the washings by molybdenum solution.

This method is also applicable to the separation of zinc and magnesia, but only when the metals are present as sulphates, unless there is only a small percentage of magnesia, when the chlorides also may be used. Excess of ammonia and disodium phosphate are first added, and the mixture allowed to stand a few hours. All the magnesia is precipitated, whereas the filtrate contains all the zinc, which, in its turn, may be precipitated as phosphate by exactly neutralising the solution.

The results are arrived at very rapidly, though without impairing their exactness, and this method, therefore, promises to render great service to those who have frequently to make determinations of zinc.—A. R.

Determination of Nickel on Nickel-plated Iron Goods.

Dr. A. Köbrich. Chem. Zeit. 10, 747.

THE following method for determining nickel on nickel-plated goods may be speedily carried out, and gives good results:—The articles are put into a mixture of equal parts of nitric acid (sp. gr. 1.18) and water. The nickel plating begins to dissolve at once, and when only iron is visible the goods are removed from the acid solution and washed. The solution is then heated with hydrochloric acid as long as there is any ferrous salt present. On now adding sal-ammoniac and excess of ammonia and gently heating for an hour, the nickelous oxide dissolves readily, and may thus be separated from ferric hydroxide. The latter is again treated with sal-ammoniac and ammonia, and washed on the filter with dilute ammonia until the filtrate is no longer coloured brown on addition of ammonium sulphide. The filtrates are united, treated with ammonium sulphide and acidified with acetic acid. The nickel sulphide thus precipitated, after being dissolved in nitric and hydrochloric acid, is determined in the usual way as metallic nickel.—A. R.

A simple Air-pump for use in the Laboratories of Works, etc.

O. N. Witt. Chem. Zeit. 10, 760.

THE author reviews the different kinds of air-pumps at present in use. The one here described does not, as the two kinds generally employed in laboratories, require either a strong pressure of water or a long column of discharged water. Now, as one or the other of these requisites is not often to be found in works, the author has constructed a pump, the principle of which depends on the hydraulic ram. It can be looked upon as a modification of Jagno's pump, the theory of which has been explained by Mendeleeff, Kupitschoff and Schmidt (*Annalen*, 165, 63). Jagno's pump works with a column of water and fall $1\frac{1}{2}$ meters high. If the pressure is stronger, the fall may be successively shortened to 40cm.; if smaller, it must be correspondingly lengthened. These are very modest requisites, and the only reason why this pump has found so little favour in laboratories is due to its liability to get out of order, and Linnemann's (*Annalen*, 177, 295) improvement on that pump is somewhat expensive. The adjoining figure will readily explain the construction of the pump as recommended and used by the author for several years. A is a T-shaped glass tube, 10mm. wide, the lower end of which, as also the end of the side-piece, is widened out. The upper end is carefully ground. B is also a T-tube, consisting of a piece 25mm. in width and a piece of the same tubing as used for A. All three extremities of B are widened out. A is connected with B by means of a very good cork stopper (not caoutchouc), which should be as long as possible, and very compact. A should fit into B in such a way that both tubes are perfectly concentric, and that while A can slide perpendicularly but with strong friction in B, the possibility of an oscillation in a

lateral direction is altogether excluded. The upper opening is closed by means of a perfect membrane of sheet caoutchouc, 5mm. thick. As it is not easy to obtain perfect caoutchouc, and the least fault may cause it to split, it is best to tie two or three thinner sheets, one over the other, on to the tube. The thickness of the sheets employed should depend on the water-pressure at disposal, and must be tried in each special case. A must be pushed into B so far that the water which enters at b, while slightly lifting the caoutchouc-sheet, is jerked out at a. Under ordinary circumstances, this occurs

Fig. 1.

Fig. 3.

Fig. 2.

when, on blowing into b, a loud sound, resembling a blast from a trumpet, is heard. C is a Bunsen valve, which must have been made with great care, and should fit perfectly. It should, moreover, be so small that it works easily in the tube, and offers a sufficient passage for the expelled air. As the whole pump oscillates very considerably when in action, the junctions must be tied with silk and thin wire, and fastened so thoroughly that the various parts cannot be displaced. Much depends on the good quality of the small valve: it is not easily made, and the black tubing which is used for it gradually loses its elasticity. It is therefore advisable to replace it by an arrangement such as the one shown in Fig. 2. This consists of a wide piece of tubing, which is drawn over and attached to the shortened adjoint piece of A by means of a cork. A thin piece of tubing, ground in front, is passed through the other end of the wide tube, and on the former glides a somewhat broader but short tube, widened at each end, over the front opening of which a strip of caoutchouc cloth is stretched (Fig. 3), just broad enough to cover the opening of the small tube.

By sliding this small valve along the tube, the best position for it must be ascertained. All junctions, again, should be carefully fastened with wire or silk thread. Before using the pump, it is fastened below *b* to a heavy stand. While working, it emits a deep humming sound. As the exhaustion of the vessel attached to the pump proceeds, the beats of the pump become heavier and slower, until finally each can be counted separately. If, now, the water be turned off, the pump of itself closes the receiver, an advantage not possessed by any other pump.

This pump cannot, of course, evacuate so thoroughly as other water-air pumps, considering each to be working under the most favourable conditions. Even if the valve is very carefully constructed, it is impossible to obtain a vacuum under 50–60mm.; but this pressure suffices for all filtrations, even for all distillations under diminished pressure.—A. R.

A New Self-regulating Arrangement for Filtering. F. W. Dafert. Chem. Zeit. 10, 762.

WHEN large quantities of a liquid are to be filtered as quickly as possible through a small filter, the following apparatus will be found useful: The liquid to be filtered, contained in *B*, is led by means of a syphon into the filter in funnel *A*, and thence passes into *B* under pressure. As the supply at *A* must be greater than a discharge at *f*, an excess of the fluid must be provided, and then again returned to *B*. This is effected through the tube *f g* by means of a weak counter pressure exerted at *h*, which can be regulated by the stop-cock *c*. When

the filter is filled to *f*, this second syphon commences to act, but in the reverse direction. The syphon *d c* is best filled by closing *f* and blowing air through *h*. Through the cork of *B*, a separating funnel may be passed, for introducing any desired quantity of the liquid to be filtered. The air admitted through *a* should just be sufficient to cause hardly any alteration in the minus pressure in *B*. The lower end of the lever *d c* should be bent upwards to guard against damaging the filter.

—A. R.

A Thermo-regulator for Low Temperatures. F. W. Dafert. Chem. Zeit. 10, 789–790.

By means of the apparatus designed by the author, constant temperatures, slightly above that of the water supply, may be obtained. The bath itself is not heated by the flame, but only a portion of the current of water with which it is constantly supplied. In the apparatus (Fig. 1) the bath *W* contains an ordinary thermo-regulator *T*, by which the flame *F* is made larger or smaller as the temperature of the water in *W* falls or

rises. The current of cold water enters the bath through the tubes *A* and *B*; the spiral is made of lead tubing. The water which enters the bath through *A* is cold; that which passes through *B* is heated by the flame; thorough admixture of the water as it enters is insured by the introduction of a slow current of air through the tube *E*. The water escapes from the bath through the tubes *C* and *D*. As this arrangement is not convenient for all purposes, the author makes use of the waste water from the first apparatus, connecting the discharge tubes *C* and *D* with *I* and *G* respectively in Fig. 2. By

FIG. 1.

passing a sufficiently rapid current through the first apparatus, the temperature of the water is not sensibly altered before it leaves the second. The author describes experiments made to test both forms of apparatus, in which, while the temperature of both the atmosphere and of the

FIG. 2.

water supply varied considerably, that of the water in the bath *W* did not alter more than $\pm 0.045^\circ$, and in the bath *L* more than $\pm 0.105^\circ$. Again, if the temperature of the water in *W* was raised or lowered by the introduction of boiling water or ice, the normal temperature was again attained after a few minutes.—S. Y.

Azotometry and Azotometer. W. Knop. *Zeits. Anal. Chem.* 25, 301–308.

THE author calls attention to the fact that in 1859 he drew attention to the possibility of using sodium hypochlorite and hypobromite for the determination of nitrogen in ammonium salts and certain organic substances. He then described the apparatus which he used, and which he called an "azotometer," in order to distinguish it from other arrangements for the determination of nitrogen. Since then Hüfner (*Zeits. f. Physiol. Chem.* 1, 335), Hofmann, and Jacoby (*Zeits. Anal. Chem.* 24, 307) have published papers on the method. The author now describes a modified apparatus, of which the following is a description. The decomposing vessel is of glass, and closed by a glass stopper, which is expanded in the centre to a cylinder, and closed at the top by a tap: the cylinder is filled with beads, with a ball of platinum wire at the bottom to prevent them from falling into the vessel. Before placing the required amount of brominated soda solution in the decomposing vessel, this stopper is removed and inverted, in order to pour some of the solution over the beads and completely wet them; the necessary amount of solution is then added to the vessel, and the stopper replaced, and allowed to remain until no more solution drops back. The glass tube containing the urine or ammonium salt is then gently placed in the vessel with

the aid of forceps, in such a way that the two liquids can be later mixed by shaking. The decomposing vessel is then connected with the one end of a U-tube, filled with water, and the ammoniacal solution slowly mixed with the hypobromite solution by gently tilting the vessel. The evolved gas is freed from any ammonia mechanically carried over by its passage through the solution on the beads. Finally the tap is closed, and the solutions well mixed by shaking, in order to complete the evolution of the nitrogen; the tap is then opened, and the whole apparatus immersed in a cylinder containing water. The illustration shows the arrangement of the apparatus, together with the cooling cylinder; the mouth of the latter is surrounded by a brass rim, to which are fixed connections for holding the vessel and the U-tube in the required positions. One limb of the U-tube is graduated, and the level of the water in the two limbs can be adjusted by means of a tube with a stop-cock, which passes through the side of the cooling cylinder. The errors in estimations made with this apparatus, due to the absorption of nitrogen by the brominated solution, and errors in measuring the quantity taken with a pipette, can be determined by making a series of determinations with a standard solution of ammonium chloride, and adding the difference in cc. between the amounts found and calculated to the number of cc. of nitrogen obtained in an actual estimation.—G. H. M.

Analysis of the Hot Spring of Leuk (Canton Wallis, Switzerland). G. Lange and R. E. Schmidt. *Zeit. Anal. Chem.* 25, 309–318.

AN analysis of the spring of St. Lorenz, carried out to test the correctness of previous analyses. The temperature of the water was 51.35° C., and the sp. gr. at 15° 1.00194, compared with water at 15° and 1.00109, compared with water at 4°. The water flows in very large quantity (about 500,000 litres in 24 hours) from a rough basin made of slabs of stone. Large quantities of gas

FIG. 1.

FIG. 2.

are given off at regular intervals. The water is quite clear and odourless, with an insipid taste. In the air small quantities of flocculent iron hydroxide separate out.

The determination of the dissolved gases was made in the nitrometer, arranged as follows:—The flask A (Fig. 1) is completely filled with the water; an indiarubber plug with a capillary tube (a) passing through it, is then inserted in the flask, and the tube is thereby completely filled with water. The whole is then weighed, and the difference between this and the weight of the empty flask and tube gives the amount of water taken. The end of the capillary tube is then connected to the side tube of the nitrometer by the tube b. The nitrometer is then completely filled with mercury, and when the tubes are quiet the flask and measuring tube of the nitrometer

FIG. 3.

are quickly placed in connection, without the introduction of the slightest trace of air. The water in the flask is then slowly heated to boiling. Some water as well as the dissolved gases collect in the measuring tube of the nitrometer. The tube N of the nitrometer should be lowered in order that the boiling may take place under reduced pressure. After boiling for 5 to 10 minutes, the stop-cock is quickly turned through 180°, so that the

flask is placed in combination with the cup B, containing mercury, and the flame removed. Since the mercury stands lower in N than in M, it is not possible for any loss of gas to take place at the moment of turning the tap. It is also impossible for any gas or steam to escape through the mercury cup, since the pressure is inward. A small bubble of gas always remains under the stopper; this is brought into M by lowering the tube N as much as possible, and then turning the stop-cock so that the flask and measuring tube are again placed in connection, and when the bubble has passed over, quickly reversing the tap again.

When the whole of the gas is collected in the nitrometer, it is connected with a second instrument O P (Fig. 2), quite full of mercury. The gas is then transferred by placing the tap I in such a position that it is closed in all directions (a section of the tap is shown in Fig. 3), and the tube M is heated by passing steam through the tube R. When it is quite hot the tube N is lowered, causing the water in M to boil, in order to expel every trace of dissolved gas. The taps are then placed in connection and the gas passes over. It can then be cooled, measured, and submitted to analysis. Two experiments gave 505 grms. water taken, gas evolved 5.06 cc., per 1000 grms. = 10.02; 502 grms. water taken, gas evolved 4.94 cc., per 1000 grms. = 9.84.

The gases evolved from the spring were also collected and analysed.

The determination of the sulphuric acid was made by adding sodium carbonate, in excess, to the hot water, in order to decompose the sulphates of calcium and strontium, the precipitated carbonates filtered off, and the analysis finished in the usual way. It is found that by the precipitation of calcium sulphate solutions with barium chloride, small quantities of calcium sulphate were precipitated as such, thus throwing the results too low.

The strontium was determined by adding sulphuric acid to a solution of the chloride, in sufficient quantity to convert all the strontium and a small portion of the calcium into sulphate. After standing, alcohol was added, and the sulphates filtered off. The precipitate was converted into carbonates, then into nitrates, and the latter separated with a mixture of alcohol and ether.

The manganese was precipitated by ammonium sulphide in the filtrate, after removal of the strontium. This prevents the possible precipitation of traces of strontium with the manganese.

No trace of arsenic was found. The results of two concordant analyses gave the following results:—

	Grms. per kilo.
Strontium Sulphate.....	0.00194
Calcium	1.4286

Determination of Nitrogen in Coal and Coke. S. Schmitz. Zeit. Anal. Chem. 25, 314—318.

THE author has been in the habit of using the methods of Dumas and Varrentrapp-Will. Dumas' method has

the following disadvantages: Coal and coke burn in an atmosphere of carbonic acid, only very slowly, and the pressure in the tube is often so great that great care must be exercised in order to prevent the tube being blown out. There is always a residue of unburnt substance after 4 to 5 hours' combustion. Varrentrapp-Will's method is the one most generally used. The author found, however, that the results were always too low with coal, whilst with coke they are quite unreliable. A sample of coal which gave 1.77 per cent. nitrogen by the method described below, gave only 1.61 per cent. nitrogen (on dissolving the soda-lime no trace of coal remained unburnt). A coke which gave 1.22 per cent. N, by the new method, gave only 0.71 per cent. by the Varrentrapp-Will's method. Similar results were obtained with other samples of coal and coke.

The author has applied Kjeldahl's method to the analysis of these substances. He proceeds as follows: 0.8—1 grm. of very finely-powdered coal (0.5—0.7 grm. of coke is sufficient) is placed in a ½-litre flask made of good potash glass, together with 1 grm. of finely-powdered mercury oxide, and 20 cc. concentrated sulphuric acid, and heated to boiling for three hours. All varieties of coal, including anthracite, are dissolved in this time. The cooled contents of the flask is then added to a ¾-litre Erlenmeyer's flask containing a little water; 120—140 cc. pure sodium hydrate of 30—32 B. and 35 cc. of a solution of yellow sodium sulphide are then added, a small piece of zinc introduced, and the flask fitted to the apparatus shown in the figure, and the distillation carried on for 20 to 30 minutes. The introduction of the bulb arrangement between the flask and condenser is to prevent the alkaline liquid being spirted over. The ammonia is distilled into $\frac{1}{10}$ normal sulphuric acid, of which 30 cc. are used for coal and 20 cc. for coke, and the excess titrated with $\frac{1}{10}$ normal barium hydrate and rosolic acid. A few of the results obtained were—

	Amount used.	H ₂ SO ₄ used.	Nitrogen found.
Cannel-coal	0.9667 grm.	24.1 cc.	1.78%
from Zeche	0.9176 ..	23.04 ..	1.76
Anthracite	0.6172 ..	1.00 ..	0.52
from Piesberg	0.6393 ..	5.69 ..	0.51

With coke the process is carried out as above, with the addition that, after the mixture has been boiled for one hour 1 grm. of mercury oxide is added, and then 2 grms. of finely-powdered potassium permanganate. The additional amount of mercury makes it necessary to add double the quantity of sodium sulphide solution. The results obtained were—

	Amount used.	H ₂ SO ₄ used.	Nitrogen found.
Coke from	0.7749 grm.	11.35 cc.	1.03%
Zeche	0.6641 ..	11.21 ..	1.18
.. .. .	0.6892 ..	15.31 ..	1.21

In carrying out the nitrogen determination in coke the following varieties must be distinguished: (1.) Coke which has been prepared in a platinum crucible. (2.) Coke from the coking oven after 24 hours. (3.) Coke after 48 hours or more in the oven (patent coke). No. 1 may be determined by the method given for coal; No. 2 gives results with the coke method, which are very

nearly correct—they do not differ more than 0.10–0.15 per cent.; No. 3 only very seldom gives results which are close to correct numbers. The author intends to carry out further experiments on this last point.

—G. H. M.

Modification of Sonnenschein's Method for the Determination of Phosphorus in Iron and Steel. N. Huss. Zeit. Anal. Chem. **25**, 319–326.

THE author has made a series of experiments with three samples of steel, and finds that it is necessary, for the accurate estimation of phosphorus, that the organic matter should be completely destroyed. If this is not done, a portion of the molybdic acid used for precipitation of the phosphoric acid after solution of the iron or steel in acid, is reduced, and comes down with the precipitate of ammonium molybdo-phosphate, and makes the results too high. On the other hand, if the excess of ammonium chloride is not completely driven off, a double decomposition between this salt and the nitric acid takes place, resulting in the formation of aqua-regia, which keeps a portion of the phosphate precipitate in solution, and gives too low results. The author has made direct experiments on the solubility of ammonium molybdo-phosphate, both in aqua-regia and in a mixture of hydrochloric acid and ammonium chloride, and finds that both acid mixtures possess solvent action upon it. In order to avoid the prolonged treatment with potassium chlorate and hydrochloric acid, and subsequent roasting necessary to effect complete destruction of the organic matter and ammonium chloride, Huss recommends the following procedure: 10grms. of steel are dissolved in 200cc. nitric acid of 1.20 sp. gr., and when dissolved, boiled for fifteen minutes to dissolve the carbon, then cooled, and the exact quantity of ammonium chloride solution necessary to convert the whole of the iron into chloride added. This must be accurately calculated, and the amount added from a burette (10cc. of a 28.65 per cent. solution are required for 10grms. steel). 50cc. of an aqueous solution of ammonium molybdate, containing 20 per cent. crystallised salt, is then added. The precipitate begins to separate out at once in the cold, and by heating to 50° the precipitation is complete. At the end of 15 minutes the precipitate is filtered, thoroughly washed with a solution of ammonium molybdate in dilute nitric acid, and then with 1 per cent. solution of nitric acid. The precipitate is spread on a watch-glass and dried not above 80°. The precipitate is then removed from the paper as completely as possible, the latter burnt in a weighed crucible, the precipitate added, and the whole again heated, cooled and weighed. The weight multiplied by the fraction $\frac{1.63}{10}$ gives the percentage of phosphorus. This gives results which closely agree with those obtained by the more elaborate process. The small quantity of reduced molybdenum compound does not affect the results in this determination, since a difference of 0.01grm. on the 10grms. of steel taken only makes a difference of 0.00163 per cent. phosphorus. If, however, the precipitate is dissolved in ammonia, and the determination made with magnesia mixture, the error affects the results, and it is necessary to oxidise with bromine before precipitation with magnesium mixture.—G. H. M.

The Determination of Iron Oxide in the presence of Alumina. E. Donath and R. Jeller. Zeit. Anal. Chem. **25**, 361–363.

ADVANTAGE is taken of the fact that when oxide of iron is heated with zinc-dust or finely-ground zinc, a very energetic reaction takes place, and the oxide is reduced to metallic iron. In order to determine iron in presence of aluminium, the precipitated mixed oxides are finely-powdered, mixed with an equal quantity of zinc-dust in a porcelain crucible, the mixture covered with a small layer of zinc-dust, and the crucible then heated for 5 to 8 minutes. The mass is then transferred to a flask and boiled with dilute sulphuric acid, taking care that the iron does not become oxidised. The solution is then made up to a determined volume, and the ferrous salt

estimated with standard potassium permanganate. If commercial zinc-dust is used for the reduction, it is necessary to determine the amount of reducing action which the quantity taken has upon the permanganate solution, and apply this correction to the result. The iron in all iron ores which contain the iron in the ferric state, may be estimated in this way. Iron ores and slags which contain the iron as ferrous oxide, give the results too low; if, however, they are previously oxidised by moistening with ammonium nitrate and subsequent ignition, good results are obtained.—G. H. M.

Apparatus for Washing and Drying Precipitates in the absence of the Carbonic Acid of the Air. A. Dolles. Zeit. Anal. Chem. **25**, 369–371.

THE apparatus is shown in the annexed figure. It consists of a glass cylinder to which a glass plate is fitted perfectly air-tight. The plate has three orifices, *a*, *b*, *c*, to which are fitted india-rubber bungs. Through *a*, a stoppered funnel is passed, through *b* a bent bulb tube connected with a small bottle filled with solid caustic potash; through *c* a syphon with a tap *d* is passed in such a way that it can be slipped up and down without removal. The precipitation is effected in the cylinder and the precipitate washed by decantation, distilled water being added through the funnel and

drawn off by lowering the syphon and turning on the tap. If it is wished to wash the precipitate with hot water, the bulb in the tube prevents any condensed steam from getting to the caustic potash. When the precipitate is thoroughly washed it can be freed almost entirely from water by attaching a porous cylinder to the inner end of the syphon and bringing it down to the level of the precipitate; the other end of the syphon is connected with one neck of a Woulfe's bottle, which is connected to a filter pump by the second neck. After an hour or two's suction the precipitate can be transferred to a desiccator.—G. H. M.

Apparatus for the Volumetric Determination of Nitrogen. A. Sonnenschein. Zeit. Anal. Chem. **25**, 371–372.

THE accompanying figure shows an apparatus for measuring the nitrogen evolved in Dumas's method for determining this in nitrogenous substances. The

arrangement consists of a measuring tube with a suction tube attached to the side. This is placed in a dish with a handle and the whole is then placed in a larger dish filled with caustic potash. A pipette is then fitted to the end of the suction tube by means of a bung, and the

apparatus is filled with the solution by suction; this is repeated until the tube is quite free from bubbles. When the whole of the nitrogen is collected the small dish and tube are transferred to a vessel of water, and the volume of nitrogen read off.—G. H. M.

The Drying of Fats. A. Sonnenschein. Zeit. Anal. Chem. 25, 372–373.

FATS and fatty acids are usually dried by being heated to 100–110 °C. for some time, and finally placed over sulphuric acid. The method is very imperfect, since the water collects below the fat and only slowly evaporates

through it. The author tares the flask *a*, as shown in the annexed figure, together with the straight tube *b*, weighs in the fat, attaches the flask to a filter pump, and draws dry air through the melted fat until the weight is constant.—G. H. M.

A New Method of Distinguishing Vegetable from Animal Fibre. Hans Molisch. Dingl. Polyt. J. 261, 135–138.

This method is founded on the discovery, made by the author, that by adding to a solution of any kind of sugar first an alcoholic solution of α -naphthol and then concentrated sulphuric acid in excess, a beautiful deep violet colour is produced. On diluting the solution with water a bluish-violet precipitate is formed. When thymol is used in place of naphthol the colour of the solution and precipitate is carmine-red. Both reactions are extremely sensitive, and in this respect surpass both Fehling's and Trommer's tests. As by the action of sulphuric acid upon the carbohydrates and glycosides

sugar is formed, the reaction is also applicable for ascertaining the presence of these substances. The following method is recommended for textile fabrics: To about 0.01 g. of the sample, previously well boiled and washed with water, first 1 cc. of water, then two drops of an alcoholic solution of α -naphthol (15 to 50 per cent.), and at last 1 cc. of sulphuric acid are added. In case of vegetable fibres the liquid at once assumes the characteristic deep violet colour, whereas animal fibres produce a more or less intense colouration, varying from yellowish to reddish-brown. The reliability of this test was proved by applying it to all fibrous materials used in the textile and paper manufactures, as also to cork and the cellular tissue of fungi. Some kinds of silk seem to form an exception to the other fibrous materials of animal origin, as in their behaviour they resemble cellulose. The colouration is, however, quite faint and transient, and therefore cannot mislead. In the case of dyed fabrics the nature of the material composing them can be ascertained by the same process, for the colour does not interfere with the reaction.—F. M.

On the Detection of Liquorice in Beer. H. Hager. Industrieblätter, 1886, 202.

THE constituents of liquorice extract are partly precipitated from their solution by organic acids, such as acetic, succinic, benzoic, salicylic, etc., acids. A small quantity of liquorice added to beer during the process of brewing therefore escapes detection after fermentation, as by the acids invariably formed during the latter process it is converted into an insoluble form, and collects at the bottom of the fermenting vat. Beer to which salicylic acid has been added, or which has turned sour, would likewise appear free from liquorice. The presence of this substance might, however, be proved in the sediment formed in the cask. In order to detect glycyrrhizin, the chief constituent of liquorice juice, in beer, the latter is evaporated to one-fourth its original volume, and the sediment formed mixed with plaster of Paris, and after drying extracted with 90 per cent. alcohol. The hop constituents may be separated by mixing this extract with calcium hydroxide, evaporating to dryness, and again extracting with alcohol. Calcium glycyrrhizinate is left undissolved, from which, by means of acetic acid, the glycyrrhizin is separated.—F. M.

A Method for Rapidly Determining Manganese in different kinds of Iron by means of Permanganate. Meineke. Rep. Anal. Chem. 6, 252.

THE following method has several advantages over those at present in use—viz., more efficient oxidation and solution, reduced filtration and a wide range of application, it being independent of the percentage of manganese present. 0.5–1.0 gm. of ferro-manganese or specular iron, or 1–2 grms. of pig or ingot iron, are dissolved in 15 cc. of a mixture of 3 vol. dilute sulphuric acid (sp. gr. 1.13), and 1 vol. of nitric acid (sp. gr. 1.4); 0.5 cc. of a strong chromic acid solution is then added (100 grms. CrO_3 in 100 cc.), and the mixture, after boiling for a short time, transferred to a 500 cc. flask. Here 20–25 cc. of a saturated barium chloride solution, and very finely powdered zinc oxide, suspended in water, are added, until flocculent ferric oxide has separated. Should the solution not yet be colourless, a further quantity of barium chloride and zinc oxide, but only traces, should be introduced. Having filled up to the standard point, the solution is mixed, filtered through a dry folded filter, and 250 cc. of the filtrate gradually poured into another 500 cc. flask containing an excess of permanganate solution of known strength, and also 20 cc. of a zinc chloride solution (about 25 grms. zinc to 100 cc.). Water is added to the mark, the solution again passed through a dry folded filter, and in 250 cc. of the clear filtrate excess of permanganate is titrated back with antimony chloride.

Having regard to the volume of the precipitate, it must be assumed that, with a dilution of 500 cc., 100–52 Mn

are found instead of 100 Mn, supposing 1grm. to have been weighed off. It is, therefore, necessary either to take 0.9947grm. of iron instead of 1grm., or to multiply the result obtained by 0.9947. Presence of nitric acid is of no consequence if the titration with antimonious chloride is carried out at ordinary temperatures. The more dilute the permanganate solution, and the faster the solution is filtered, the less is the filter attacked. Consequently as little substance should be used as possible, or after precipitating with zinc oxide, the solution should be diluted to a larger volume than 500cc. The strength of the permanganate solution is best chosen such that 1cc. = 1.0–1.5grms. manganese, whatever the amount of the latter in the solution to be titrated.—A. R.

Quantitative Separation and Estimation of Zinc. S. Bein. Rep. Anal. Chem. 275–283.

THE author has investigated the various methods of determining zinc, with special reference to their applicability. To separate zinc from ferrous salts, he recommends the precipitation of the latter by means of sodium succinate. The zinc is then precipitated from the boiling-hot concentrated solution by the addition of sodium carbonate. The precipitate is dissolved in nitric acid, ignited, and weighed as zinc oxide.—D. A. L.

On the Determination of Phosphorus in Steel and Iron. C. Meineke. Rep. Anal. Chem. 6, 303 and 325.

THE author recommends the following modification of the molybdate method, in which the precipitate is ignited and weighed as $P_2O_5 \cdot 4MoO_3$.

The iron solution should consist almost entirely of nitrate. The solution, after filtration, should contain 25 to 30grms. of ammonium nitrate and about 12.5grms. free N_2O_5 or 25cc. of nitric acid of 1.4 sp. gr. The molybdate solution is formed by dissolving 150grms. ammonium molybdate in 1000cc. five per cent. ammonia, and adding this to 1000cc. of nitric acid of sp. gr. 1.4. The iron is dissolved in 50cc. of nitric acid of 1.2 sp. gr.; to this solution 60cc. of nitric acid of sp. gr. 1.4, and 2cc. of chromic acid solution containing 2grms. CrO_3 , are added, and the mixture is boiled for ten minutes. 100cc. of water, and 50cc. of ammonia—sp. gr. 0.91—are now introduced. Now 75cc. of molybdate solution are added to the carefully-stirred iron solution at a temperature of 90° to 95°, and the mixture is allowed to stand for an hour at the ordinary temperature. The precipitate is washed with a fifteen per cent. ammonium nitrate solution containing five per cent. of free nitric acid until free from iron, then placed with the filter without drying in a porcelain basin, and ignited at a moderate temperature. It is advisable to cover the basin and to avoid too high a temperature in order to prevent the further oxidation of the molybdenum oxide. If the precipitate has a bluish colour after ignition, it should be moistened with ammonia and again ignited.

When organic compounds are present, chromic acid should be added or the solution of iron evaporated and ignited. The presence of silicon in iron does not interfere with the process.—S. Y.

The Estimation of Extract and Glycerol in Wine. R. Bensemann. Rep. Anal. Chem. 6, 313.

THE author finds that the method III. 2 b (*Chem Zeit.* 10, 335) gives good results. The extract dried at 110° is completely free from glycerol. The method referred to is as follows (*loc. cit.*):—The alcoholic extract is evaporated in the flask in which it was obtained, on the water-bath, to a stiff syrupy condition. The residue is dissolved in 90 per cent. alcohol; the solution is brought into a 50cc. cylinder graduated in cc., and furnished with a glass stopper, and there treated with 20cc. of alcohol of 90 per cent. 50cc. of ether are then added. After clearing, 25cc. of the ether-alcohol solution are taken (corresponding to 50cc. of wine), and

brought into a flask of 5 to 6cm. diameter, and with a neck 1.5 to 2cm. in width, and the same height. The solution is evaporated to dryness, perfectly dried, and weighed from the desiccator until a constant result is obtained. The weight of the dry residue is the weight of the glycerol, from which the weight of the ash is to be deducted, a weight which is obtained by igniting the residue obtained on drying as aforesaid.—S. Y.

Detection of Free Sulphuric Acid or Hydrochloric Acid in Vinegar. H. Hager. Pharm. Centralt. N.F. 7, 292.

THE author's method, which takes only two or three minutes, is based on Jorissen's reaction. Two drops of East Indian copaiba balsam, and 30 or 40 drops of pure acetic acid, are placed in a test glass and warmed. Two, or at most three, drops of the vinegar are added to the warm liquid, when, if either of the mineral acids are present, a blue-violet colour is produced. The colour is produced more rapidly with hydrochloric than with sulphuric acid. Its appearance is hastened by warming the mixture above 60°.—S. Y.

Two Reactions for Morphine. J. Donath. Journ. Prakt. Chem. 33, 563.

1. About 1mgm. of finely-divided morphine is mixed with 8 drops of concentrated sulphuric acid, and to this a small crystal of potassium arsenate is added and thoroughly broken up. When the mixture, which should be kept in motion, is heated until acid vapours begin to be evolved, a blue-violet colour is produced, which, by further heating, changes to brown-red. When diluted with water, the colour is at first red, but with more water becomes green. When shaken with this liquid, chloroform is coloured violet and ether violet-red, the aqueous solution being brown.

2. A drop of a solution of one part of potassium chlorate in 50 parts of concentrated sulphuric acid is added to the mixture of morphine and sulphuric acid, when a very permanent grass-green colour is produced. A faint rose-red colouration is observed at the edge of the liquid.—S. Y.

A New Air Thermometer for the Measurement of Small Variations of Temperature. G. Grassi. Rep. d. Phys. 22, 155.

A VERTICAL TUBE is sealed to, and passes to within a few millimetres of, the bottom of the small glass reservoir A. The vertical tube is bent at right angles, and connected by means of india-rubber tubing with the straight tube of small bore N, which is graduated in

millimetres, and is inclined at an angle given by the equation $\cos a = - \frac{N_0}{V_0} (p + p_1)$, where s is the area of a cross section of the tube N, V_0 is the volume of gas contained in A, and $p + p_1$ the original pressure. The change of volume of the gas in A is registered by the liquid M, which fills the vertical tube and part of

the inclined tube, and occupies a portion of the reservoir A. The original paper contains a discussion of the methods of construction of sensitive air thermometers.

—S. Y.

The Estimation of Nitrogen in Nitrates by Kjeldahl's Method. M. Jodlbauer. Chem. Centralb. **17**, 433.

THE author finds that when benzoic acid is employed in place of sugar, as recommended by Asboth, the results obtained are far too low. The author bases his method on an observation by Kjeldahl, that in his process the nitrogen in amines is readily converted into ammonia. The nitric acid is first converted into a nitrophenol, and subsequently reduced by zinc dust. For this purpose, 0.2 to 0.5 gm. of the nitrate is treated with 20 cc. of concentrated sulphuric acid and 2.5 cc. of phenolsulphonic acid (100 cc. contain 50 grms. phenol), and then with 2 to 3 grms. of zinc dust and a few drops of a solution of platinum chloride. The action is complete in about four hours; it is more rapid when phosphoric anhydride is mixed with the sulphuric acid, but the flasks are then strongly attacked.—S. Y.

Potassium Permanganate as a Reagent for Alkaloids. H. Beckurts. Pharm. Zeit. **31**, 358.

IT has recently been shown by E. Giesel that potassium permanganate produces a violet precipitate of cocaine permanganate when added to a concentrated solution of the hydrochloride of that alkaloid. The author has studied the action of a ten per cent. solution of this reagent on other alkaloids, employing in each case a cold saturated solution of the hydrochlorides. Reduction and precipitation of manganese dioxide occurred with quinine, cinchonidine, cinchonamine, cinchonine, brucine, veratrine, colchicine, coniine, nicotine, aconitine, physostigmine, codeine and thebaine. The hydrochlorides of hyoscyamine, pilocarpine, berberine, piperine, strychnine and atropine were coloured red, and the reduction of the permanganate occurred gradually. A white crystalline precipitate of oxydimorphine was produced in a solution of morphine. Apomorphine was coloured a dark green. Nareine, narcotine and papaverine behave like cocaine, giving cherry-red precipitates, which, however, are less stable than the cocaine compound, and are destroyed by excess of permanganate.—S. Y.

Titration of Phosphoric and Arsenic Acids. A. Joly. Compt Rend. 1886, **102**, 316.

TO the acid solution a few drops of phthalein are added and then the baryta solution of known strength until a gelatinous precipitate is formed. This is a tribarium salt, which changes to the crystalline dibarium compound on standing, or by agitating. By a further addition of baryta solution a fresh gelatinous precipitate is formed, which changes similarly. This process is complete when a drop of baryta solution gives an intense and permanent red colouration.—J. B. C.

Estimation of Arsenic in Ores. G. W. Lehmann and W. Mager. Chem. News, **53**, 302.

THE finely-powdered substance is mixed with about six times its weight of equal parts of Na_2CO_3 and KNO_3 , fused and extracted with hot water and filtered. The filtrate is then acidified with nitric acid and boiled to expel carbonic and nitrous acids. To the cool solution silver nitrate is added, and then ammonia to neutral reaction. The silver arsenate is filtered, washed out with cold water until no silver is found in the washings, and the silver determined by Vollard's method. 108 parts of silver correspond to 25 parts of arsenic. In the case of metallic copper containing about one-tenth per cent. of arsenic, the following modifications are introduced:—100 grms. copper are dissolved in nitric acid, diluted to 500 cc. with water, and 100 cc. (20 grms.) taken for each determination.

A piece of iron sulphate about the size of a pea, is dissolved in nitric acid, added to the copper solution, and then ammonia in excess; the solution is well stirred and the precipitate of oxide of iron filtered hot, washed out with hot water, dried, removed carefully from the filter, mixed with the fusing mixture, etc. In another series of experiments the authors added lead and antimony, but found that their presence did not interfere with the results.—J. B. C.

New Method of Separating and Estimating Cadmium and Copper. L. Backelandt. Bull. Acad. Belg. **10**, 756—759.

THE separation is based on the fact that in the presence of glycerol, and by means of potash, cadmium is precipitated as hydroxide, whilst copper remains in solution. For quantitative purposes the precipitate of cadmium is first washed with potash, containing glycerol, to free it from copper, and then with hot water to remove alkali. The copper is precipitated from the filtrate by boiling with glucose, ignited and weighed as cupric oxide. Analytical data speak for the utility of the method.

—D. A. L.

Witt's Filtering Apparatus. A. Bornträger. Ber. **19**, 1690.

IN referring to the filter recently described by Witt (this Journal, 1886, 391), the author states that he has employed a similar arrangement for several years in determining the insoluble residue and the potassium bitartrate in lees or tartar, according to the Warington-Grosjean method. The apparatus in question was originally devised by Casamajor (*Chem. News*, **32**, 45), and was subsequently modified by Grosjean (*J. Chem. Soc.* **35**, 341).—D. B.

Note on Vapour-density Determination. V. Meyer. Ber. **19**, 1861.

THE author states that in determining the vapour densities of substances boiling above 300° , it is necessary to employ, instead of the glass tubes with bulbs used as baths, jackets made of iron. As the bulbs of the glass baths so frequently break, after having been used for but a

short time, owing to the alternate heating and cooling to which the glass is subjected, an arrangement has been devised to obviate this defect. The heating agent, such as naphthalene, thymol, etc., is contained in a small cast-iron crucible, the rim of which is grooved in such a manner as to admit of the insertion of a glass tube, which is sealed in mercury. A glass protecting tube like this seldom cracks, and when it does it can easily be replaced by another. Reference to the drawing which accompanies the paper will render the appliance more intelligible.—D. B.

New Books.

THE METHODS OF GLASS-BLOWING. For the use of Physical and Chemical Students. By W. A. SHENSTONE, Lecturer on Chemistry in Clifton College. London: Rivington's, Waterloo Place. 1886.

SMALL 8vo volume, bound in cloth. Price 1s. 6d. Contains a Preface, Table of Contents, eighty three pages of subject matter, an Alphabetical Index, and forty-two woodcuts. Two pages of the eighty-three referred to form an Appendix, devoted to the subject of Glass-tubing. These two pages are illustrated with thirty cuts representing sections of glass-tubing of different sizes.

The little work is subdivided as follows:—GLASS-BLOWER'S APPARATUS: The Working-place; the Blow-pipe; the Bellows; Automatic blower; Blow-pipe flames. VARIETIES OF GLASS AND THEIR MANAGEMENT: Characters of good glass; Cleaning and preparing a tube; Presenting glass to the flame; Methods of working with lead and soft soda-glass respectively; Annealing. CUTTING AND BENDING GLASS. FORMING GLASS APPARATUS BEFORE THE BLOW-PIPE. MAKING AND GRINDING STOPPERS TO APPARATUS, ETC.: Cutting glass tubes; Bending glass tubes; Rounding and bordering the ends of tubes; Sealing; Choking or contracting the bore of a glass tube; Widening tubes; Piercing tubes; Welding, or uniting pieces of glass to each other; Blowing a bulb of glass; Making and grinding stoppers. MAKING THISTLE-FUNNELS, U-TUBES, ETC. COMBINING THE PARTS OF COMPLICATED APPARATUS. MERCURY AND OTHER AIR-TIGHT JOINTS. VACUUM-TAPS. SAFETY-TAPS. AIR-TRAPS. Electrodes; U-tubes; Spiral-tubes; Thistle-funnels; Closing-tubes containing chemicals; Modes of combining the parts of heavy apparatus; Mercury-joints; Modes of lubricating taps; Air-traps. GRADUATING AND CALIBRATING GLASS APPARATUS: To calibrate tubes, etc.; to divide a line into equal parts; to calibrate a burette; to calibrate tubes for measuring gases.

ANALYSIS TABLES FOR CHEMICAL STUDENTS. Adapted for the Advanced Stage of the Science and Art Departments' Examinations in Practical Inorganic Chemistry, and the Elementary and Advanced Stages of Practical Organic Chemistry. By R. L. TAYLOR, F.C.S., F.I.C., Teacher of Chemistry and Physics in the Central Higher Grade Board School, Manchester. London: Sampson Low, Marston, Searle & Rivington, Crown Buildings, 188, Fleet Street. 1886.

SMALL 8vo pamphlet-book, bound in limp cloth. Contains—Preface, Table of Contents, forty-four pages of subject matter, devoted to the systematic and tabular arrangement of the qualitative tests and methods of analytical separation of the more commonly occurring acids and bases. An Alphabetical Index at the end is usefully arranged to indicate at once, not the page merely, but the analytical table or group of tests.

THE GAS ENGINEER'S CHEMICAL MANUAL. By J. ALFRED WANKLYN. London: The Scientific Publishing Company, Limited, 22, Buckingham Street, Strand, W.C. 1886.

8vo VOLUME, strongly bound in cloth. Contains—Preface, Table of Contents, seventy-four pages of subject matter, and an Alphabetical Index. In the

text are interspersed four woodcuts. In the INTRODUCTORY CHAPTER the subjects treated of are—The extent of the Gas Manufacture in the United Kingdom, Sketch of the Operations carried on in Gas Works, Carbonisation—its Nature; Products from a ton of Newcastle Coals. CHAP. II. is devoted to COAL—its Nature, etc.; CHAP. III. to COAL-GAS; CHAP. IV., TAR; CHAP. V., AMMONIACAL OR GAS-LIQUOR; CHAP. VI., COKE; CHAP. VII., PURIFICATION OF GAS.

DIE CHEMIE DES STEINKOHLENTHEERS MIT BESONDERER BERÜCKSICHTIGUNG DER KÜNSTLICHEN ORGANISCHEN FARBSTOFFE. Von Dr. GUSTAV SCHULTZ. Zweite vollständig umgearbeitete Auflage. Erster Band. Die Rohmaterialien. Dritte Lieferung. Braunschweig, Druck und Verlag, von Friedrich Vieweg & Sohn. 1886. London: H. Grevel & Co., 33, King Street, Covent Garden.

IN the June number of this Journal, p. 393, the appearance of Parts I. and II. of this treatise was duly noticed. It was there stated that Part II., page 384, terminated with an account of Phenyl- α -naphthylamine. Part III. commences with an account of Phenyl- β -naphthylamine (CHAP. XII.), on page 385, and concludes, in CHAP. XVIII., page 608, with a special description of the Oxyquinolines. CHAP. XIII. is devoted to the Tertiary bases and substituted Ammonium compounds; CHAP. XIV. to the Pyridine bases with the Quinolines, Quinaldines, and Acridines; CHAP. XV., the Diazo compounds and Hydrazines; CHAP. XVI., the Azo compounds specially considered; CHAP. XVII., the Sulphonic derivatives and acids, their behaviour and modes of production; CHAP. XVIII., the Phenols, their modes of preparation and behaviour. This, of course, includes the Naphthols and their derivatives. Under the head of the Oxyquinolines, an account is given of the substance of the German patents devoted to the technological development of certain of them as febrifuges and anti-pyretics.

THE CHEMISTRY OF WHEAT, FLOUR, AND BREAD, AND THE TECHNOLOGY OF BREAD-MAKING. By WILLIAM JAGO, F.C.S., F.I.C., etc., Author of "A Confidential Report on Wheat and Flour Supply," "Inorganic Chemistry, Theoretical and Practical," etc. Brighton: William Jago, 138, Springfield Road. 1886.

VOLUME of large 8vo size, bound in cloth. Price 10s. 6d., post free to any address within Class A of the Postal Union. The book contains—Preface, Table of Contents, and 465 pages of text, with which ninety-one woodcuts are interspersed, and it concludes with a complete Alphabetical Index. Numerous valuable tables and tabulated results are also interspersed in the text. The subject matter is included in twenty-six chapters, which are devoted to the consideration of the following subjects:—The first and introductory one treats of the Principles of Chemistry and Physics; CHAP. II., Description of the Principal Chemical Elements and their Inorganic Compounds; III., Description of Organic Compounds; IV., The Microscope and Polarisation of Light; V., Constituents of Wheat and Flour—Mineral and Fatty Matters; VI., The Carbohydrates; VII., Transformation of the Carbohydrates; VIII., Albumenoids, or Proteids; IX., Fermentation (fermentation and fermentative changes are very fully treated in Chaps. IX. and XI.); X., Lactic and Putrefactive Fermentation; XI., Technical Researches on Fermentation; XII., Manufacture and Strength of Yeasts; XIII.,

Moulds and Fungoid Growths; XIV., Physical Structure of Wheat Grain; XV., Chemical Composition of Wheat; XVI., Chemical Composition of Flour and other Milling Products; XVII., Bread-making; XVIII., Modern Baking Machinery and Appliances; XIX., Analytical Apparatus; XX., Commercial Testing of Wheats and Flours; XXI., Determination of Mineral and Fatty Matters in Wheats and Flours; XXII., Acidimetry and Alkalimetry; XXIII., Soluble Extract, Acidity and Albumenoids; XXIV., Estimation of Carbohydrates; XXV., Bread Analysis; XXVI., Adulteration.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

- 10806 J. H. Lorimer, London. Improvements in drying machines. Complete specification. August 24
 10818 A. Harrison, Barrow-in-Furness. An improved radiating hood cover for soaking pits. August 25
 10880 T. D. Williams, London. Improvements in amalgamating apparatus. August 25
 10883 F. W. Browldow, Manchester. Improvements in or applicable to filters. August 26
 10990 S. S. Bromhead, London. From A. Legend, France. "The Gyropulsator" or fluid agitator. August 28
 11025 S. Hoyle, Acerington. Improvements in apparatus for preventing corrosion of, preventing incrustation in, or facilitating the removal of incrustation from steam and other boilers. August 30
 11063 T. Smith, Newcastle-on-Tyne. Improvements in apparatus for burning liquid fuel for steam boilers and other purposes. August 31
 11070 J. A. Walker. See Class II.
 11079 J. E. Slack, London. Improvements in the construction of the roofs of furnaces, and in bricks to be used therefor. August 31
 11169 J. Williamson, Glasgow. Improvements in filter-presses. September 2
 11214 A. W. Anderson, London. Improvements in filter-presses. September 1
 11304 C. Bird, Halifax. Improvements in filters for filtering water for manufacturing purposes. September 6
 11335 R. Romaine, Liverpool. Improved apparatus for condensing steam or other vapour by the cooling action of an induced current of air. September 6
 11339 J. Sturgeon, Birmingham. Improvements in shut-off valves for pipes or mains, more especially applicable for compressed air mains. September 6
 11383 J. L. Peslin, London. Improved smoke consuming furnace. Complete specification. September 7
 11116 R. Scott, Newcastle-on-Tyne. Improvements in and connected with furnaces. September 8
 11195 J. F. Schnell, Manchester. Improvements in motive power engines actuated by an explosive mixture of air and gas, or by an explosive mixture of air and the vapour of a hydrocarbon or hydrocarbons. September 9
 11579 M. Slade and E. J. T. Digby, London. Improvements in the manufacture of crucibles. September 11
 11589 D. K. Clark, London. Improvements in filter-presses. September 11
 11654 A. Baird and M. B. Baird, Glasgow. Improvements in air compressors and receivers. September 11
 11711 J. E. Brown, Brighton. Improved means of consuming smoke in steam boiler furnaces. Complete specification. September 15
 11731 W. H. Twine, A. M. D. Churchill, and H. J. Honnor, London. Improvements in cocks and valves especially adapted for steam, hot or cold water, or other fluids under high pressure. Complete specification. September 15
 11763 J. C. Brentnall, Manchester. Improvements in furnace bars. September 16
 11896 W. H. Ack, London. Improvements in refrigerating apparatus. Complete specification. September 18

COMPLETE SPECIFICATIONS ACCEPTED.*

1885.

- 10151 F. Elmore. Manufacture of metal pans, cylinders, boilers, containers, etc. September 3
 12612 E. J. Jones and T. Johnson. Taps and valves for drawing off liquids. August 21
 12773 A. F. Vuylsteke. Filter-presses. August 21
 13772 Furnace blast apparatus for economising fuel, consuming smoke, and increasing power of steam boilers. September 3

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

- 13071 W. Armitage, Sheffield. Apparatus for supplying air to furnaces above the fuel. September 11
 13301 R. J. Billington and R. M. Deeley, jun. Improvements in blast pipes. September 3
 13631 H. J. Allison. From R. P. Ambler and H. Dietz. Apparatus for burning liquid fuel. August 24
 13859 J. G. Robinson. Regenerative or recuperative furnace applicable to gas, iron, steel, glass or other furnace. September 11
 11081 C. S. Madan. Injectors for raising fluids and feeding steam boilers. September 11
 11412 F. Siemens. Method for lining furnaces. September 17

1886.

- 1352 R. Scott. Improvements in furnaces, whereby chimneys are dispensed with, the heating properties of fuel increased, and smoke consumed. September 21
 2854 G. Teidman. Filter taps. September 3
 9312 B. D. Healey. See Class XVII., B.
 5562 E. Bollig and G. O. Heyne. Apparatus for eliminating air, gases, and carbonate of magnesia from feed water purified by magnesia. September 3
 9838 E. C. Allam. Improvements in filters. August 31
 10169 G. A. Hagemann. Improvements in furnaces. September 10

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

- 10891 W. Finlayson, Glasgow—From R. Hargrave Martin, United States. Improvements in manufacturing or preparing asbestos for use as a non-conductor of heat and otherwise. August 26
 10969 A. Brin and L. Q. Brin, London. Improvements in means for heating steam boilers and the like, and for decomposing steam and burning its constituent gases for the production of light and heat generally. August 27
 10983 H. Montgomerie, Newcastle-on-Tyne. Collecting and using the waste heat from steam boilers. August 28
 11070 J. A. Walker, London. An improved means of obtaining greater heat and generating steam more rapidly in boilers. August 31
 11161 F. L. Rawson and W. S. Rawson, London. Improvements relating to the production of light by the incandescence of refractory materials. September 1
 11287 A. Paget, London. Improvements in the manufacture of what are known as mantels, used in what is called incandescent gas lighting. September 4
 11300 A. C. Thomson, Glasgow. Improvements in apparatus for washing or treating mineral oils with acids or alkalis. September 6
 11358 J. Orchard and H. Lane, London. Improvements in means and apparatus for producing and utilising light and heat arising from the combustion of gases. September 7
 11496 J. F. Schnell, Manchester. Improvements in and in apparatus for impregnating or charging air with the vapour of a hydrocarbon or hydrocarbons for actuating motive-power engines, and for certain other purposes. September 9
 11497 J. F. Schnell, Manchester. Improvements in and in apparatus for impregnating or charging air with the vapour of a hydrocarbon or hydrocarbons for illuminating, for actuating motive-power engines, and for heating and certain other purposes. September 9
 11538 J. Neil, Glasgow. Improvements in or connected with the burning of hydrocarbon or mineral oils and other such liquid fuel in steam boiler or other furnaces, and in apparatus therefor; also applicable for other heating and lighting purposes. September 10
 11632 E. Eich, H. Sepulchre, and J. Pasque, London. Improvements in the manufacture of compounds for use as fuel. September 13
 11651 R. Howson and W. P. Ingham, Middlesbrough-on-Tees. An improvement in gas producers. September 14
 11681 R. Pringle, London. A process of and apparatus for obtaining purified carbon from soot and other similar carbonaceous products of combustion. September 14
 11691 G. R. Cottrell, London. Method of and apparatus for carburetting and mixing gas and air. Complete specification. September 14
 11701 J. Murrie, Glasgow. An improved method of generating vapour and of liquefying vapour so or otherwise generated. September 15
 11767 J. Murrie, Glasgow. Improvements in generating and in accumulating and applying the energy of elastic vapour, and in the arrangement of apparatus therefor. September 16
 11829 P. M. Justice, London. From A. P. Rockwell, United States. Improvements in carburetting compounds. Complete specification. September 17
 11833 J. M. Turnbull, Glasgow. Improvements in the manufacture of gas from mineral oil, and in apparatus therefor and connected therewith. September 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11661 J. Foord and W. W. Paddon. Apparatus for carburetting air for production of light and heat. August 27
 11713 H. Howell. Apparatus for making illuminating gas from volatile hydrocarbons. August 31

12638 H. Harris. Purification of gas in its passage from the meter to the service pipes. September 3
12721 J. L. Balfour and J. Lane. Manufacture of illuminating gas and volatile liquid hydrocarbons. August 21
13061 J. A. Yeadon and R. Middleton. Apparatus for the manufacture of artificial fuel. September 10
13067 J. A. Yeadon and R. Middleton. Apparatus for the manufacture of artificial fuel. September 10
13096 A. Morton and J. Fyfe. Furnaces for distilling and refining mineral oils. August 31
13147 G. A. Sweetser, D. W. Bell, and W. Rohm. Manufacture of candles and apparatus therefor. September 7
13488 T. G. Marsh. Gas lighting and heating. September 7
11269 P. Tarbutt. Method of effecting combustion of liquid fuel. September 7

1886.

2498 G. Beard. Heating feed water, and utilising the waste heat of "low heating furnaces." September 16
6059 J. Holden. Use of liquid fuel as auxiliary to solid fuel in certain boilers. August 31
6617 E. Mansfield. Apparatus for manufacturing gas from oil. August 24
9116 J. Roberts. Process and apparatus for manufacturing heating and illuminating gas. August 21
9167 H. Süß. Magnesium lamps. August 21

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

APPLICATIONS.

10910 C. L. Remy and C. A. Erhart, London. An improved process for obtaining anthracene from substances containing anthracene. August 26
10957 A. Nikiforoff, London. Improvements in the manufacture or production of benzol, anthracene, naphthalene, and other products from naphtha and naphtha residues. August 27
11131 J. Jones, Edinburgh. Improvements in retorts for the destructive distillation of shale, coal and other bituminous substances. September 1
11301 A. C. Thomson, Glasgow. Improvements in distilling or obtaining oil from shale or other oil-yielding minerals, and in apparatus therefor. September 6
11345 J. A. Yeadon and R. Middleton, Leeds. Improvements in retorts or furnaces for the distillation of coal, shale and other materials. September 7
11581 T. Rouet, London. Improvements in the construction and arrangement of mechanical retorts for the destructive distillation or the revivification of animal, vegetable and mineral matters. September 11
11702 J. Jones, Edinburgh. Improvements in retorts for distilling shale, coal and other bituminous substances. September 15

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

11356 O. Imray, London. From H. M. Baker, United States. Manufacture of a resorcin blue. Complete specification. September 7
11822 W. R. Hodgkinson, London. From L. Limpach, Germany. Improved process or method for effecting the separation of isomeric xylinines from commercial xylinine in a pure state for the production of colouring matters. September 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

14962 H. H. Lake. From A. Leonhardt & Co. Manufacture of colouring matters. August 31
15206 P. Jensen. From The Actiengesellschaft für Anilinfabrikation. Production of mixed azo colours. September 14

1886.

9176 L. J. B. A. J. Bouillet. Manufacture of ultramarine, and apparatus therefor. August 24
9751 L. Schad. Production of a bluish-black colour. August 31

V.—TEXTILES, COTTON, WOOL, SILK, ETC.

APPLICATIONS.

10829 W. R. Lake, London. From C. Orlay, Italy. Improvements relating to means for rendering textile fabrics and other substances impermeable, or for protecting them from injury by moisture. August 24
11370 E. Tremblay and A. Dietus, London. Improvements in the process of washing wool, and apparatus therefor. September 7
11427 R. Punshon, London. An improved method for waterproofing cloth, paper, linen, cotton goods, and other suitable materials. September 8

11601 D. Hall, J. H. Kay, and T. Wagstaffe, Manchester. An improved oven for drying raw cotton and other substances, chiefly for testing purposes. September 13
11795 E. Donner and E. Corssel, London. Improvements in the treatment of cocoons of silk preparatory to unwinding the silk therefrom. Complete specification. September 16

COMPLETE SPECIFICATION ACCEPTED.

1885.

13391 E. H. Hargraves. Method and apparatus for treating cotton, etc., to produce therein greater softness or flexibility. September 10

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

10842 J. Gibson and F. M. Gibson, Glasgow. Improvements in bleaching fibrous materials. August 25
10933 E. Sutcliffe and G. E. Sutcliffe, Halifax. Improvements in the method of and apparatus for bleaching, dampening, and dyeing loose fibre, yarns, threads, or other fibrous materials. August 27
10998 B. J. B. Mills, London—From F. V. Serikoff and W. E. Smith, Russia. An improved process of and apparatus for bleaching cotton, linen, and other textures and materials. August 28
11161 W. E. Heys, Manchester—From H. Danzer, A. Simian, and De Marcien, France. A new or improved method of dyeing and finishing textile fabrics, simultaneously without immersion. September 2
11207 M. Hilton, Prestwich. Finishing cotton, linen, or union cloth grey, bleached, dyed, or printed. September 3
11302 H. Ledger, Leek. Improvements in bleaching fibrous materials, textile fabrics, also paper pulp of vegetable origin, and the recovery of useful products therefrom. September 6
11581 W. G. Young, London. An improved mordant for dyeing cotton and other fibrous substances. September 11
11730 H. J. Hadden, London—From A. Henry, France. Improvements in dyeing. September 15

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

13029 T. Salt. Apparatus for dyeing or treating woven fabrics. August 24
13214 W. H. Lake—From V. Gaillot. Improvements in dyeing silk, wool, etc. August 31
13790 T. Holliday. Production of azo-colours on cotton or other vegetable fibre. September 11
14031 H. H. Ainsworth and E. B. Mauby. Apparatus for scouring, washing, dyeing, etc. September 14
14637 J. C. Mewburn—From La Société Leblois, Piceni, et Cie. Bleaching cotton, and apparatus therefor. September 3

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

10798 H. J. P. Sprengel, London. An improvement in the production of sulphuric acid. Complete specification. August 24
10868 J. Lea and H. R. Hammond, London. Operating on zinc ore for producing chlorine, also zinc, and the utilisation of the said zinc for coating metals galvanically. August 25
10955 J. I. Watts and W. A. Richards, Liverpool. Improvements in the manufacture, purification, or separation of sodium bicarbonate. August 27
11152 B. J. B. Mills, London—From the Verein für Chemische Industrie, Germany. An improved process of producing muriatic acid. September 1
11461 H. Clay Ball, Liverpool. A new or improved manufacture of and process for making sodium, and apparatus employed therein. September 9
11472 G. E. Vaughan, London—From A. E. Schwirthe, France. Improvements in the manufacture of sulphate of soda, and in obtaining ammonia. September 9
11548 J. M. Collett, Gloucester. Improvements in the manufacture of sodium sulphates. September 10
11891 A. Brin and L. Q. Brin, London. Improvements in the manufacture of bleaching liquid. September 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

11219 F. G. Riley. Apparatus for generating carbonic acid gas. August 24

1886.

7395 P. M. Justice—From H. Y. Castner. Manufacture of sodium and potassium. August 24
10009 H. H. Lake—From R. de Montgela. Apparatus for the manufacture of chlorine gas. September 21

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

- 11233 H. Boulton, London. An improvement in the process of making the description of pottery known as Bristol stone-ware. September 3
- 11262 C. J. Allport, London. The manufacture of cullet for making glass and similar silicious products from granulate, and similar forms of granite and felspar. September 4
- 11629 C. J. Heaton, London. Improvements in the manufacture of ornamental cloisonné work, specially applicable to decorative building purposes, and to vases, jewellery, and other articles. Complete specification. September 13
- 11769 R. A. Gibson and W. J. Boorer, London. Improvements in gas-heated ovens and kilns for firing tiles, porcelain vases, bending and firing glass, painted and stained, and for other purposes. September 16
- 11870 R. Kelsall and W. Lee, Longport. Improvements in machinery for drying pottery ware. September 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 10378 G. J. Atkins. Furnace for firing stained or painted glass and enamels, etc. August 31
- 12814 J. Wilson. Preparing clay for potters' use. August 21
- 11462 J. M. Beurel. Manufacture of articles of glass, porcelain, earthenware, etc. August 31

1886.

- 8022 M. Schreiber. Annealing glass tubes, cylinders, hollow-ware, etc. September 3
- 10019 E. Walsh, jun. Manufacture of rolled plate glass. September 21

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

- 10788 A. Smith and J. Robertson, Glasgow. Improvements in making Portland cement, and in apparatus therefor. August 21
- 10829 C. J. Dobbs, London. An improved manufacture of scoria paving blocks. August 24
- 11023 F. Wicks, Glasgow. An improvement in paving, flooring, or building material. August 30
- 11079 J. E. Slack. See Class I.
- 11091 J. C. Anderson, London. Method of, and apparatus for, manufacturing bricks, tiles, etc. Complete specification. August 31
- 11108 P. P. de la Sala, London. Improvements in the treatment and application of wood to the covering of surfaces. August 31
- 11144 F. Dixon, London. Improvements in the preservation of wood with special regard to its application for sleepers and paving purposes. September 1
- 11208 H. Wilson. See Class XVII. A.
- 11303 E. Larsen, Liverpool. Improvements in the manufacture or preparation of furnace slag, and of cement partly made therefrom. September 6
- 11377 W. Bull, London. Improvements in and connected with the manufacture of tiles for roofing or other purposes. Complete specification. September 7
- 11613 H. Macevoy, H. Holt, and W. Wilders, Northfleet. Improvements in the manufacture and burning of Portland cement. September 13

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 12908 S. Pitt—From L. Pillivuyt. Lime cement, for production of cements, mortars, hydraulic concretes, and artificial stone. August 27
- 13132 R. Bennett and H. Peet. Composition for use in mural decorations. September 10
- 13595 A. G. Brookes—From R. A. Meyn and J. F. O. Arnack. Manufacture of artificial stones or marbles. September 10
- 13766 W. H. Lindsay. Fire-proof floors. September 14

1886.

- 9408 H. H. Leigh—From B. Dubois. Method of constructing ornamental masonry columns. September 10

X.—METALLURGY, Etc.

APPLICATIONS.

- 10789 C. While, Darlington. Improvements in hot banks for iron and steel works. August 21
- 10822 A. Brin, London. Improvements in the manufacture of iron and steel. August 24
- 10823 J. Y. Johnson, London—From La Compagnie Anonyme des Forges de Chatillon et Commeny, France. Improved means for tempering or hardening metal. August 21
- 10868 J. Lea and H. R. Hammond. See Class VII.

- 10936 C. G. Jordan, J. E. Jordan, and F. Herbert, Newport. Improvements in core bars. August 27
- 11082 W. Annable, Sheffield. Improvements in the manufacture of armour plates. August 31
- 11211 C. J. L. Leffler, Sheffield. A method of reducing aluminium ore or alumina into metal or into metallic alloys, when in combination with other ores or oxides of metals. September 3
- 11312 D. G. Fitzgerald. See Class XVIII.
- 11201 R. K. Boyle, London. Improvements in and apparatus or means for electroplating. September 4
- 11385 F. E. Hainley, London. An improved method of utilising the expansion and contraction of metals due to changes of temperature. Complete specification. Sept. 7
- 11412 R. L. Short, J. Short, and J. B. Short, West Hartlepool. A real safety lamp for the use of miners. September 8
- 11413 M. Settle, Manchester. Improvements in electric safety lamps for use in mines. September 8
- 11529 W. Banks, London. A new or improved miner's safety lamp. September 10
- 11551 J. Morley and W. Gaskill, London. An improved method of manufacturing homogeneous, seamless or endless steel, iron or other tubes, rings, etc., suitable for light or heavy ordnance, engine, propeller, and other shafts, hydraulic cylinders, pumps, columns, locomotive and other tyres, etc. September 11
- 11600 A. E. Tucker, Smethwick. Improvements in the linings of copper, lead and other similar furnaces, as well as steel or Siemens furnaces and steel converters. September 13
- 11617 C. Shaw, Sheffield. An improved method of and apparatus for running the castings in steel or other suitable metal, so as to render them free from air or pin-holes. September 13
- 11756 S. Gratrix, Manchester. An improvement in apparatus for the manufacture of lead and other metal pipes. September 16
- 11776 J. E. Baugh and C. Hinksman, London. Improvements in fuel-saving quiescent furnaces for economically generating chlorine and concentrating gold, silver, copper, and other metals from pyrites and ores generally, together with the process in connection therewith. September 16
- 11787 H. J. Coles, London. Improvements in rock drills. Complete specification. September 16
- 11816 A. Brin and L. Q. Brin, London. Improvements in the manufacture of metallic oxides. September 17
- 11817 J. S. McArthur, R. W. Forrest, W. Forrest, and G. Morton, Glasgow. Improvements in obtaining gold, silver, and other noble metals from ores or other compounds. September 17
- 11876 S. Thompson and R. Thompson, Newcastle-on-Tyne. Improvements in boring machines for coal, stone, and other materials. September 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 10024 R. Oxland and C. Oxland. Treatment of ores, etc., containing sulphur for extraction of metals, etc. August 21
- 12066 H. Baxter. Crucible cast-steel waggon cradles. September 7
- 12101 S. Hannah. Steel ships' and other steel plates. September 7
- 12795 T. Turner. Moulds for casting ingots of metal. August 21
- 13169 R. Hadfield. Manufacture of steel and other projectiles. September 10
- 13260 L. Kleeman. Furnace for smelting ores, etc., containing zinc. August 31
- 13275 W. Deighton. Furnaces, apparatus and appliances for melting and treating ores, metals, etc. August 31
- 13574 J. Guest. Rolling plates, sheets, strips, etc., of iron and steel. September 11
- 13763 W. H. Lindsay. Manufacture of corrugated plates of metal. September 11
- 13892 C. Cherry. Processes and apparatus for the treatment of ores. September 11
- 13982 W. F. Richards. Production of metallic zinc, and recovery of ammonia from the products resulting from the galvanisation of iron. September 17
- 11136 J. Lewthwaite. Producing malleable castings. Sept. 21
- 11113 F. Siemens. Regenerative gas furnace for continuous reduction of iron ore. September 17
- 11235 R. Gratzel. Production of aluminium and aluminium bronze. September 17
- 11411 R. Heathfield. Utilising waste products obtained in galvanising iron.
- 13357 S. Thomas. Finishing tin and terne plates. Sept. 7

1886.

- 3540 A. M. Clark—From La Société Scola et Ruggieri. Electric fuse for blasting purposes. September 17
- 4369 T. H. Johns. Process and machinery for cleaning tin and terne plates. September 3
- 9663 M. R. Moore. Machines for making sand moulds for casting metals. August 27
- 9806 C. A. von Weisbach. Obtaining compounds of the rarer metals from their carths.
- 9926 H. J. Allison—From J. Robertson and J. Hardie. Hydraulic lead presses for coating wire and cable with lead. September 3
- 10605 W. R. Lake—From R. de Montgelas. Extracting aluminium from chlorides of the same, and of aluminium and sodium. September 21
- 10606 W. R. Lake—From R. de Montgelas. Extracting aluminium from its chlorides. September 21

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

- 10833 N. Coste, London. Improvements in apparatus for expressing oil from oleaginous substances, and for similar purposes. August 24
- 10968 A. Brin and L. Q. Brin, London. Means for bleaching and disinfecting animal, vegetable, or mineral oils and fatty matters. August 27
- 11068 J. F. Johnstone, London. A new mode or means of extracting oil and water from waste fish blood. August 31
- 11069 A. H. Allen and B. Nickels, Sheffield. The treatment of spent soap leys, crude glycerine and other solutions containing glycerine, for the removal of impurities and the recovery of glycerine and other products therefrom. Aug. 31
- 11136 O. E. Pohl, Liverpool. An improved anti-heating lubricant. September 1
- 11138 T. Berliner, Berlin. Improvements in a method and apparatus for extracting the fat from bones, etc. Complete specification. September 1
- 11192 H. W. Langbeek, London. A process for the treatment of wool fat to produce unguent material therefrom. Sept. 2
- 11560 J. E. Quayle, Liverpool. An improved washing powder. September 11
- 11741 W. Graff, London. Improvements relating to the separation of fat and fatty acids from compounds containing the same. September 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11380 R. Ross. Manufacture of soap for toilet and cleansing purposes. September 21

1886.

- 9591 J. Thomson. An improved antiseptic soap. Sept. 7
- 10226 H. H. Lake—From N. J. Clute, P. B. Rose, and J. M. Aubery. Manufacture of soap. September 10

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

- 10960 M. Benedictus, London. Manufacture of material for the removal of old paint. August 27.
- 11493 A. McLean and R. Smith, London. Improvements in the preparation of colours for artistic purposes. September 9
- 11491 A. McLean and R. Smith, London. Improvements in the manufacture of pigments. September 9
- 11589 F. Maxwell Lyte, London. Improvements in the manufacture of pigments. September 18
- 13115 J. Haylor, H. S. Read, and H. G. Percival. Apparatus for the manufacture of white lead. August 31
- 13159 J. Pointon. Anti-fouling and anti-corrosive paints or compositions. August 31.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 10538 A. J. Ward. Compound for manufacture of pigments, applicable also in place of white lead. September 10
- 13396 E. Jackson. Composition or paint for coating ships' bottoms. September 3
- 13891 J. B. Freeman. An improved white pigment. Aug. 31
- 14128 J. B. Spence. Preparation of materials for making paint. September 17

1886.

- 9027 E. Schaal. Production of resin acid esters suitable for the manufacture of varnishes and lacquers. August 24

XIII.—TANNING, LEATHER, GLUE AND SIZE.

APPLICATIONS.

- 10987 J. Townsend, Glasgow. Improvements in treating hides or skins. August 28
- 11005 C. Wagner, jun., London. Improvements in machines for skiving or sharpening leather. August 28
- 11031 E. Edwards, London—From H. Hobuss, Germany. An improved process for treating the skins of oxen or cows to produce an imitation hog or pig skin, or leather. August 30

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

- 7145 A. H. Mangin. Product for depilating and preserving hides. September 11
- 7692 W. P. Thompson—From J. W. Fries. Tanning and currying hides and skins. August 24
- 8143 T. N. Ashman. Composition for treating leather. September 7.

XIV.—AGRICULTURE, MANURES, ETC.

APPLICATIONS.

- 11620 W. H. Nevill, London. Improvements in the treatment of excreta or pail-stuff, in order to render it available as manure. September 13

- 11841 A. Blackie, London. An improved method of applying arsenic and sulphur for destroying animal and vegetable parasites and preventing their attacks. September 17
- 11883 J. H. Barry, London. A treatment of excreta and sewage sludge for production of manure. Complete specification. September 18

XV.—SUGAR, GUMS, STARCHES, ETC.

APPLICATIONS.

- 10873 A. Rossi and C. Hellfrisch, London. A process for the manufacture of gum. August 25
- 10911 P. Laberie, London. Improvements in apparatus for evaporating the juice of beetroot, sugar-cane, and other juices or liquids. August 26
- 11048 F. Candy, London. Improvements in the manufacture of materials for use in purifying and decolorising liquids and solutions. August 30
- 11451 S. Vickess, Liverpool. Improvements in apparatus for making lump sugar. September 9
- 11557 E. M. Knight, Halifax. Improvements in the manufacture of liquid gum for mounting photographs, lithographic printing, commercial and domestic use. September 11
- 11861 T. C. A. Currie, London. Improvements relating to the moulding of sugar, and apparatus therefor. September 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 10936 H. J. Haddon—From L. E. Vial. Removal of gum from grass and plants. August 27
- 13792 A. Crum Ewing—From T. Shields. A combined eliminator and filter for treating sugar-cane juice and other liquids. September 11

1886.

- 9992 A. G. Wass. Utilisation of lime, etc., impregnated with saccharine matter. September 17

XVI.—BREWING, WINES, SPIRITS, ETC.

APPLICATIONS.

- 11522 J. E. Guild, London—From D. R. S. Galbraith, New Zealand. A new or improved potable malt liquor. September 10
- 11559 J. Crawford, Glasgow. Improvements in apparatus for raising or forcing beer and other liquids. September 11
- 11588 N. Harris, London—From J. Farinaux, France. An automatic apparatus for producing carbonic acid or other gas under constant pressure, specially applicable to raising beer and the manufacture of aerated liquids. September 11
- 11627 E. F. Daniel, London. Improvements in utilising the otherwise waste heat of hot water which has been used for cask washing in breweries, or for the like. September 13

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 9328 J. P. Jackson. Machines for charging liquids with carbonic acid under pressure. September 3
- 12136 E. R. Southby and W. T. Ramsden. Method of bottling and preserving beer, etc., and apparatus therefor. September 7
- 12294 T. Webb. Distilling spirits by heating wash before its entry into distilling apparatus. August 27
- 13006 H. J. H. King. Automatically regulating the temperature of malt and hop kilns, and indicating the same. September 17

1886.

- 9630 L. Béchaux. Distillation and rectification of alcoholic and other liquids. September 10

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

APPLICATIONS.

A.—CHEMISTRY OF FOODS.

- 10903 P. Jensen, London—From K. G. Dahl, Norway. Improvements in preserving milk, and in vessels or containers therefor. August 26
- 10938 H. J. Haddon, London—From S. Heumann and E. Heimann, Austria. Improvements in or connected with the preservation of meat. August 27
- 10995 H. P. Madsen, London. Improvements in the utilisation of blood from slaughterhouses in and for the preparation of food and drink for man and cattle, and other animals. Complete specification. August 28
- 11128 A. Drummond and J. McAdam, jun., Glasgow. Improved apparatus for heating and cooling milk, and for facilitating the separation of the cream therefrom. September 1

- 11208 H. Wilson, Stockton-on-Tees. Extraction of moisture from timber, grain, fibrous material, textile, and other fabrics; also for seasoning timber, and preserving articles of food, prints, etc., at low temperatures. September 3
- 11732 A. B. Lester and A. Meaby, London. A method of preparing malted wheat, oats, and other cereals (barley excepted), and of employing them in the manufacture of bread and other food, and a method of preparing a special ferment. Complete specification. September 15
- 11835 G. F. Redfern, London—From L. J. Eriksson and E. E. R. Nordling, Sweden. The manufacture of dry rennet, and process therefor. September 17

B.—SANITARY CHEMISTRY.

- 11165 J. B. Hannay, Glasgow—From R. W. E. MacIvor, New South Wales. Improvements in treating night soil, and in apparatus therefor. September 2
- 11366 W. P. Thompson, Liverpool—From V. D. Anderson, United States. Improvements in apparatus for drying oil and the like. Complete specification. September 7
- 11409 A. Forrest and W. Welsh, Manchester. Improvements in machines for drying and powdering blood, town sewage, or other material. Complete specification. September 8
- 11461 V. L. E. Miller, London. The extraction of the water, liquid or volatile elements from sewage, brine or other fluid or partially fluid substances, either chemical solutions or mechanical mixtures. September 9
- 11620 W. H. Nevill. See Class XIV.
- 11820 G. H. Leane, London. The application and use of carbon for the compression of sewage sludge. Complete specification. September 17
- 11870 C. H. Geison, London. Improvements in filtering and cleaning water, preferably waste water of factories and other industrial establishments. September 17

C.—DISINFECTANTS.

- 11011 J. W. Knights and W. D. Gall, London. Improved manufacture of disinfecting powder. August 28

COMPLETE SPECIFICATIONS ACCEPTED.

A.—CHEMISTRY OF FOODS.

1885.

- 12917 H. C. Johnson. Dehydrating and refrigerating air for transportation of meat, etc., and apparatus therefor. August 27

1886.

- 4062 J. G. Johnson—From C. Marchand. Treating rancid butter, etc., for purifying, flavouring, and mixing same, and apparatus therefor. September 10
- 10318 A. H. Reed—From R. Ellin. Production of evaporated milk. September 17

B.—SANITARY CHEMISTRY.

1885.

- 13750 J. W. Lester and the Native Guano Co. Preparation of agents to be used in treatment of sewage, etc., and treatment of such sewage, etc. September 7

1886.

- 9342 B. D. Healey. Improvements in refuse furnaces and apparatus therefor, partly applicable to other furnaces. September 14

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

- 10824 J. T. Armstrong, London. Improvements in the construction of electrical batteries, and in the method of and means, materials, and appliances for working the same. Complete specification. August 24
- 11001 W. H. Beck, London—From La Société Perreux-Lloyd et Bève, France. An improved galvanic battery. Aug. 28
- 11010 E. Andreoli, London. A new secondary battery. August 30
- 11101 T. J. Jones and W. H. Tasker, London. Improvements in secondary batteries. August 31
- 11159 F. C. Hills, London. Improvements in secondary batteries or electric accumulators. September 1
- 11239 H. Carter, London. An improved arrangement of electric battery, with means for regulating the submersion or withdrawal of the negative electrodes. September 3
- 11242 D. G. Fitzgerald, London. Improved means for effecting the electro-chemical generation of chlorine in metallurgical operations for the extraction of gold from its ores and for other purposes. September 4
- 11487 S. Farbaký and S. Schenek, London. Improvements in the manufacture of positive pole-plates for secondary batteries or accumulators. September 9
- 11634 J. C. Sargeant and R. E. George, London. Improvements in instruments for the measurement of electric currents. September 13
- 11653 R. H. Courtenay, London. Improvements in voltaic electric batteries. September 14

- 11823 P. Bailly, London. Improvements in primary and secondary batteries. Complete specification. September 17
- 11831 C. E. O'Keenan, London. An improved automatic primary battery. September 17
- 11910 D. Cook, Glasgow. An improved electric furnace. September 20
- 11917 D. Cook, Glasgow. Apparatus for measuring currents of electricity. September 20
- 11919 D. Cook. Apparatus for generating, integrating, and automatically regulating currents of electricity. Sept. 20
- 11920 D. Cook. Dynamometer for measuring the power absorbed by dynamo-electric machines or the work being done by electro-motors. September 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11876 T. V. Hughes and C. R. Chambers. Manufacture of carbon filaments. September 10
- 12724 J. E. Liardet. Galvanic or primary batteries. Aug. 21
- 13443 S. P. Thompson. Constant current dynamo-electric machines. September 11
- 13639 W. Maxwell. Manufacture of carbon filaments. September 21
- 11612 A. Dun and F. Hasslacker. Improved galvanic battery. September 10

1886.

- 1845 P. Bailly. Manufacture of active electrodes, and their application to primary and secondary batteries. Sept. 17
- 10644 A. Millar. Electrodes for secondary batteries. September 21

XIX.—PAPER, PASTEBOARD, ETC.

APPLICATION.

- 11293 W. B. Nation, London. Improvements in the treatment of vegetable fibres for paper-making and other useful purposes. September 4

COMPLETE SPECIFICATION ACCEPTED.

1886.

- 10267 J. B. Scammell. Paper for cigarettes. September 11

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11846 A. Brin and L. Q. Brin, London. Improvements in means for the manufacture or production of ozone. Sept. 17
- 11002 A. G. Brookes—From T. S. Nowell. Acid bases for beverages and tonics. September 17

XXI.—EXPLOSIVES, MATCHES, ETC.

APPLICATIONS.

- 11043 D. Lindo, London. Improved method of making wax and other matches to light pipes or cigars in the open air, and for other purposes. August 30
- 11140 R. H. Punshon, London. Explosive compounds. September 1
- 11197 T. Nordenfelt, London. Improvements in fuzes for projectiles. September 2
- 11276 D. Campbell and G. L. Schnitz, London. Improvements in submarine mines. September 4
- 11414 L. Sanderson, London. Improvements in torpedoes. September 8
- 11437 W. Holmstrom, London. Improvements in machinery for applying igniting material to match-sticks or splints. Complete specification. September 8

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 12778 O. Inray—From R. Bernstein. Manufacture of granular nitro-cellulose. September 17
- 12837 H. Inray—From H. Dulitz. Manufacture of an explosive compound. September 17
- 11052 O. Bowen. Manufacture of gunpowder. Sept. 17

XXII.—GENERAL ANALYTICAL CHEMISTRY.

COMPLETE SPECIFICATION ACCEPTED.

1885.

- 12074 J. G. Lorrain. The composition and decomposition of compound or complex bodies. September 21

THE JOURNAL

OF THE

Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 10.—VOL. V.

OCTOBER 29, 1886.

Non-Members 30s. per annum; Members
21s. per Set; Single Copies 2s. 6d.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S. . .	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S. . .	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.

COUNCIL FOR YEAR ENDING JULY, 1887.

President: David Howard.

Vice-Presidents:

Sir I. Lowthian Bell, Bart., F.R.S.	Sir H. E. Roscoe, M.P., F.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
Dr. Peter Griess, F.R.S.	E. C. C. Stanford.
Dr. Ferdinand Hurter.	J. C. Stevenson, M.P.
E. K. Muspratt.	John Williams.
Dr. W. H. Perkin, F.R.S.	Philip J. Worsley.

Ordinary Members of Council:

John Calderwood, F.R.S.E.	John Pattinson.
Eustace Carey.	S. A. Sadler.
R. Forbes Carpenter.	Sir Bernhard Samuelson, Bart., M.P.
Henry Doulton.	Sir Chas. Tennant, Bart.
Dr. John Evans, F.R.S.	Lewis T. Wright.
S. H. Johnson.	
Ivan Levinstein.	

With Sixteen Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

THE JOURNAL.

Publication Committee:

The President,

Sir F. A. Abel, F.R.S.	F. Hurter, Ph.D.
Joseph Bernays, M.I.C.E.	Ivan Levinstein.
H. Brunner.	Prof. R. Meldola, F.R.S.
W. Lant Carpenter.	Ludwig Mond.
Prof. Frank Clowes, D.Sc.	E. K. Muspratt.
George E. Davis.	C. O'Sullivan, F.R.S.
W. Y. Dent.	John Pattinson.
Prof. Dewar, F.R.S.	Dr. W. H. Perkin, F.R.S.
Prof. Chas. Graham, D.Sc.	Sir H. E. Roscoe, M.P., F.R.S.
Peter Griess, Ph.D., F.R.S.	John Spiller.
D. B. Hewitt, M.D.	A. Norman Tate.
J. J. Hummel.	Thomas Tyrer.
Prof. A. K. Huntington.	

Editor: Watson Smith, The Owens College, Manchester.

ASSISTED BY THE FOLLOWING STAFF OF

Abstractors:

G. H. Beckett.	C. F. Cross.
D. Bendix.	A. R. Davis.
E. E. Berry.	A. G. Green.
E. J. Bevan.	S. Hamburger, Ph.D.
W. Dalrymple Borland.	James Hulme.
T. L. Briggs.	Bertram Hunt.
E. G. Clayton.	C. C. Hutchinson.
Julius B. Cohen, Ph.D.	D. E. Jones.

Abstractors:

W. E. Kay.	A. Rée, Ph.D.
A. J. King, B.Sc.	F. W. Renaut.
D. A. Louis.	James Taylor, B.Sc.
F. Machenhauer.	Bertram Thomas.
Wm. Macnab, Junr.	Eustace Thomas.
W. G. McMillan.	V. H. Veley, M.A.
G. Harris Morris, Ph.D.	Alex. Watt.
J. M. H. Munro, B.Sc.	Sydney Young, D.Sc.
H. A. Rademacher.	

NOTICES.

The supply of copies of the Journal for January, 1882, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of that number, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the number will be reprinted.

The number of Subscriptions at the old rate which are being received from members for the year 1887, renders it necessary to call attention to the fact that, under the provisions of the Bye-Laws, as revised at the last General Meeting, the Annual Subscription to the Society will be in future 25s., instead of One Guinea as heretofore.

Arrangements are being made whereby those who have given Orders on their Bankers may exchange them for Orders at the new rate. Meanwhile, members wishing to make payments in advance are earnestly requested to note the alteration, and thus save much correspondence.

THE CHEMICAL INDUSTRIES AT THE MANCHESTER JUBILEE EXHIBITION OF 1887.

Manufacturers of chemicals, and all those in whose processes Chemistry plays a principal part, will be interested to know that in Section III. of this Exhibition it is intended that a system and method will be followed, both as to arrangement and style, such as has never been attempted before.

We understand that not only will the exhibits be arranged in suitable groups, classified according to their chemical nature, but that in these groups themselves a kind of natural order will be observed—a certain chemical consecutiveness—tending to enhance in a degree never before attained the instructiveness and usefulness of an examination and study, whether by the experienced manufacturer, or the student of Chemical Technology.

It will, we understand, be the aim and endeavour of the Committee of Section III. of the Jubilee Exhibition in Manchester so to classify and arrange, and so to illustrate by means of raw material, specimen of product, model and diagram, that the visitor may be mentally transported into the factory and works; and that without the danger of learning *too much*, in the shape of trade and manufacturing secrets, he may be enabled to grasp the general methods of procedure and the outlines of those processes with their

chemical reactions, which, starting with the raw materials, at length furnish the finished products and wares, ready for the market. For such a display considerable space will be required, and the Executive Committee, fully aware of the fact, has wisely allotted a large share of space for the purpose, probably a larger area than ever before devoted in an exhibition to exhibits relating to Chemical Industry.

The justification for such a large scale illustration of the modern attainments, as well as the progress, of Applied Chemistry in an exhibition like the one fast hastening to its completion in Manchester, is not far to seek, for we may with truth say that of all the great industrial branches, those in which Applied Chemistry plays a principal part have almost entirely risen and developed during the VICTORIAN ERA.

This, we consider, is justification sufficient for the special stress which it is proposed to lay upon the exhibits relating to the rise and development of the Chemical Industries in the Manchester Jubilee Exhibition of 1887.

Intending exhibitors in Section III. will be able to obtain particulars of the classification to be adopted, and the names of the gentlemen forming the Committee, from the Sectional Programme already issued with the last number of this Journal, and which, with the general programme, giving names of Executive Committee, Plan of Exhibition, Notices to Exhibitors, etc., may be obtained at the offices of the Exhibition, Albert Square, Manchester. We understand the time during which applications for space can be received, is now to be extended to December 1st.

CHANGES OF ADDRESS.

R. L. Barnes, 1/o The Savoy; Phoenix Chemical Works, Hackney Wick, E.
C. W. Duckworth, 1/o North View; Garner's Buildings, North Road, Clayton, Manchester.
J. A. Graham, 1/o St. Leonards; Sherborne Lodge, Werter Road, Putney, S.W.
Jno. Gray, 1/o Loanhead; Clippens Oilworks, by Johnstone, N.B.
Thos. Harris, 1/o Old Quay; The Union Acid Co., Runcorn.
E. Hore, 1/o Hampstead; 88, King Henry's Road, Chalk Farm, N.W.
M. Ikuta, 1/o Freiburg; Universitäts Laboratorium, Erlangen, Bavaria.
T. H. Leeds, 1/o Stoke Newington; "Wearside," Forest Gate, E.
W. Jesse Lovett, 1/o Alverthorpe Road; Jessamine Cottage, Thornes, near Wakefield.
W. Cossar Mackenzie, 1/o Linlithgow; 2, Grove Terrace, Edinburgh.
Dr. E. von Salis Mayenfeld, 1/o Clayton; Verein Chemischen Fabriken, Waldhof bei Mannheim, Germany.
Dr. Hugh R. Mill, 1/o Granton; 3 Glenorchy Terrace, Edinburgh.
L. Percival, 1/o Carlyle Road; 15, Reservoir Road, Edgbaston, Birmingham.
J. Pettigrew, 1/o Greenock; Varnish Manufactory, Carpenter's Road, Stratford, E.
J. M. Roberts, 1/o Manchester; 16, St. Paul's Street, Southport.
Thos. Royle, 1/o Silvertown; The Cedars, West Ham Park, E.
Jas. Russell, 1/o Carlisle; Coats Steel Works, Coatbridge, N.B.
T. Shimidzu, 1/o College of Engineering; c/o T. Hirano, H. Ginza Shichome, Tokyo, Japan.
D. A. Sutherland, 1/o Clippens; Burntisland Oil Co., Limited, Burntisland, N.B.
R. Tervet, 1/o Johnstone; Forth House, Fisherrow, Musselburgh, N.B.
Leonard T. Thorne, 1/o London; University College of Wales, Aberystwith.
A. Waché, 1/o Paris; Sucrerie de Crépy en Laonnois, Aisne, France.
J. C. Watson, 1/o Church; The Rhyddings, Oswaldtwistle, near Accrington.

CHANGES OF ADDRESS REQUIRED.

C. S. Gorman, 1/o Eglinton Chemical Works, Irvine, N.B.
James Wood, 1/o Foxhill Bank Printworks, Church, Accrington.

Deaths.

J. Spear Parker, 297, Western Bank, Sheffield, Oct. 8.
Wm. Southall, Sir Harry's Road, Edgbaston, Birmingham.

LIST OF MEMBERS ELECTED, 29th OCTOBER, 1886.

Arthur J. Banks, 229, Wavertree Road, Liverpool, chemist, butterine works.
Clayton Beadle, Beadonwell, Belvidere, Kent, papermaker.
Edw. M. Bruce, Omaha, Nebraska, U.S.A., chemist, Union Pacific R.R.
E. E. Burnett, 118, Huddleston Road, Tufnell Park, N., scientific chemist.
Hamilton Y. Castner, 218, West 20th Street, New York, U.S.A., and 23, Cecil Street, Strand, W.C., chemist.
Jno. H. J. Dagger, 3, West Bank Road, Edge Lane, Liverpool, analyst-assayer.
Orrin S. Doolittle, Altoona, Pa., U.S.A., chemist, Pennsylvania R.R.
W. Lawrence Gadd, 50, Richmond Grove, Manchester, chemist.
Geo. Haller, 86, Leadenhall Street, London, E.C., merchant.
W. H. H. Harland, 111, Hyde Park Street, Glasgow, sanitary engineer.
Arthur Hartley, Cannon Brewery, Brighton, brewer.
Wm. Jago, Science Schools, Brighton, analyst and consulting chemist.
Alf. J. Liversedge, c/o Watson, Laidlaw and Co., Kingston, Glasgow, engineer.
Wm. Mackinlay, Laboratory, Silicate Paint Works, Charlton, Kent, chemist.
Robt. Oxland, 32, Portland Square, Plymouth, public analyst.
Francis R. Palmer, Debdon Hall, Loughton, Essex, printing ink manufacturer.
W. Grant Paton, Greenbank Alkali Works Co. (Limited), St. Helens, manager.
Richard Smith, Metallurgical Laboratory, Royal School of Mines, South Kensington, S.W., metallurgist.
Arthur H. Tuer, 40, Rock Street, Bury, and 51, Arcade Chambers, St. Mary's Gate, Manchester, analyst.
J. Veitch-Wilson, Queen Street, Bradford, Manchester, oil manufacturer.
J. Millar Wilson, Box 42, Chester, Pa., U.S.A., chemist.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.	I. Messel.
H. E. Armstrong.	P. E. R. Newlands.
W. Lant Carpenter.	B. Redwood.
W. Crowder.	T. Royle.
C. Graham.	John Spiller.
S. Hall.	G. C. Trewby.
A. K. Huntington.	J. Williams.

Hon. Local Sec. and Treasurer: Thos. Tyrer, Garden Wharf, Church Road, Battersea, S.W.

SESSION 1886-87.

Prospective Arrangements.

Nov. 1.—Mr. Lewis T. Wright, C.E., "What shall we do with our Tar?"
Dec. 6.—Mr. E. H. Trachsel, "On Strontium Hydrate," Mr. T. Fairley, on "Various Forms of Filter Pumps and Water Jet Aspirators."
Jan. 3.—Mr. Watson Smith, "On the Explosive, 'Kinetite.'"
Feb. 8.—Mr. W. Jago, "On Fermentation in its relation to Bread Making."

Notices of Meetings and Papers will be found in the Scientific Journals.

Notices of papers and communications to be made to the Local Secretary.

Liverpool Section.

Chairman: Prof. J. Campbell Brown.

Vice-Chairman: Dr. F. Hurter.

Committee:

Ernest Bibby.	H. Brunner.
J. W. Kynaston.	J. C. Gamble.
E. K. Muspratt.	D. Herman.
Jas. Simpson.	F. Hurter.
J. Atleek.	A. Norman Tate.
E. G. Ballard.	A. Watt.

Local Sec. and Treasurer: W. P. Thompson, 6, Lord Street, Liverpool.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

The next Meeting will be held at the University College, Ashton Street, on Wednesday evening, Nov. 3, 1886, when an Address by the Chairman will be delivered, after which Dr. G. Schack-Sommer will read a paper on "Sugar Refining."

Obituary.

WILLIAM RIPLEY NICHOLS,

Late Professor of Chemistry in the Massachusetts Institute of Technology, Member of the Society of Chemical Industry.

WILLIAM RIPLEY NICHOLS was born in Boston, April 30, 1847, and died at Hamburg, July 14, 1886. He graduated at the age of 16 years from Roxbury Latin School, and then went upon a travelling expedition to Europe for about two years, a considerable portion of which time was spent in Greece and Germany. In the latter country Mr. Nichols acquired an almost complete mastery of the German language, and in the former such a proficiency that he was able to give instruction for a time in the modern Greek tongue.

Entering Harvard College on his return to the States, he remained there a few months, and then removed his connection to that institution, from which "he was not separated till death, either in love or service." He appears to have been a born linguist, and to have given instruction in the languages with which his study abroad had made him familiar, and with great effect. It is stated that from the time his entrance fee at college was paid he had never looked beyond his own services for funds, so that he began to draw a salary very early after his matriculation as a student. In 1869 and 1870 he was instructor; from 1870 to 1872 assistant professor; from 1872 onward to the time of his death he occupied the Professor's chair in the Massachusetts Institute of Technology.

From the time he entered the institution till the spring of 1882 his important printed catalogued reports and treatises number 40, besides a multitude of minor articles and reports—more than one important book or careful scientific report for every year he had lived. He became eminent in the subject of chemical analysis, on which he worked and wrote considerably, and on the special subject of water analysis he is said to have been a standard, if not the most eminent, authority in the United States, and his counsel and opinion on the subjects of health-topics and water supply were sought by the representatives of most of the large cities and towns of New England. His hope this year had been to be present at the meetings of the British Association. He appears to have erred in over-taxing his strength, and thus injuring and destroying a strong constitution. He had literally strung his bow, and kept it strung day and night. Early in 1882, Professor Nichols published a catalogue of the writings of the graduates, students, and faculty of the Massachusetts Institute of Technology. The preface closes with these words, characteristic of the earnest and self-denying, self-forgetful man:—"The work will be kept in such shape that in case of accident to the present compiler someone else can readily take it up and carry it on."

Journal and Patent* Literature.

I—GENERAL PLANT, APPARATUS, AND MACHINERY.

A Heat-regulator in connection with the Thermostat.
R. Muencke. Chem. Zeit. 10, 998.

THE heat-regulator is based on the same principle as L. Meyer's, but has the advantage of being less breakable and more simply handled. A steel tube, of 25cm. length

and 10mm. diameter, is provided at one end with a screw-cap *g*, and at the other with a thread and collar *c*. The cap closes the steel tube quicksilver-tight, the collar serving for adjusting the depth to which the regulator is put into the socket of the thermostat. 12cm. from the bottom are three small projections, which keep in its place a small cylindrical tube *f*, closed at the top. A glass tube *c*, with a branch *r*, is cemented into the steel tube, and the tube *b* conveying the gas to the apparatus is inserted into *c* by the india-rubber joint *d*. In order to use the regulator, the cap *g* is unscrewed, and after filling the glass tube *f* almost completely with quicksilver, the remaining space is filled with some drops of that liquid, with the vapour of which the regulator is intended to work. The tube *f* is then closed with the thumb, turned upside down, and immersed in a basin with mercury. The steel tube is put over the glass tube *f*, and the cap screwed up under mercury. By loosening the joint *d*, the tube *b* is removed, and so much mercury poured into the steel tube as will make it visible in the tube *c*. The tube *b* and joint *d* are replaced, and *b* moved down until it nearly touches the quicksilver. The regulator is now ready to be adjusted for the special purpose required. It is put in water and warmed to the degree

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Lack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.,	4d.
Above 8d., and not exceeding 1s. 6d.,	1d.
" 1s. 6d., "	2s. 4d.,
" 2s. 4d., "	2s. 4d.,
" 2s. 4d., "	2d.

of temperature which is not to be exceeded. The vapours in *f* force the mercury from *f* into *c*, closing up the opening of *b*. The latter must therefore be raised so that it is just closed by mercury at the highest temperature which is admissible. It is then put into the thermostat. Prof. Fraenkel testifies to the accuracy

out, that it prevents the possibility of the admission of air to the apparatus, and reduces the temperature of the gas before leaving the apparatus. The main features are the generating vessel *A*, provided at the top with the stuffing-box *B*, having a chamber, *b*, in it, the acid vessel *I*, and the cooling and washing arrange-

of the apparatus; the temperature never varies more than 0.1°C ., provided the barometric pressure remains constant.—S. II.

Improvements in and relating to Apparatus for Generating Carbonic-acid Gas. F. G. Riley, London. Eng. Pat. 11,219, Sept. 21, 1885. 8d.

THE advantages claimed for the apparatus are, that it can be made of enamelled iron, that it automatically controls the supply of acid and obviates the risk of its blowing

out, that it prevents the possibility of the admission of air to the apparatus, and reduces the temperature of the gas before leaving the apparatus. The main features are the generating vessel *A*, provided at the top with the stuffing-box *B*, having a chamber, *b*, in it, the acid vessel *I*, and the cooling and washing arrange-

ment *M* and *O*. The generator *A* is furnished with a mechanical agitator driven by friction gearing. The acid vessel *I* is connected to *A* by the pipe *J*; this has interposed in it the valve chamber *K*, which has a seating both on its upper and lower orifices for the floating valve *V*, which, when the vessel *I* is full of acid, covers the upper orifice, but allows the acid to pass into the main vessel *A* till sufficient gas is generated to close the valve and shut off the supply of acid. When the pressure of gas is reduced by the withdrawal of some gas, it opens and allows acid to pass. This operation continues till

the acid is exhausted, when the valve K floats with the last portion of the acid and covers the bottom orifice, thus preventing the entrance of air into the apparatus. The gas passes into the chamber *b*, and thence through the coil N, which is externally cooled, into the bottom of the purifier O, which may be made of glass, and is partially filled with water. The gas ascends and descends the double tube P, bubbles through the water, and is drawn off at R. If it be desired to work the apparatus continuously, a duplicate generator, A, is provided, and connecting it to the cooler and purifier at U, it enables the generating vessels to be alternately charged.—S. H.

Improvements in Filter-presses. A. F. Vuytsteke, Belgium. Eng. Pat. 12,773, Oct. 24, 1885. 8d.

THIS invention relates to sundry improvements in the details of filtering presses, such as the fastening of the filtering cloths, means for easy removal of the imprisoned air, a method of clearing the passages, and the quick opening and closing of the press, for detailed description of which the specification should be consulted.—B.

Improvements in Filters. E. C. Allam, London. Eng. Pat. 9838, July 30, 1886. 6d.

THE inventor claims the use of a mechanical separator, composed of asbestos and porous earthenware or stone, in combination with a chemical purifier consisting of carbon, oxide of manganese, magnetic oxide of iron and lime, and with one or more shelves for spreading out the

filtered water in contact with filtered air as aëerator, substantially as shown in the arrangement of a domestic filter, represented by the accompanying sketch.

1. Unfiltered water.
2. Layer of asbestos cloth.
3. Perforated shelf for supporting the cloth.
4. Partially filtered water.
5. Vessel of porous stone or earthenware, held in position upon a solid plate by means of a stopper provided with a passage-tube.

6. The chemical ingredients mentioned above secured in the vessel, either separate or mixed together.
7. A layer of asbestos.
8. A layer of asbestos cloth.
9. Space for filtered air.
10. Spreader for the filtered water.
11. Perforated plate or shelf.
12. Chamber for filtered and aërated water.
13. Passage for air, closed with a plug of filtering wool.

—B.

Improvements in Apparatus for Evaporating Sea-water, Nitrate, or other Solutions of Liquids. F. B. Doering, Liverpool. Eng. Pat. 10,657, Sept. 9, 1885. 8d.

THIS invention has reference to evaporating apparatus in which a solution contained in tubes is heated by the action of steam surrounding the tubes, part of the steam given off by the liquid on evaporation being used again for aiding the heating of the remaining liquid. This is accomplished by the application of an injector, which withdraws the steam from the top of the pan and returns it to the space around the tubes. The description of one modification of the apparatus will make the arrangement clear without a sketch.

An upright cylindrical evaporating pan is divided into three sections by two horizontal diaphragms, which act also as tube-plates to a number of small upright tubes connecting the upper with the lower space. The part shut off by the two tube-plates is supplied with steam which surrounds and heats the tubes, and forms a "steam drum." The liquid to be evaporated is put into the pan, and fills it beyond the height of the steam drum, leaving sufficient space above for evaporation. To the top of the pan is attached an ejector, which withdraws the vapour arising from the liquid and discharges it, together with the live steam from the boiler, into the steam drum. There are contrivances for separating the liberated air from the vapour or steam, for removing condensed water, for promoting circulation in the liquid, for collecting crystals or sediment, and for other contingencies or requirements.—B.

II.—FUEL, GAS, AND LIGHT.

On the manner in which Sulphur in Coal and Cokes is combined, and on the Production of Cokes poor in Sulphur. Dr. F. Muck. Stahl u. Eisen, 1886, 6, 468.

THE author contradicts the widespread assumption that the amount of sulphur contained in coal is chiefly due to pyrites, and points out that almost all classes of coal contain what he calls "organic" sulphur, the presence of which it will hardly be possible to prove directly. But it cannot be doubted in all those cases where the iron contained in a specimen of coal does not suffice to bind all the sulphur present for forming FeS_2 . There can hardly be a question of sulphur being lost by burning in the furnace, for during the chief period of "de-gasification" an actual combustion is not going on; also a diminution in the quantity of sulphur would necessitate a much larger waste in coke than it is possible to assume under normal conditions, or than actually takes place. Nor is a great loss in sulphur possible when the cokes are quenched, as the mass cools down rather quickly, and the water only penetrates to a small depth. Coals that are poorest in sulphur do not of necessity furnish cokes equally poor in sulphur. The iron compounds (carbonate, oxide, and silicate) contained in coals are reduced in the coke-oven to iron, just as in the blasting-furnace, and this iron binds the sulphur which is expelled simultaneously or later, forming ferrous sulphide probably. Lime and magnesia compounds have a similar effect as the iron compounds. Carbon bisulphide, which is undoubtedly, if only temporarily, formed in the coke-oven, is acted on by iron, and also by ignited oxides of the alkaline earths, with production of sulphides. The quantity of sulphur emitted from the pyrites, or the quantity of "organic" sulphur which escapes with the coking gases, or which remains with the cokes as sulphides, is consequently not so much

dependent upon the total amount of sulphur contained in the coal as upon the nature of the mineral ingredients. In order to get an idea of the amount of sulphur really contained in a specimen of coke, the only method is to convert a certain quantity of the particular coal into coke, by igniting in a platinum crucible, etc., and then examining the cokes obtained. To produce coke poor in sulphur, the coal should not only be selected with reference to the size of the grains, but also—though this is much more difficult—by having regard to the quality. One can never expect to obtain from coal poor in sulphur coke also containing a small percentage of sulphur, if the ash of the coal is found rich in lime and magnesia, and particularly so if large quantities of iron are present.—A. R.

Manufacture of an Illuminant Appliance for Gas and other Burners. C. A. von Welsbach, Vienna. Eng. Pat. 15,286, March 15, 1886. 6d.

THIS invention consists in the application of a cap or hood to gas or other burners, to increase their illuminating power. The cap is made of cotton or other suitable material, impregnated with the oxides of lanthanum and zirconium, or of these with yttria. Proportions recommended are 60 per cent. zirconia, 20 per cent. yttria, and 20 per cent. oxide of lanthanum. The fabric is strengthened and supported with fine platinum wire, and suspended in the flame. On igniting in the flame the fabric is quickly reduced to ash, the cotton being burnt away and the earthy matter still retaining the form of a cap or hood.—A. R. D.

Improvements in the Generation of Gas for Lighting and Heating Purposes, and the necessary Apparatus therefor. B. Andreol, Vienna. Eng. Pat. 9720, May 7, 1886. 8d.

THE generator is supplied with fuel from above, through a hopper shaped like an inverted cone. Round this hopper are channels, through which the generated gases pass, so that the fuel is already heated when it reaches the generator. It is recommended that two generators be worked together. To one an air blast only is supplied, while in the other steam takes the place of air. The two kinds of gas thus formed may be mixed or used separately. For further particulars the drawings accompanying the specification must be consulted.—A. R. D.

Improved Construction and Arrangement of Apparatus for conducting Gas-flame Heat to Hydrocarbon containing Vessels for Increasing the Brilliancy or Lighting Power of Coal Gas. H. E. A. Wallis, London. Eng. Pat. 10,778, June 10, 1886. 8d.

THIS invention consists in arranging a solid conductor so that one end of it absorbs the waste heat of a gas flame, while the other end communicates with a vessel containing a hydrocarbon (preferably solid), such as naphthalene. The heat-absorbing end of the conductor is conical or cup-shaped, and is placed above the flame. The heat thus absorbed is communicated by conduction to the hydrocarbon, which is thereby vapourised and rendered available for enriching the gas used.—A. R. D.

Improvements in Apparatus for Manufacturing Illuminating Gas from Volatile Liquid Hydrocarbons. H. Howell, Wrexham. Eng. Pat. 11,713, June 17, 1886. 11d.

THIS invention relates to improvements upon the apparatus described in Eng. Pat. 3863, of 1872. The illuminating gas is made by allowing liquid hydrocarbon to trickle down a series of towers, wherein it meets an ascending current of air. The towers are fitted with perforated zinc shelves, and the spaces between these are filled loosely with curled horsehair. The current of air is forced through the apparatus by any suitable mechanical means.—A. R. D.

Improvements in Apparatus for Carburetting Air to be employed in lieu of Coal Gas for obtaining Light and Heat. J. Foord and W. W. Paddon, London. Eng. Pat. 11,664, June 28, 1886. 8d.

THE current of air set in motion by a ventilating shaft is made to work a fly similar to a smoke jack. This puts in motion a horizontal axis, the ends of which project into two carburetting vessels, and are provided with agitators. A portion of the air current is intercepted at the entrance to the shaft, and led through these carburetting vessels. Here it is impregnated with the vapours of the contained hydrocarbon liquid, and converted into a gas available for lighting and heating purposes.

—A. R. D.

Improvements in the Manufacture of Illuminating Gas and Volatile Liquid Hydrocarbons. J. L. Balfour and J. Lane, Tamworth. Eng. Pat. 12,721, July 12, 1886. 6d.

THIS invention consists in adding from 5 to 10 per cent. of pitch (preferably the kind known as soft coal-tar pitch) to the coal used in the manufacture of illuminating gas. The distillation is conducted in other respects in the usual manner. The chief advantages claimed are an increased yield and illuminating power for the gas, with a greater richness in benzene, while the coke is denser and more free from sulphur.—A. R. D.

Invention for the Purification of Gas in its Passage direct from the Meter previously to entering the Service Pipes for Household Consumption. H. Harris, London. Eng. Pat. 12,638, July 19, 1886. 6d.

A BOX filled with granulated animal carbon, thoroughly cleansed with a solution of soda, is so placed that the gas leaving the meter must pass through it before it reaches the point of consumption. The advantages claimed are the checking and purifying of the gas, and a great saving in the quantity used to produce a given effect.—A. R. D.

Improvements in Apparatus for Manufacturing Gas from Oil. E. Mansfield, Manchester. Eng. Pat. 6647, July 21, 1886. 8d.

THIS invention relates to improvements in the apparatus known as "Mansfield's Oil Gas Apparatus." The annular space surrounding the retort is divided into two by a partition extending from the bottom to the top. The object of this is to keep the heated products of combustion longer in contact with the retort, as they now have to pass up on one side thereof, and downwards on the other. The feed pipe supplying the oil is passed through the "bonnet" of the retort itself, instead of through the casing, and reaches nearly to the bottom of the retort, so that the oil is already hot when it drops upon the heated metal.—A. R. D.

Method of obtaining Compounds of the Rarer Metals from their Earths, for use as Incandescence Bodies for Illuminating Purposes. Carl Auer von Welsbach, Vienna. Eng. Pat. 9806, July 29, 1886. 6d.

THIS patent has reference to Patents 15,286 of 1885, and 3592 of 1886, relating to the preparation of solutions for the production of "incandescence" bodies. The patent essentially is a process of the chemical treatment of cerite, orthite, and similar minerals containing cerium, didymium, lanthanum, and zirconium, with a view to their separation in a state of purity, not only from each other, but especially from iron, which is found to exert a most detrimental action on the "incandescence" of these bodies.—T.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

A New or Improved Substitute for Turpentine. S. Banner, Liverpool. Eng. Pat. 12,249, Oct. 14, 1885. 6d.

THIS product is essentially prepared by selecting, during the distillation of petroleum, coal oil, and other similar

heavy hydrocarbons, groups of fractions containing hydrocarbons of specific gravity, varying from 0.730 to 0.840. These fractions are suitably mixed or blended together.

—E. G. C.

Process for the Production of Resin-acid Esters (Ethers) applicable as Substitutes for the Resins or Gums usually employed in the Manufacture of Varnishes and Lacquers.* Dr. E. Schaal, Württemberg. Eng. Pat. 9027, July 10, 1886. 6d.

THE resin-acid esters (ethers) are prepared by first condensing the resin acids to esters by treatment with alcohols, phenols, and hydrocarbons, under heating, with or without pressure, and with or without the addition of substances that facilitate the reaction, and then separating the product by distillation into soft and hard resinous bodies. For the manufacture of varnishes or lacquers, the resin-acid esters are combined with volatile or fatty oils, hydrocarbons or alcohols.—E. G. C.

IV.—COLOURING MATTERS AND DYES.

Improvements in the Production of Colouring Matters. Wm. Clark, London. From the "Farbfabrik vorm. Bröner," of Frankfurt-on-the-Main, Germany. Eng. Pat. 10,377, Sept. 1, 1885. 4d.

THE colouring matters described are azo-compounds, obtained by diazotising paranitraniline, and combining the paranitrodiazobenzene chloride with the β -naphthylamine-sulphonic acids obtained by the action of ammonia upon the salts of the β -naphthol-sulphonic acids, according to the Patent 3724 of 1882. Thus, by acting with diazotised paranitraniline upon β -naphthylamine-mono-sulphonic acid (sodium salt) in an alkaline or acetic acid solution, a colour is formed which dyes like archil.

—R. M.

Improved Method of Treating Antimonial Ores or Compounds for the Production of Pigment. T. C. Huntington and Marco Chiapponi, Italy. Eng. Pat. 12,723, Oct. 23, 1885. 6d.

THE finely-divided ores or compounds are treated with an aqueous solution of barium sulphide, heat being applied if desired. The solution is run off into a second receptacle, for treatment with a current of air and carbonic acid. This combined current first precipitates the barium in the form of carbonate, and afterwards the whole of the antimony as "hyposulphite." The former precipitate is separated by decantation or otherwise, and the latter, after filtering and drying, is ready for use as a pigment.—E. G. C.

Improvements in the Manufacture of Colouring Matters. H. H. Lake, London. From Messrs. Wirth & Co., of Frankfurt-on-the-Main, agents for Messrs. A. Leonhardt & Co., of Muhlheim a/Esse, Germany. Eng. Pat. 14,962, Dec. 5, 1885. 4d.

THE colouring matters described in this specification are nitro-chrysoïdines obtained by the action of diazotised nitranilines, and their homologues, upon metaphenylene diamine and its homologues. The compound produced from metanitraniline is said to dye wool, cotton, and silk, of a similar shade to chrysaniline. Paranitraniline gives a browner yellow, and orthonitraniline a brown-red. Sulphonic acids are obtained by using the sulphonic acids of the nitranilines, and carboxylic acids by combining nitroamidobenzoic acids with the diamines. The inventors call these colours "azophosphines."—J. M.

* The word "ester" is a convenient term adopted in Germany to signify that class of ethers which is formed by replacing hydrogen in the hydroxyl of mineral and other acids by alcohol radicles.

Improvements in the Manufacture and Application of Blue Colouring Matters for Laundry Purposes. R. Barringer, J. H. Wallis, and W. Barringer, Mansfield. Eng. Pat. 5938, May 1, 1886. 6d.

ANY suitable blue colour or dye is combined with a readily soluble adhesive material, and applied to a convenient absorbent fabric—such as paper, for instance. The material so prepared is put up in rolls, or cut into leaves or sheets, of any required size or shape. These are made up in envelopes, books, or other convenient form, for the market.—E. G. C.

Improvements in the Manufacture of Ultramarine, and in Furnaces and Apparatus to be used therein. L. J. B. Bouillet, London. Eng. Pat. 9176, July 14, 1886. 8d.

THE colour-producing materials are formed into brick-like packets or masses of uniform dimensions, contained in envelopes of paper highly charged with mineral matter, and arranged in mufles within a furnace having a floor of fire tiles laid over flues, passing transversely beneath the mufles. The mufles are provided with hollow sides, within which the heat can circulate, and with arched roofs abutting upon them. The ceiling of the furnace consists of fire tiles, supported upon bars of iron, easily removable to give access to the mufles.

—E. G. C.

Process for the Production of a Bluish-black Colour. Ludwig Schäd, Berlin. Eng. Pat. 9754, July 28, 1886. 4d.

THIS colouring matter is a secondary azo-compound produced by the action of diazo-azobenzene-disulphonic acid upon paratolyl- β -naphthylamine. The latter substance is dissolved in alcohol and hydrochloric acid, and then the diazo-azobenzene-disulphonic acid added. The free acid of the colouring matter separates out on the addition of salt, and is purified by solution in alkali, filtration and salting out.—R. M.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Improved Process for Removal of Gum from Grass and Plants. H. J. Haddan, London. From Louis Emile Vial, Marseilles. Eng. Pat. 10,936, Sept. 15, 1886. 6d.

THIS invention consists in the steeping of raw flax, China grass, and other textile vegetable matter, first in a bath of olein or other fatty acid "in a fluid or saponaceous state," until impregnated. The textile matter is next steeped in a bath of carbonate or caustic alkali solution, kept at a nearly boiling temperature, by which the pectose is transformed into alkaline pectate. The fibre is then steeped in a bath of pure water, or water slightly acidified, after which it only requires washing. Directions are given for the recovery of the fatty acids and pectic acid.—B. H.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

On Iron- and Chromium-Alizarates. L. Liechti and W. Suida. Mittheilungen des Tech.-Gew. Museums. 3 [1], March, 1886, 1—17.

A.—COMPOUNDS OF IRON AND ALIZARIN.

I. Ferrous Alizarate.

THIS substance is produced by the double decomposition of FeSO_4 and ammonium alizarate solutions, as a black violet precipitate. On washing with water, it is partially dissolved, and becomes more oxidised. It is noteworthy that even after long-continued exposure (four weeks) in the moist condition, the oxidation of the ferrous oxide in this compound ceases with the formation of the ferroso-ferric oxide, $(\text{Fe}_2\text{O}_3)(\text{FeO})$, so that the fully-oxidised compound corresponds to the normal alizarin-red previously described (see Journal, vol. iv. p. 587), in which ferric oxide is replaced by Al_2O_3 , and ferrous oxide by CaO .

Freshly-prepared moist ferro-alizarate dissolves readily in ammonia, and the solution mixes with Turkey-red oil without change. The alizarin prevents, therefore, the precipitation of ferrous hydrate by the ammonia.

The ferro-ferric alizarate forms, on drying, a black violet powder, possessing a bronze lustre.

II. Ferric-alizarate.

If solutions of ferric chloride and ammonium alizarate are mixed together according to the equation $\text{Fe}_2\text{Cl}_6 + 3\text{C}_{14}\text{H}_6\text{O}_4(\text{NH}_4)_2 = \text{Fe}_2(\text{C}_{14}\text{H}_6\text{O}_4)_3 + 6\text{NH}_4\text{Cl}$, a brownish-black precipitate of ferric-alizarate is thrown down; it is somewhat soluble in distilled water, and very soluble in ammonia, giving a violet-coloured solution, which mixes with Turkey-red oil without alteration. If the precipitate is well washed, dried, and extracted with ether, a moderately large amount of alizarin dissolves out, and the residue, on re-drying, forms a black powder which, on analysis, gives the formula $\text{Fe}_2\text{O}_3(\text{C}_{14}\text{H}_6\text{O}_4)_{2.25}$.

III. Action of Calcium Acetate on Ferric-alizarate.

Solutions of ferric chloride, containing definite proportions of calcium acetate, are poured into ammonium alizarate solutions, when a fine violet-black precipitate is produced, which is well washed with water, extracted with ether, and dried.

If the materials are employed in the following ratio, $\text{Fe}_2\text{Cl}_6 : 6\text{NH}_3 : 3\text{C}_{14}\text{H}_6\text{O}_4 : \text{Ca}(\text{C}_2\text{H}_3\text{O}_2)_2$, the precipitate is only partially soluble in ammonia, and the filtrate from it contains no lime. If larger proportions of calcium acetate are used (2 and 3 mols.) the same precipitate is produced, and the excess of lime is found in the filtrate. An analysis of the various precipitates showed their composition to correspond to the formula $(\text{Fe}_2\text{O}_3)\text{CaO}(\text{C}_{14}\text{H}_6\text{O}_4)_3\text{H}_2\text{O}$. It appears, therefore, that when excess of calcium acetate is used, the compound formed is always analogous in composition to that of normal alizarin-red.

IV. Action of Ferric Hydrate on Alizarin and Calcium Acetate.

Freshly-precipitated and washed ferrous and ferric hydrate may be partially dyed by alizarin, but only slowly. The dyeing, however, proceeds rapidly and most thoroughly as soon as calcium acetate is added to the mixture.

If pure ferric hydrate, freshly prepared and well washed, is stirred up with a quantity of alizarin paste and water, in proportions corresponding to the formula $(\text{Fe}_2\text{O}_3)3\text{C}_{14}\text{H}_6\text{O}_4$, and the mixture gradually heated to 100° , and then boiled 5 hours, the water lost by evaporation being replaced, a precipitate is produced which is soluble to some extent in distilled water, giving a violet solution. If this is washed, dried, and then extracted with ether, the ether dissolves out a large quantity of alizarin. The residue, redried and analysed, has the formula $(\text{Fe}_2\text{O}_3)_3(\text{C}_{14}\text{H}_6\text{O}_4)_2$. It is more than probable that by the long-continued boiling, a part of the ferric hydrate loses some of its hydroxyl groups as water, thus forming only a very basic compound, which may also be regarded as a mixture of a less basic compound with ferric oxide.

If another portion of ferric hydrate is mixed with alizarin and calcium acetate in the following ratio, $\text{Fe}_2\text{O}_3 : \text{CaO} : 3(\text{C}_{14}\text{H}_6\text{O}_4)$, and boiled for 5 hours in a similar manner, a deep violet coloured precipitate is produced, which may be purified by water and ether as before, the latter dissolving out some alizarin. The aqueous filtrate from this precipitate contains no trace of lime, and shows a distinct acid reaction. This lake gives, on analysis, figures corresponding to the formula $(\text{Fe}_2\text{O}_3)\text{CaO}(\text{C}_{14}\text{H}_6\text{O}_4)_2\cdot 8$, from which it is evident that the ratio of ferric oxide to lime is again that of the normal alizarin colour.

If a third experiment be made, using the materials in the ratio of $\text{Fe}_2\text{O}_3 : 2\text{CaO} : 3(\text{C}_{14}\text{H}_6\text{O}_4)$, a black violet lake is produced, the filtrate from which contains much lime. This lake, when purified and analysed, gives results corresponding to the formula $(\text{Fe}_2\text{O}_3)\text{CaO}(\text{C}_{14}\text{H}_6\text{O}_4)\text{H}_2\text{O}$.

This substance, therefore, appears to be the normal alizarin violet, of which the normal proportions are $(\text{Fe}_2\text{O}_3) : (\text{RO})$.

V. Dye Trials.

These trials were carried out to determine the behaviour of ferric hydrate towards alizarin and lime in the presence of the cotton fibre.

1. Cotton cloth was mordanted with a mixture of ferrous sulphate and sodium acetate solutions corresponding to the ratio $(\text{FeSO}_4 + 7\text{H}_2\text{O}) : (\text{NaC}_2\text{H}_3\text{O}_2 + 3\text{H}_2\text{O})$, otherwise expressed thus: $[\text{FeSO}_4 + \text{Fe}(\text{C}_2\text{H}_3\text{O}_2)_2]$.

The cloth was then aged two days, afterwards fixed in a bath of cold dilute ammonia, and finally thoroughly washed in distilled water. The iron oxide in the cloth was then estimated, and four pieces of the cloth were dyed with increasing amounts of calcium acetate, and sufficient alizarin to form the ferric-alizarate. The dyed fents were then boiled out with distilled water, and analysed to determine the ratio of the oxide of iron to the lime. It is as well to mention that the mordanted cloth, when dyed without calcium acetate, produces only a weak brownish violet colour, whilst when this salt was present in the dye-bath, a fine violet colour was given.

The analysis shows that each molecule of iron oxide on the fibre requires one molecule of lime, and that even if excess of calcium acetate is present, only the amount corresponding to this one molecule is taken up.

2. A piece of calico was padded with a colour composed of ferrous acetate, acetic acid, alizarin, starch, and increasing amounts of calcium acetate, then dried, aged, steamed, and finally boiled out in distilled water. The proportion of the substances used were: 1 mol. of iron oxide, 3 mols. of alizarin, and 0, 1, 2, and 3 mols. of calcium acetate. Again the colour without the lime-salt was poor and weak, and contained only a trace of lime, whilst those produced with the addition of calcium acetate were of a rich brownish-violet tone.

To find what effect the operation of soaping has on the ratio of iron oxide to lime, a portion of the dyed and boiled cloth was boiled for 1½ hours in an open vessel with soap solution, then well washed and finally boiled in distilled water. The samples, both soaped and unsoaped, were then analysed.

The results fully confirm those deduced from previous trials relative to the amount of lime taken up by the lake. They show, further, that in soaping, both ferric oxide and lime are removed, but always in the same relative proportions.

To sum up, these experiments with alizarin violet, with the exception of the greater insolubility of the ferric alizarate in water, and the greater resistance of the violet to soaping, all tend to confirm in a clearer manner the facts obtained in the study of alizarin-red; further the acceptance of the formula $(\text{Al}_2\text{O}_3)(\text{CaO})(\text{C}_{14}\text{H}_6\text{O}_4)_3\text{H}_2\text{O}$, for that compound, is fully justified by the formula $(\text{Fe}_2\text{O}_3)(\text{CaO})(\text{C}_{14}\text{H}_6\text{O}_4)_3\text{H}_2\text{O}$, here obtained for alizarin violet.

B.—CHROMIUM ALIZARIN COMPOUNDS.*

1. Normal Chromium Alizarate.

If a solution of chrome alum is mixed with a sodium or ammonium alizarate in the proportion necessary to form normal chromium alizarate, a precipitate is thrown down, consisting of a mixture of chromium hydrate and alizarin. This is almost completely soluble in excess of soda (especially on warming), forming a brownish-red solution; and if this is exactly neutralised with dilute H_2SO_4 , the solution becomes of a purple-red colour, but no precipitate is formed. This solution is treated with a quantity of common salt, when a purple-red precipitate is thrown down, which is separated, dried, and then treated with absolute alcohol. On evaporating the alcohol, a greenish bronze mass remains, which, on analysis, corresponds to the formula of an acid chromium alizarate, $\text{Cr}_2(\text{C}_{14}\text{H}_6\text{O}_4)_3 + 3(\text{C}_{14}\text{H}_6\text{O}_4)$. This substance

* Although incomplete, the experiments with chromium alizarin compounds are sufficiently interesting to warrant their publication.

dissolves readily in water, even when dried, and also in ammonia, and the ammoniacal solution mixes with Turkey-red oil without decomposition.

If a solution of alizarin in sodium oleate (in equivalent quantities) is treated with chrome alum solutions, there separates out a mixture of alizarin, and probably chromium oleate, which remains unaltered even on boiling. The solution described by Liechti and Schwitzer as containing $\text{Cr}_2(\text{C}_2\text{H}_3\text{O}_2)_6 + 3\text{Na}_2\text{CO}_3$, when boiled with alizarin, gives a brownish-red precipitate, whilst with the so-called one-third sulphate (from chrome alum and soda) reaction only takes place when sodium acetate is added.

A mixture of alizarin and calcium acetate, or calcium alizarate by itself, dyes chromium hydrate with difficulty, even after long boiling; on the addition of sodium acetate, however, action at once commences.

Basic chromium alizarate cannot be obtained from chrome alum, alizarin and carbonate of soda mixed in the proportions expressed by the formula $(\text{Cr}_2[\text{SO}_4] + \text{K}_2\text{SO}_4 + 24\text{H}_2\text{O}) + 1.5\text{C}_{14}\text{H}_9\text{O}_4 + 3\text{Na}_2\text{CO}_3$, since the alizarin at once separates out, and in this case even the addition of calcium acetate is ineffectual.

Normal chromium alizarate can be prepared by treating a calculated amount of chromium-nitro acetate with a proportional amount of alizarin and an excess of ammonia, and then boiling the resulting reddish-violet solution till it is quite neutral. A purple-violet precipitate separates out, whilst the supernatant liquid becomes colourless. The precipitate is filtered off, washed with water, extracted with ether, and dried, and on analysis gives the formula $\text{Cr}_2(\text{C}_{14}\text{H}_9\text{O}_4)_3$.

This normal chromium alizarate is insoluble in water, but readily soluble in ammonia, giving a violet-red solution, which mixes without change with Turkey-red oil.

II. Chromium Calcium Alizarate.

This compound can be made in the same way as the normal chromium alizarate. A solution of chromium-nitro-acetate and calcium acetate is mixed with a solution of ammonium alizarate in excess of ammonia, when a blackish-violet precipitate of calcium alizarate is thrown down. The whole is then boiled till the excess of ammonia is driven off, when the precipitate becomes reddish-brown in colour, and the liquid colourless. If the ratio of the components is 1mol. chromium oxide, 1mol. CaO , and 3mols. alizarin, the filtrate, after boiling with ammonia, contains only a trace of lime. If a larger proportion of CaO , however, is used, this filtrate contains CaO in considerable quantity, but the precipitate remains of constant composition, corresponding to the formula $(\text{Cr}_2\text{O}_3)(\text{CaO})(\text{C}_{14}\text{H}_9\text{O}_4)_3$. It is insoluble in water, and soluble in ammonia, on boiling, with difficulty. The more lime there is used in the preparation, the more the precipitate assumes a black-violet colour.

III. Dye Trials.

These trials with chromium mordants correspond to those already mentioned with iron mordants. Cotton cloth was mordanted in a solution of chromium acetate, dried, fixed in a boiling soda solution, and finally well washed in distilled water. The amount of chromium oxide thus fixed on the cloth was then estimated by calcination. Four pieces of the mordanted cloth were then dyed with alizarin alone, and also with the addition of 1, 2, and 3mols. calcium acetate (reckoned according to the amount of chromium oxide found on the cloth). After dyeing, the fents were again boiled out repeatedly with distilled water, dried, and finally analysed, in order to determine the ratio of chromium oxide to lime. Without lime, only a poor, weak chocolate colour is obtained, while in those pieces dyed with 3mols. of alizarin and 1, 2, and 3 mols. of calcium acetate, it becomes darker with the increasing amounts of lime.

The analyses of the fents show that the normal ratio of lime is only attained in the third case.

Cotton cloth was also padded with a series of colours composed of chromium acetate, alizarin paste, and starch, with and without the addition of calcium acetate. The proportions being equivalent to 1mol. Cr_2O_3 , 3mols.

of alizarin, and 0, 0.5, 1, and 2mols. CaO . The cloth was afterwards dried, steamed, and finally boiled with distilled water. Part of each fent was then analysed, and the remainder soaped 1½ hours at the boil in an open vessel, washed thoroughly, and also analysed. Again the colour without lime was weak and worthless, and it became considerably paler on soaping, whilst where lime was present, a dark chocolate colour was produced (the colours being considerably stronger where 1 and 2mols. CaO were present than the others).

The above results show that like the aluminium and iron compounds of alizarin already mentioned (see this Journal, vol. ii. p. 537), the chromium compounds also tend to contain chromium oxide and lime in the ratio $\text{Cr}_2\text{O}_3 : \text{CaO}$, which ratio, however, is more altered during the operation of soaping than is the case with the iron compounds.

SUPPLEMENTARY NOTES ON CALCIUM AND ALUMINIUM ALIZARATES.*

I. Action of Calcium Hydrate on Normal Calcium Alizarate.

If normal calcium alizarate is mixed with perfectly clear lime-water in a closed vessel, and allowed to stand for some time, a portion of the calcium alizarate dissolves, forming a ruby-red solution. If this solution is then boiled for only a short time, a brownish-red precipitate separates out, whilst the supernatant liquid becomes quite colourless, and contains much free lime. This precipitate is soluble on continued washing with water, forming a violet solution. On analysis, it proves to be a basic calcium alizarate, having the formula $(\text{CaO}.\text{C}_{14}\text{H}_9\text{O}_4 + \text{CaO})$.

This is the compound originally dissolved in the lime-water, the behaviour of which solution, on warming, points to the existence of a much more basic calcium alizarate in the cold solution. Experiment shows, indeed, that about 5mols. CaO can hold in solution 1mol. of the basic calcium alizarate.

II. Aluminium Calcium Alizarate,

—This compound is readily produced as a fine dark-red precipitate by the action of calcium acetate and aluminium acetate on ammonium alizarate.

This lake is soluble on continued washing with water, and is also partially soluble in ammonia. The ammoniacal solution, when filtered and evaporated to dryness, leaves a residue which, according to analysis, possesses the formula $(\text{Al}_2\text{O}_3)(\text{C}_{14}\text{H}_9\text{O}_4)_4$, while the portion insoluble in ammonia is found to have the formula $(\text{Al}_2\text{O}_3)(\text{CaO})(\text{C}_{14}\text{H}_9\text{O}_4)_3$, the original lake having the formula $(\text{Al}_2\text{O}_3)(\text{CaO})(\text{C}_{14}\text{H}_9\text{O}_4)_4$. It appears, therefore, that ammonia dissolves out alizarin and normal aluminium alizarate, leaving behind an aluminium calcium alizarate, which is more basic than the normal alizarin-red.

III. Trials on Cloth.

Two colours made up with starch, aluminium acetate, calcium acetate and alizarin, and corresponding in their composition to the normal red and the normal red + 1mol. of alizarin respectively, were padded on the cloth, which was then dried, steamed, and finally well boiled in distilled water. A part was then analysed at once, whilst another part was soaped for 1½ hours at the boil in an open vessel, well washed in distilled water, and analysed. Both fents assumed a fine red colour on steaming. The cloth containing the extra amount of alizarin, however, showed spots of free alizarin on its surface, and alizarin was also removed when it was washed with hot water. After soaping, both samples were very similar in shade.

These experiments show that normal alizarin-red $[\text{Al}_2\text{O}_3.\text{CaO}(\text{C}_{14}\text{H}_9\text{O}_4)_3]$ is able to take up alizarin, but that the excess is removed by alkaline liquids. This can be

* See this Journal, vol. iv. p. 587.

readily shown by taking a piece of cloth dyed with the normal alizarin-red, steamed, and either soaped or left unsoaped, and dyeing it again in alizarin, when a further quantity of alizarin is taken up, which, however, is again abstracted on re-soaping.—J. F. C. S.

Studies in Mordanting Wool. L. Liechti and H. Schwitzer. Mittheilungen des Tech. Gew.-Museums, 41—109, Aug. 1886.

IN continuation of the work of Liechti and Suida relative to the behaviour of aluminium, iron, and chromium mordants towards cotton (this Journal, ii. p. 537) the authors have studied their action towards the woollen fibre. The behaviour of tin mordants was also examined. Woollen cloth was boiled with various solutions of mordants, and afterwards dyed with suitable colouring matters—e.g., alizarin, nitro-alizarin, alizarin blue S., cerulein S., gallein, old fustic, quercitron bark, weld, and cochineal. The natural colouring matters were specially selected for studying the action of the tin mordants. The behaviour of the mordants—i.e., the condition and amount of mordant fixed on the fibre—was determined by an examination of the dyed patterns. The water used being magnesian and calcareous, was previously neutralised with hydrochloric acid in the mordanting bath and with acetic acid in the dye-bath. Each sample was mordanted or dyed in thirty times its weight of water. In the mordanting operation the wool was put into the solution at 30–40° C., and the temperature raised to 100° C. in the course of half-an-hour, the boiling being continued for half-an-hour. Before dyeing the mordanted patterns were well washed. The mode of dyeing was similar to that of mordanting, but it varied somewhat according to the requirements of each colouring matter, the best method being selected for each. The amounts of mordant and colouring matter used were expressed in terms of percentage of the weight of wool operated upon. In the course of the experiments it was proved that the dyer's practice of allowing the mordanted or dyed wool to remain in the respective baths till cold possesses no advantages. Wool is only able to decompose and fix mordants in hot solutions, and the increased intensity of colour frequently produced by the practice referred to is of an illusory character, since it is merely owing to a superficial precipitation of colouring matter which is readily removed by hot water. The dyed patterns were not submitted to the operation of "fulling" or "milling."

I. Aluminium Mordants.—Wool was mordanted with equivalent amounts of aluminium sulphate, oxalate, and tartrate, corresponding to 1–10 per cent. of the first-named salt.

Wool mordanted with *aluminium sulphate* and boiled repeatedly with distilled water, always yielded an acid solution; when dyed with alizarin all the colours were dull-reds.

Wool mordanted with *aluminium oxalate* gave better reds, while those with which *tartrate* had been used gave still fuller and brighter colours. In each case the dye-bath solutions had an acid reaction. It was evident, from an examination of the spent mordant and dye-liquors, that the mordanting was most perfect in the case of the tartrate, the whole of the alumina being evidently fixed upon the fibre in a permanent manner. Subsequent experiment showed that aluminium tartrate may, without any disadvantage, be replaced by a mixture of 1 mol. aluminium sulphate, and 3 mols. cream of tartar. A suitable amount of mordant to use is 6 per cent. aluminium sulphate, or its equivalent. Suitable amounts of colouring matter to use are as follows: 5 per cent. alizarin blue S., 5 per cent. cerulein S., and 15–20 per cent. gallein (10 per cent. paste), 10 per cent. alizarin (yellow shade), 20 per cent. paste.

Similar conclusions relative to the above-mentioned mordants were arrived at with each colouring matter.

Experiments made with a view of determining whether a less proportion of cream of tartar than 3 mols. per 1 mol. aluminium sulphate could be used, showed that it could be reduced to 1½ mols. without serious detriment to the colours produced. Since the employment of

Seignette salt as an assistant was proved to be less advantageous than that of cream of tartar, in which case the mordanting bath contains, in addition to aluminium tartrate, a certain proportion of acid potassium sulphate, and since the general practical experience of dyers is that wool is better mordanted in an acid-bath, it was thought possible, perchance, to replace the cream of tartar by an acid—e.g., sulphuric acid. Experiment showed, however, that although a small addition (1 mol.) of sulphuric acid slightly increases the amount of alumina absorbed by the fibre, it cannot replace the cream of tartar; since, further, the addition of a larger amount (3 mols.), although it hinders the dissociation of the mordant solution, yields very unsatisfactory colours, it is evident that the beneficial action of cream of tartar cannot be ascribed merely to its retarding the dissociation of the mordant.

On submitting wool mordanted in a solution of aluminium tartrate to the repeated action of boiling water, it was found that the mordant was extremely well fixed, the further liberation of a small quantity of acid being the only essential result.

Boiling with water, after mordanting, would, therefore, be beneficial in all cases where the presence of acid in the dye-bath is objectionable, and in any case mordanted wool ought always to be thoroughly washed previous to dyeing.

Since it has already been shown by Liechti and Suida that the presence of potassium or sodium sulphate retarded the dissociation of certain aluminium and chromium salts used as mordants for cotton, it was thought possible that the presence of these salts in a mordanting bath of aluminium sulphate might retard the dissociation of the aluminium sulphate outside the fibre, to which action, in part at least, the beneficial employment of tartaric acid as an assistant is in some measure due. An experiment made with aluminium sulphate as a mordant, with and without the addition of sodium and potassium sulphate, showed that alum is no better—in fact, slightly worse—as a mordant, than aluminium sulphate, and does not support, therefore, the persistent preference which dyers have for alum.

An experiment was made with a view of determining whether the tartaric acid used along with aluminium salts played the rôle of a carrier, so that it might be possible to use any free acid along with only a small quantity of tartaric acid. The result obtained, however, proved that the tartaric acid plays no such intermediary part in mordanting wool with aluminium salts; on the contrary, a considerable amount of tartaric acid must be present (at least half the theoretical amount necessary to form aluminium tartrate) in order to fix on the wool sufficient alumina to yield full bright colours.

II. Tin Mordants.—Wool was mordanted with stannic and stannous tartrate, prepared by precipitating the respective chlorides with sodium carbonate, and dissolving the washed stannic hydrate in the calculated quantity of tartaric acid. Stannous hydrate being, however, little soluble in tartaric acid, was dissolved by means of cream of tartar. By adding 2 mols. cream of tartar to 1 mol. stannous hydrate and heating, complete solution of the latter is effected; no doubt the double salt $\text{SnC}_4\text{H}_4\text{O}_6 + \text{K}_2\text{C}_4\text{H}_4\text{O}_6$ being formed. The solution is capable of dissolving even a small quantity of stannous hydrate, or what amounts to the same, it is possible to dissolve 1 mol. stannous hydrate by means of 1½ mols. cream of tartar, in which case the liquid corresponds to a solution of 1 mol. stannous hydrate in 3 mols. of the above double salt. When such a warm concentrated solution is allowed to cool, crystals containing tin are formed, but they have not been further examined.

In all the experiments with tin mordants, the percentage of the latter employed refers to the weight of wool, and is expressed in terms of the equivalent amount of stannic chloride ($\text{SnCl}_4 + 5\text{H}_2\text{O}$).

Stannic tartrate, as a mordant, gives bad results, much of the tin being precipitated in the bath in such a form as not to be subsequently attracted by the fibre.

Stannous tartrate in the form of a solution of 1 mol. stannous hydrate in 1½ mols. cream of tartar proves not to be a satisfactory mordant, since it does not yield a

sufficient amount of tin to the fibre, probably because the solution is not acid enough. Incidentally, it was observed that in dyeing with 15 per cent. cochineal the addition of 4 per cent. sodium bisulphate to the dye-bath improved the red very much, making it yellower and more intense.

The employment of a mixture of 1 *mol.* stannous chloride with 1 *mol.* oxalic acid gives, on the contrary, very good results, an amount (about 4 per cent. $\text{SnCl}_2 + 5\text{H}_2\text{O}$) equivalent to 6 per cent. $\text{SnCl}_4 + 5\text{H}_2\text{O}$ giving the best scarlet on dyeing with cochineal. The fact that the more NaHSO_4 the dye-bath contained the higher is the temperature at which the development of colour takes place, and that the same is observed in the case of increasing amounts of tin mordant, seems to indicate that the tin is fixed on the fibre as a basic salt, while, during the formation of the scarlet-coloured tin-lake, exchanges its acid for the colouring principle of cochineal. The larger the amount of acid present, the higher is the temperature at which the exchange takes place. In this connection, it is strange that the presence of a certain amount of acid in the dye-bath (4 per cent. NaHSO_4) is necessary in order to exhaust the dye-bath more thoroughly, a circumstance which explains why, in practice, good results are obtained in dyeing cochineal-scarlet even when mordant and colouring matter are present in the same bath. If $1\frac{1}{2}$ *mols.*, or even 2 *mols.*, oxalic acid, are employed instead of 1 *mol.*, the results are essentially the same, the main difference being that the colour is yellower; an addition of 2 per cent. NaHSO_4 to the dye-bath suffices.

The general result of the mordanting experiments with mixtures of stannous chloride and oxalic acid is, that although an almost insoluble stannous oxalate is formed in the bath, this is by no means disadvantageous, since the wool takes up the tin most thoroughly. With a mordant equivalent to 1—4 per cent. $\text{SnCl}_4 + 5\text{H}_2\text{O}$, the spent mordant-liquors contain no tin; and even if 10 per cent. be employed, they contain only a small quantity. If the oxalic acid is increased beyond 1 *mol.*, a corresponding increase in the absorption of tin does not take place, but more oxalic acid is taken up; it is not removed by washing, and is probably present as a less basic stannous oxalate. In the case of dyeing with cochineal, it saves acid in the dye-bath, but in the case of other colouring matters—*e.g.*, alizarin—it is injurious.

Dissociation experiments made with a view of explaining why stannic tartrate, stannic chloride, and mixtures of the same give such bad results as mordants, showed that, in dilute solution, all dissociate readily on heating; those containing a mixture of stannic tartrate and chloride dissociate on heating even more readily than stannic chloride alone. To pour the tin solutions into the water is more unfavourable than the opposite mode of dilution. When the wool-fibre is present, dissociation is accelerated, and the condition of the precipitate formed is such that the wool is not able to take it up; the reaction may be called "injurious dissociation." It is evident, from their behaviour, that stannic salts are not suitable as mordants.

Stannous Chloride and Cream of Tartar.—Wool was mordanted with various percentages of stannous chloride + 1 *mol.* cream of tartar. It is best to mix the two salts in the solid state, then stir up with a little water, and afterwards dilute still further. In this way one avoids the dissociation of the stannous chloride, which would occur if the stannous chloride were put into the mordant-bath alone. The stannous tartrate produced in the manner described is not so sensitive. During the mordanting a precipitate is certainly produced, but it is gradually taken up by the wool. Patterns dyed with cochineal exhibit weaker colours than the corresponding patterns in which 1 *mol.* oxalic acid replaces the cream of tartar, and it is evident that less tin is fixed upon the fibre. Strange to say, the cream of tartar colours are yellower in tone, except where no NaHSO_4 is added to the dye-bath, in which case the reverse is obtained. Addition of 4 per cent. NaHSO_4 gives the fullest and yellowest tone of scarlet. The use of 4 per cent. stannous chloride gives a good colour.

With $1\frac{1}{2}$ *mols.* cream of tartar, yellower colours are

obtained than with 1 *mol.* The addition of 4 per cent. NaHSO_4 to the dye-bath behaves as in the previous trial.

The general conclusion is that it is sufficient to employ 1 *mol.* cream of tartar with 1 *mol.* stannous chloride. An increase of the former does not increase the amount of tin fixed on the wool, and its action in causing more level dyeing, producing a yellower colour, and exhausting the bath better, is purely the effect of its acid character; so that the same result can be obtained by adding acid to the dye-bath—*i.e.*, when the colouring matter behaves like cochineal; with alizarin, of course, such an addition would be injurious.

Oxalic acid is preferable to cream of tartar as an assistant in the case of cochineal-scarlet dyeing, since it fixes more tin upon the fibre, and the yellower scarlet given by using cream of tartar can be obtained, if required, either by an addition of more acid or of flavine to the dye-bath, or by mordanting and dyeing in the same bath.

Stannous Chloride and Tartaric Acid.—When mordanting wool with a mixture of stannous chloride and $\frac{1}{2}$ *mol.* tartaric acid, or, as it might be expressed, with a mixture of the following:— $(\text{SnCl}_2 + \text{SnCl}_4 \cdot \text{H}_2\text{O}_6 + 2\text{HCl})$, "injurious dissociation" of the excess of SnCl_2 takes place, which the presence of the stannous tartrate and HCl are not able to prevent. Cochineal only dyes a tolerably useful scarlet when about 5 per cent. $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ is employed, although there is fixed on the wool much less tin than in previous trials. With 5 per cent. $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ a good orange is obtained, which is considerably improved if the mordanted wool is boiled with water in order to remove the absorbed acid before dyeing. If the dyeing is prolonged, the colour becomes duller, probably in consequence of the formation of stannous sulphide. Nitro-alizarin gives a dull orange. Alizarin-blue S., cerulein-blue S., and gallein do not yield useful colours.

With the addition of 1 *mol.* tartaric acid to the mordanting bath, cochineal dyes slightly better and yellower shades than when 1 *mol.* oxalic acid is employed. With alizarin, yellower shades of orange are obtained.

The authors state that with all the colouring matters they employed, where tin mordant was at all useful, very passable results were obtained, even when only about 1.3 per cent. $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ was employed—*i.e.*, equivalent to 2 per cent. $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$.

With the addition of $1\frac{1}{2}$ *mol.* tartaric acid to the mordanting bath, similar results are obtained, the shades yielded by alizarin being still yellower. Excess of tin yields a dull colour when dyeing with nitro-alizarin. In dyeing with alizarin-blue, if the mordanted wool contains a small quantity of acid, a blue precipitate is thrown down in the dye-bath, with more acid present the precipitate is brown.

When wool is mordanted with stannous tartrate + 1 *mol.* HCl , only a small quantity of useful tin is fixed on the fibre, the largest portion is lost through "injurious dissociation." Cochineal and other colouring matters give dull colours. By mordanting with stannic chloride + 2 *mols.* cream of tartar, a similar result ensues.

From all the foregoing experiments it appears that stannous chloride gives much better results than stannic chloride. The addition of 1 *mol.* tartaric or oxalic acid to stannous chloride is better than an equivalent amount of cream of tartar in cochineal dyeing, because of the greater acidity of the bath.

If a mixture of 1 *mol.* stannic chloride and 1 *mol.* stannous chloride is dissolved in water, a solution is obtained which, even when much diluted, can be boiled without dissociation taking place. After boiling or mordanting wool with this mixture, the filtered spent mordant liquor still contains tin; this shows, therefore, that that portion of tin which is not taken up by the wool is not dissociated on boiling. Although, on dyeing the mordanted wool with various colouring matters, it is evident that little tin is fixed on the fibre, and that the colours obtained are not nearly so good as those given with stannous chloride and an organic acid, still the colours are much better even without the addition of an organic acid in the mordant-bath, than in the case of stannic

chloride with such addition. Some of the "scarlet spirits" of the woollen dyer, prepared by dissolving tin in a mixture of nitric and hydrochloric acids, are evidently similar mixtures of stannic and stannous chloride.

If to a solution of 1mol. stannous chloride and 1mol. stannic chloride, 3mols. oxalic acid are added, turbidity and even a precipitate is produced, but on boiling wool in it the solution becomes clear, and nearly the whole of the tin is taken up by the wool.

If the wool has been mordanted with such an amount of the mixture equivalent to 4, 6 or 8 per cent. $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$, cochineal gives bright scarlets very similar to those obtained with the use of stannous chloride and oxalic acid. With alizarin very bright reddish oranges are obtained, especially with the highest percentage of mordant mentioned. From the reddish appearance of the orange it is evident that the wool has not taken up very much free acid from the mordant-bath, although the spent dye-baths have invariably an acid reaction. If the mordanted cloth is well washed with a solution of sodium acetate, the wash-water has still an acid reaction and contains a large quantity of chlorides. Cloth so treated gives greyer and duller shades when dyed with alizarin.

It is evident from the foregoing experiments that, although stannic chloride, even with the assistance of an organic acid, is a very unsatisfactory mordant, the addition of stannous chloride in equivalent amount renders it a very good one.

If wool is mordanted with a mixture of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O} + \text{SnCl}_4 \cdot 5\text{H}_2\text{O}$, equivalent to 6 per cent. $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$ —i.e., the best amount as previously found—with the addition of 1–6mols. oxalic acid + 1–6mols. cream of tartar the turbid baths gradually become clear, since the precipitate is taken up by the wool. If the mordanted patterns are washed with water, those with which only little oxalic acid was used yield turbid wash-water, while with the others the turbidity is only slight. This shows that by increasing the oxalic acid, much less mordant is fixed on the wool in a merely mechanical way. The patterns mordanted with the addition of cream of tartar yield a turbid wash-water. The filtered mordant-baths only contain traces of tin.

In dyeing with cochineal, the addition of sodium bisulphate hinders exhaustion of the bath. Those mordanted with the addition of oxalic acid give a yellower shade than those in which cream of tartar is used, though in both cases the scarlet is very satisfactory. The best results are obtained in each case when 3mols. of the assistant are used.

On dyeing with alizarin, a fine reddish orange is produced, and the baths are not perfectly exhausted in either case, and little is removed in washing. Where only 1mol. of oxalic acid or cream of tartar was used, the colour is much paler, evidently an insufficiency of tin being fixed upon the fibre. Those patterns where oxalic acid was used are much redder in tone, and since the acidity of the bath is larger and tends, according to previous experiments, to produce a yellower tone, the cause of this redness must be that a larger amount of tin is fixed on the fibre. Nevertheless, supposing equal amounts of tin to be fixed upon the fibre, the latter must contain less acid, when oxalic acid is used, than in the case of cream of tartar. On dyeing with nitro-alizarin, all the baths are equally well exhausted, a bright yellowish orange being produced; little colour is removed by boiling water. On dyeing with alizarin blue, the oxalic acid patterns do not exhaust the bath so well as when cream of tartar is used. With the use of 3mols. in each case a full bright reddish-blue is obtained.

On dyeing with corallin, the baths are not completely exhausted, although best in the case of oxalic acid. The dyed patterns show this difference very decidedly. Where cream of tartar is used, blackish-green is produced, whereas in the case of oxalic acid, the colour is much brighter except where only 1mol. oxalic acid is used. The blackish appearance of the corallin colours is always a sign of too little mordant on the fibre, so that a portion of the colouring matter becomes fixed in a substantive manner. On dyeing with gallein, the baths are fully exhausted, except where 1mol. of either assistant

is used. No colour is removed on washing with hot water. Where 1mol. of the assistant is employed the colour is brownish-red, the rest being violet, the oxalic acid patterns having a reddish tone of colour, the others a bluish tone.

The foregoing experiments show that a tin mordant consisting of equivalent amounts of stannous and stannic chloride gives excellent results, especially when used with the addition of organic acids. Stannous chloride alone dissociates on diluting with water; stannic chloride, in the most concentrated mordanting bath experimented with, dissociates at a temperature of 80–90° C., whereas the mixed mordant (Sn_2Cl_6) does not dissociate either on heating or by dilution to the extent usual in a mordanting bath.

Stannic chloride is a bad mordant, even with the addition of organic acids; but by the further addition of stannous chloride its bad properties are masked, and it then gives good, or, sometimes, even better results than stannous chloride and organic acids. It is probable that the "scarlet-spirits" so much esteemed by the woollen dyers for cochineal-scarlet owes its action to the presence of this mixture of stannous and stannic chloride.

The mordant, Sn_2Cl_6 , does not exhibit the "injurious dissociation" to which SnCl_2 and SnCl_4 separately are subject. The best amount of organic acid to use is that which is just sufficient to replace the whole of the chlorine of the Sn_2Cl_6 —i.e., 3mols. oxalic acid or cream of tartar per 1mol. $\text{SnCl}_4 \cdot 5\text{H}_2\text{O} + 1\text{mol. SnCl}_2 \cdot 2\text{H}_2\text{O}$. Without serious detriment even 2mols. of the assistant can be used.

Reckoning that full colours are produced by using an equivalent of 6% $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$, 1kilo. wool should be mordanted with the following solution: 30 litres water, 19.28grms. stannous chloride, 30grms. stannic chloride, with the addition of either 48.34grms. cream of tartar or 32.4grms. oxalic acid.

Additional experiments have shown that long keeping of stannic chloride or tartrate solutions renders them more sensitive to dissociation, and renders them less efficient as mordants, the dissociation being of an injurious character, since the wool is unable to attract the precipitates formed. Long keeping of a solution of the mordant Sn_2Cl_6 produces a similar condition.

On mordanting wool with a fixed quantity of aluminium tartrate (=6% $\text{Al}_2(\text{SO}_4)_3$) and varying amounts of stannous tartrate—i.e., SnCl_2 ($\frac{1}{3}$ mol. – 1mol.), with addition of 2mols. cream of tartar to each mol. of SnCl_2 , the following observations were made: Where $\frac{1}{3}$ – 1mol. SnCl_2 were used, the baths were turbid, but became clear on boiling; but the wash-water of all the patterns was clear. The filtered mordanting baths showed no trace of alumina; but where $\frac{1}{3}$ – 1mol. SnCl_2 were employed, traces of tin were detected.

On dyeing with alizarin, all the baths are exhausted, and are acid; on washing with hot water nothing is removed.

With increasing amounts of tin, the dyes become yellower. With $\frac{1}{3}$ mol. SnCl_2 the shade is distinctly yellow; with 1mol. SnCl_2 it is a decided orange; the peculiar bluish and somewhat dull red peculiar to alizarin alumina shades is only exhibited where no tin is used.

A further advantage of mordanting with aluminium and stannous tartrate is that the dyed patterns do not rub off, whereas those dyed with aluminium tartrate alone do to a slight extent. The addition of $\frac{1}{3}$ mol. $\text{SnCl}_2 + 1\text{mol. cream of tartar}$ completely prevents rubbing off.

On dyeing with quercitron bark, the baths are pretty well exhausted. As the boiling continues, the yellow colour becomes duller. Alumina mordant gives a pale greyish yellow; with increase of SnCl_2 in the mordanting bath the yellow is redder.

With old fustic, similar results are obtained, the colours being deeper but not so bright.

On dyeing with weld, the baths are very well exhausted. Alumina used alone, gives a bright pale yellow; with addition of SnCl_2 , the colour becomes paler and greener.

A further series of mordanting experiments were made,

in which *aluminium tartrate* and *stannic tartrate* were used, in place of stannous chloride. They gave the following results: The turbidity of the mordanting bath does not disappear on boiling; the mordanted wool, when washed, yields a turbid wash-water, and the filtered mordanting liquors contain no tin.

On dyeing with alizarin, the baths are well exhausted; the dyed fentls lose nothing on washing. The addition of stannic tartrate to the mordanting bath produces no difference of shade, and the colour rubs off just as much as if aluminium tartrate alone had been used, evidently showing that very little tin is fixed on the wool along with the alumina, a result confirmed in the case of dyeing with quercitron bark, old fastie, and weld.

These experiments show that it is irrational to use stannic salts in combination with aluminium salts as a mordant, and that to obtain an effect on dyeing due to a mixed mordant of tin and alumina, one must add to aluminium tartrate a mixture of stannous chloride and cream of tartar.

GENERAL CONCLUSIONS.

From the whole of the foregoing mordanting experiments with aluminium and with tin salts, it is shown that the wool has a number of properties which come into play during the mordanting process.

1. That the wool fibre has the property of attracting finely-divided precipitates of a flocculent nature from solutions and retaining them with considerable power. In the cold this attraction is only feeble, but it increases on raising the temperature, and by continued boiling considerable amounts of such precipitate are boiled on to the wool. The precipitate thus boiled on is removed by washing and rubbing.

If the suspended precipitate is basic aluminium sulphate, the wool is able to retain it moderately fast by virtue of its finely-divided condition, and if, after rinsing, it is dyed with alizarin, the mechanically-fixed alumina is changed into lake, and at the same time to some extent removed from the fibre.

Basic stannic salt precipitates boiled on to the wool in this way only adhere feebly to the fibre, and by rinsing are easily removed. Hence on dyeing, removal of the lake, as above, does not take place. Aluminium mordants which behave in the above manner, yield dyes possessing in a high degree the defect of rubbing off.

2. Wool fibre has the property of extracting acid from acid-liquors, and retaining them with considerable power. As a matter of course, this power varies with the different acids, and at different temperatures. It is known, for example, that wool easily takes up sulphuric acid, retaining it to such a surprising degree that it is very difficult to extract by mere washing in water. The last portions of acid in "extracted wool" (carbonised wool) are only removed by a passage through soda solution.

3. Wool fibre has the property of decomposing certain metallic salts in solution, and this takes place most completely at the boiling-point. On this property rests the possibility of mordanting wool by boiling with salt solutions without any further operation.

It is found that the wool can only decompose the mordanting salts into more or less basic salts, and either free acid or acid salts. This explanation of the reaction which takes place during the mordanting process has much in its favour, and may be deduced from the properties of such basic salts and the corresponding acids.

The authors have found that by boiling wool with aluminium sulphate a white flocculent precipitate separates in the liquors; on rinsing the wool with water the wash-water is clouded with the same, and on dyeing with alizarin a red lake separates already in the bath, a further quantity being removed by the final washing. When examined overhand, the dyed colours are grey and lustreless, and examined underhand possess no intensity. Further, an examination of the dyed fibre under the microscope shows that the alizarin-lake is deposited chiefly on the surface in small particles, and the colours rub off strongly in consequence. The results appear somewhat improved by the addition of sulphuric

acid to the liquor in the proportion of not more than 1mol. to the sulphate employed.

These phenomena are explained in the following manner:—Wool-fibre decomposes the sulphate at high temperatures, and in the presence of water, with great ease into basic and acid salts (see this Journal, vol. ii. p. 537). An insignificant dissociation is sufficient, particularly at the boiling-heat, to form an insoluble basic sulphate from aluminium sulphate, consequently the formation and deposition of insoluble basic salts naturally begin on the surface of the fibre—i.e., before the mordant solution can penetrate to the interior of the fibre. The soluble basic sulphates are absorbed by the fibre, whilst the insoluble basic salts partly adhere to the scales of the fibre and partly float in the liquor.

An excess of aluminium sulphate consequently removes basic sulphate from the fibre (Havrez), and produces poorer results in mordanting. If the wool is boiled with aluminium tartrate no separation takes place in the bath, on rinsing no insoluble compound separates, on dyeing no mechanically adhering lake is removed. The mordanted fibre feels soft, and the dyed fibre, when examined under the microscope, seems equally dyed throughout its mass, and shows no particles of colour-lake on the surface; examined overhand, the fibre is evenly and intensely coloured. In the case of aluminium tartrate, it is evident that since insoluble basic salts are only formed with difficulty, such a deposition on the surface of the fibre is prevented, and the mordant solution can penetrate the fibre unimpeded, and is decomposed only in the interior, the liberated tartaric acid is absorbed by the fibre only in small quantity; the basic aluminium tartrate retained by the fibre changes on dyeing, with the separation of acid, into a coloured lake permeating the whole substance of the fibre.

A similar result is to be expected from tin-salts, but the examination is rendered difficult by their special behaviour.

The tin-salts examined (chloride, tartrate) decompose even on heating their diluted solutions, without the wool fibre being brought into the liquor; the basic precipitates thus formed are not taken up by the wool.

Stannous chloride is dissociated on dilution alone, the separated matter is not taken up by the wool fibre. Stannous oxalate and stannous tartrate, produced in the form of crystalline precipitates by adding oxalic and tartaric acids to stannous salt solutions, are almost insoluble in water, but disappear from the turbid solution and are taken up by the fibre on boiling. Hence they are to be distinguished from the flocculent precipitates caused by the dissociation of stannic salts which are not taken up by the fibre.

From the preceding it follows:—

4. A rational mordant for wool must be so constituted that it must be certainly decomposed by the fibre, but it must at the same time offer a certain resistance to decomposition, just sufficient to allow the solution to penetrate the fibre in its undecomposed state, and be only there decomposed. Therefore all mordants which decompose on the exterior of the fibre, either through the influence of increase of temperature, dilution, or the wool-fibre itself, produce bad results. As it is the acid present which modifies the character of the mordant salt as here indicated, so a substitute for cream of tartar must be a body whose aluminium, iron, etc., salts behave as described above.

5. In general only salts with organic acids comply with the stipulations mentioned in 4.

6. The wool fibre takes up basic salts during the dissociation of mordant liquors, and retains them so firmly that no amount of washing will remove them. That the wool takes up true basic salts, and not hydrates, is shown by the fact that in the authors' experiments, in all cases of dyeing mordanted cloth, the waste dye-liquors show an acid reaction. A rational mordant must necessarily deposit these basic salts in the fibre in such a manner and molecular state that the optical properties of the lake produced are enhanced in the highest possible degree.

7. A special fixing is unnecessary when mordanting wool, the fixing and mordanting taking place together

in one operation. Where possible, the longer boiling in the mordant liquor is always carried out, since it is certain that the mordant already taken up becomes thereby still further dissociated, and a greater saturation of the fibre with mordant takes place.

8. On washing after mordanting, the basic salt taken up is still further dissociated, and the acid thereby produced is partially removed. Free acid is always liberated on the formation of the colour lake in the dye-bath. A further quantity is also introduced by badly-washed wool (carbonised wool), and a thorough washing is hence absolutely necessary in every case where free acid in the dye-bath is injurious, since it prevents the formation of the lake. Where such acid is not injurious, or even advantageous, as with cochineal, a thorough washing of the wool is unnecessary, and the mordanting and dyeing can be carried out in one bath.

9. All the acid cannot be removed from the wool by washing with water, a basic salt invariably remains behind in the fibre; the total removal of the acid is in most cases not necessary for the production of good colours. Such a total removal of the acid can be effected by a treatment with sodium-acetate solution. By dyeing tin-mordanted wool thus treated with alizarin, which permits of exceedingly little acid being left in the wool, the colour is grey and unsightly, which shows that even with alizarin a certain minimum of acid is required in the basic salt on the fibre in order to produce a fine colour (lake). An alkaline treatment of the mordanted wool, or the presence of alkali in the dye-bath, is not conducive to the production of fine colours. The dyes look bare and dull, especially when examined overhand.

10. Acidification of the mordanting bath is in general beneficial, but if this be overdone bad results are then produced; indeed less mordant is then fixed on the fibre. The above conclusions do not profess in the least to give an exhaustive explanation of the processes under consideration. They appear to the authors to be the first conclusions to be drawn from the appearances observed, but a complete explanation of the reactions taking place during mordanting can only be obtained by scientific research, which is already in progress.

The special results of the authors' experiments may be formulated as follows:—

1. Wool always contains fat, however well purified by the ordinary means; if this be extracted by ether better results are obtained on dyeing.

2. An amount of aluminium tartrate equal to 6 per cent. $Al_2(SO_4)_3$ on the weight of wool is very favourable; from 7 to 8 per cent. produces a brighter colour.

3. It is sufficient to mordant with such a quantity of $SnCl_2 \cdot 2H_2O$ (i.e., 4 per cent.) as corresponds to 6 per cent. $SnCl_4 \cdot 5H_2O$, with the addition of organic acids, to produce full colours.

4. Even with the use of $SnCl_2$ corresponding to so little as 2 per cent. $SnCl_4 \cdot 5H_2O$, very fair results are obtained.

5. $SnCl_4$ gives very poor results.

6. Mixed stannous and stannic chloride gives excellent results, but must not be kept in solution.

7. By dyeing with cochineal, it is observed that by mordanting with stannous salts much more acid is taken up by the wool (per each mol. of tin) than with stannic salts; with the latter only a small amount of tin is taken up by the fibre, and although the liquors compared with the stannous chloride liquors are considerably more acid (i.e., for equal amounts of tin), yet less acid is taken up by the fibre.

8. The same holds good in the case of the mordant, consisting of stannous and stannic chloride.

9. When mordanting with $Al_2(SO_4)_3$, 3mols. of cream of tartar should be taken to 1mol. of $Al_2(SO_4)_3$, although in practice it can be reduced by one-half without much interfering with the beauty of colour.

10. On mordanting with $SnCl_2$ and 1mol. cream of tartar, oxalic or tartaric acids, more tin is fixed on the fibre by tartaric acid than by oxalic acid, and both of these acids fix more than cream of tartar.

11. On mordanting with the mixed stannous-stannic chloride, it is best to use 3mols. oxalic acid to 1mol.

$SnCl_2$ and 1mol. $SnCl_4$. Oxalic acid in this case fixes more tin than cream of tartar.

12. For the purpose of mordanting with alumina and tin, the best results are given by aluminium tartrate and stannous chloride, with cream of tartar.

With reference to the colouring matters employed in the above experiments, the following is worthy of notice:—

1. Alizarin gives with alumina mordant a beautiful somewhat brownish red. With tin mordants the most varied shades from dull leather yellow to a deep scarlet coloured orange can be obtained. The less tin and more acid present on the fibre, the duller and dirtier is the yellow thereby obtained. The finest scarlet orange is obtained by employing from 4 to 5 per cent. $SnCl_4$ + $\frac{1}{2}$ mol. tartaric acid. The ratio of 1mol. of $SnCl_4$ + $\frac{1}{2}$ mol. tartaric acid fixes a maximum of tin with a minimum of acid on the fibre, hence the beautiful colour it gives with alizarin. The mixed chlorides of tin give with 3mols. oxalic acid similarly beautiful results.

2. Alizarin orange on unmordanted wool produces a brownish-red shade of orange, with alumina mordant a brownish orange, with tin mordant a brownish-yellow shade of orange.

3. Alizarin blue S. on unmordanted wool produces a light greyish-blue, with alumina mordant a violet-blue, with tin mordant a deep violet-blue; with sufficient tin on the fibre useful colours are obtained.

4. Cœrulein S. on unmordanted wool produces a greenish-blackish grey, which, examined overhand, appears bare and dull; with alumina mordant a somewhat olive-green, which, examined overhand, is very lustrous and full; with tin mordant cœrulein is not applied with advantage.

5. Gallein on unmordanted wool produces a bright reddish but loose brown; with alumina mordant a very beautiful bluish-violet; the same with tin mordant.

6. Cochineal produces with tin mordant the well-known scarlet, which, to a certain degree, becomes yellower the more acid the bath is.

7. Fustie with alumina mordant produces a somewhat greyish-yellow colour, with tin mordant a purer yellow.

8. Quercitron with alumina mordant produces a somewhat greyish-yellow, with tin mordant a fine slightly-less reddish-yellow.

9. Weld with alumina mordant produces a somewhat intense greenish bright yellow; with tin mordant the yellow is still more greenish, but paler than with the alumina mordant.—J. J. H.

On the Influence of Lime and Magnesia Waters in Wool Dyeing. Max Becke. Mitt. des Tech. Gew.-Museums, 123—128, August, 1886.

NATURAL WATER always contains salts in solution, the action of which is of great importance. Water of this sort, when tested, has been found to contain 400mg. of solid matter per litre, consisting of 99.5mg. CaO and 36.2mg. MgO, combined partly with carbonic acid and partly with sulphuric and hydrochloric acids. The following trials are intended to show the influence these quantities of lime and magnesia have on the dyeing of wool.

EFFECT ON THE SCOURING BATH.

If a solution of soap be added to a bath the water of which contains lime and magnesia, a sticky insoluble body (lime and magnesia soap) is formed. This partly floats on the surface of the bath and can be skimmed off, and partly is disseminated as a white amorphous precipitate throughout the bath, giving it a milky appearance. This entails, of course, great loss of soap; it is also injurious to the goods. It seems probable from practical data obtained, that wool washed and soaped in such water, when entered in a dye-bath, is almost always more or less charged with lime soap.

DYEING IN AN ACID BATH.

If this wool is dyed in the usual way with the addition of sulphuric acid and Glauber's salts, the sulphuric acid effects a partial decomposition of the lime soap, forming

sulphate of lime and free fatty acid, which adheres to the wool, and not only gives it a fatty feel, but also becomes dyed, since it acts as a mordant towards many colouring matters, especially those of the triphenyl-methane group. This colour lake adheres only superficially to the fibre, and rubs off—as, for instance, in goods dyed or “topped” with methyl violet or magenta. Alkali-blue, which belongs to this category of colours, is generally dyed in an alkaline bath, and the colour is developed in an acid bath; it also has a strong affinity for all fatty bodies, and consequently dyes not only the wool, but the lime soap as well, and it is well known how much goods dyed with this colour “rub off.”

DYEING WITH ALUM, ETC., IN THE BATH.

When metallic salts are used as mordants, the effect is still worse, for double decomposition takes place with the formation of compounds of the metal with the fatty acid, and an insoluble lime salt (if the metal was present as a sulphate, or if oxalic or tartaric acid were in the bath) which is deposited on the fibre as a whitish powder, giving it an unsightly dusty appearance. The metallic soap formed acts also as a mordant in a double respect, both in consequence of the fatty acid and of the metallic base which it contains; most colouring matters dye these metallic soaps, and frequently these superficial sticky substances have a greater attraction for the colouring matter than the wool itself, consequently becoming more intensely dyed than the wool; this substance cannot be removed by careful washing, but if the goods are dried a simple rubbing with a cloth removes the intensely coloured sticky lake—that is, the goods “rub off.” The appearances here described occur in greater or less degree; with logwood blacks and blues; with cochineal colours; with all anthracene colours; further, in acid baths, to which alum has been added, as is done on the one hand for the better fixing of indigo carmine and also of certain azo-colours, and on the other hand to retard the felting of soft yarn, and to strengthen weak yarn.

ACTION OF LIME IN THE DYE-BATH.

In acid dye-baths the lime only acts in a freshly-prepared bath, first by precipitating a large quantity of the colouring matter, which thereby becomes more or less useless; secondly, by dulling many colours—indeed it forms a dull-coloured lime lake; and lastly, it prevents the equal deposition of the colouring matter, and by this thus hinders the level dyeing of the goods. At the present time a series of azo colours is used in wool-dyeing, all of which have the property of only dyeing evenly when the goods are entered into the dye-bath cold and the temperature gradually raised to the boil. Consequently a fresh bath is always required, and the above-mentioned injurious action of the lime appears in each dyeing operation. The lime in the water produces worse effect, however, with all those colours which require two baths (the mordant and the dye-bath) for their production, as in this case it acts twice. If alizarin blue, carulein, or galloxyanin is used, not only is the depth of colour considerably reduced, but the fibre rubs off to a larger extent as well. Liechti recommends for the correction of calcareous water, the use of caustic soda; in cases where the amount of bicarbonate of calcium and magnesium much exceed the amount of the sulphate and chloride present, it is well to use caustic lime and caustic soda (Gaillet and Huet), and when the sulphate and chloride exceed the bicarbonate, then to apply caustic soda in combination with carbonate of soda or caustic lime and carbonate of soda. Correction by means of caustic lime (Porter and Dixon), or with chloride of barium and lime (De Haen), is not so satisfactory, as in both methods the remaining hardness is not reduced.—J. F. C. S.

Study on the Fixing of Alumina Mordants on Cotton.

Engmont Kutschera and Adolf Utz., Mittheilungen des Tech. Gew.-Museums, August, 1886.

It is the aim in this paper, firstly, to search for a compound of alumina which exhibits specially favourable

properties as a mordant; secondly, to determine which fixing agent is best, and under what conditions it is best applied.

The conditions of all experiments were as far as possible the same, as regards, for example, the concentration and temperature of the liquids, duration of their action, etc. Experiments were made with the following compounds:—

- (1.) $\text{Al}_2(\text{SO}_4)_3, 18\text{H}_2\text{O}$.
- (2.) $\text{Al}_2(\text{SO}_4)_3, (\text{C}_2\text{H}_3\text{O}_2)_2$.
- (3.) $\text{Al}_2(\text{SO}_4)_3, (\text{C}_2\text{H}_3\text{O}_2)_4$.
- (4.) $\text{Al}_2(\text{C}_2\text{H}_3\text{O}_2)_6$.
- (5.) $\text{Al}_2(\text{SO}_4)_3, (\text{OH})_3$.
- (6.) $\text{Al}_2(\text{SO}_4)_3, (\text{C}_2\text{H}_3\text{O}_2)_3, (\text{OH})$.
- (7.) $\text{Al}_2\text{O}_3, \text{Na}_2$.

Such a concentration of the mordant solution was used as yielded a good alizarin red; each contained exactly the same amount of alumina, which corresponded to that contained in a solution of 50grms. $\text{Al}_2(\text{SO}_4)_3$ per kilo. of mordant solution. Nos. 2, 3, 4 were prepared from the calculated amounts of sulphate of alumina, and respectively 1, 2, 3 equivalents of lead acetate. For example, No. 2 is prepared thus: 50grms. $\text{Al}_2(\text{SO}_4)_3$ are dissolved in warm water, and 28.38grms. of $\text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2$ are also dissolved, the solutions are cooled and mixed together.

the mixed solutions, which now contain 22.68grms. PbSO_4 , are diluted with water till the whole weighs 1022.68grms., and then only filtered, thus avoiding loss of actual mordant, which would occur if filtered previous to dilution. No. 5 is prepared by adding a cold solution of soda crystals to a cold concentrated solution of $\text{Al}_2(\text{SO}_4)_3$ till the precipitate first formed redissolves. This mordant solution naturally contains sodium sulphate. No. 6 is prepared by adding the calculated amount of soda crystals solution to sulphate of alumina, then adding a solution of lead acetate. No. 7 is ordinary aluminate of soda, containing 24.1 per cent. Al_2O_3 , of which 32grms. correspond to 50grms. $\text{Al}_2(\text{SO}_4)_3$.

Padding.—For the experiments, cotton cloth was padded by hand, with the various mordant solutions, using every precaution to ensure that a given surface of the material should contain an equivalent amount of mordant solution. A slight error is unavoidable, as is already shown by L. Liechti, owing to the slight unequal dissociation of the various mordant solutions during the padding process, and also to the fact that it is impossible to pad the middle and sides perfectly equal.

Fixing.—The subsequent fixing is effected in two stages: 1st, exposure to air (ageing); 2nd, the passage through different alkaline baths. After the first operation the padded samples, dried in the cold, are hung in a warm moist atmosphere at the usual temperature (34°C .) for 48 hours. In studying the action of the fixing bath, three points were observed—the concentration of the bath, the temperature, and the duration of action. Having previously learnt that 15grms. of sodium phosphate per litre gave good results, the question of concentration was not further studied, and the other fixing materials were calculated so as to contain an equivalent proportion of alkali, as follows: 15grms. sodium phosphate, 8grms. ammonia (18 per cent.), 12grms. soda crystals, 14grms. commercial ammonium carbonate, 32.4cc. sodium silicate 34°B ., 16.8grms. sodium arsenate. The following were taken arbitrarily as recommended in works on dyeing: 50grms. chalk, 15grms. soap, 20grms. lime (per litre of water). Previous experiments made with ammonium carbonate showed that a better result was obtained by using a larger amount than the 14grms. indicated above, hence a second series of the solutions were made equivalent to 20grms. sodium phosphate per litre. The authors studied the action of the fixing bath at three temperatures—viz., in the cold (12 – 15°), a medium temperature (45 – 50°), and lastly the boiling point; and one noteworthy result obtained is that all fixing agents at high temperatures have a greater or less solvent action, proving therefore

that the well-known unsatisfactory results obtained by fixing at the boiling point are not, as was formerly believed, owing to the dehydration of the fixed Al_2O_3 , which thus became inactive, but to the fact that a portion had been stripped off. Only in the case of fixing with lime could it be concluded that a portion of the fixed alumina had been rendered inactive. The duration of action—i.e., passage in the fixing bath—lasted five minutes, thus securing complete action. After the fixing the samples are carefully washed, then divided, one portion being used to estimate the alumina contained in a given area, the other being dyed with alizarin.

Dyeing.—Samples were dyed with an excess of alizarin, then squeezed, dried, and steamed for three-quarters of an hour without pressure (see abstract, p. 525), half the dyed samples were then soaped at the boil for fifteen minutes, and the amount and quality fixed on the fibre, or, in other words, the mode of action of each fixing agent, was judged of by the appearance of the dyed and soaped samples.

Analysis.—As a general result of these experiments, the authors recommend the mordant $\text{Al}_2(\text{SO}_4)_3(\text{OH})_2$ as the best, because, next to $\text{Al}_2(\text{SO}_4)_3$, it is the cheapest; its solutions, either concentrated or dilute, keep well, and give good results on dyeing. The mordant $\text{Al}_2(\text{SO}_4)_3$ is fixed with difficulty, and gives dull tones of colour on dyeing. Pure alumina acetate is not to be recommended, owing to its expense, and because it gives no better result than Nos. 2 and 3.

The results of the various fixing baths are as follows:

(a) **Water.**—Aluminium sulphate by mere exposure to air, and afterwards washing in the water, deposits only 12 per cent. of alumina on the fibre; on the other hand, the whole of the alumina in Nos. 2 and 4 is fixed.

(b) **Ammonia** as a fixing agent gives poor results; this is not surprising, since alumina is so readily soluble in this liquid.

(c) **Carbonate of Soda.**—Although good results might have been expected from this bath, they are, on the contrary, very poor; the cause of this may possibly be that the evolution of carbonic acid forces off alumina from the fibre. In the most favourable instance only 10 to 12 per cent. of the alumina is fixed.

(d) **Ammonium Carbonate** gives the best result both as to the amount of alumina fixed and the beauty of colour produced, the best results being obtained in the cold, since the salt is decomposed even at 60°C .

(e) **Sodium Phosphate** gives the next best results after ammonium carbonate. This fixing bath gives almost equally good results even at the boil. Whenever, therefore, a warm fixing bath appears to be necessary as in the fixing of printed thickened mordants, the use of sodium phosphate is to be recommended.

(f) **Sodium Silicate** also gives very good results. At a higher temperature it has a greater solvent action than phosphate. The temperature to be recommended both in the case of phosphate and silicate is 45°C , since the solvent action commences from this point. The phosphate gives better colours than silicate.

(g) **Sodium Arsenate**, though so closely related to phosphate, gives much worse results.

(h) **Chalk** at 45° gives very good results with mordant No. 5, but at the boil it is absolutely injurious. The unsatisfactory result may possibly be owing to the formation of basic calcium aluminate, as in the case of lime.

(i) **Lime.**—Although analysis shows that a large amount of alumina is fixed very irregularly, dull pinks are obtained, and since the same result is obtained in cold as well as in warm baths, it is not due to a passive state of the alumina caused by dehydration, but to the formation of calcium aluminate, which prevents the formation of the colour-lake.

(k) **Soap** gives unsatisfactory results. Only a small quantity of alumina is fixed, and the colour is irregular and poor, evidently due to the aluminium oleate melting and being partially removed as an emulsion.

(l) **Ammonium Chloride** used only in connection with sodium aluminate produces good results, as may be expected. If the solution be too concentrated the effect is injurious.

General Conclusions.—From these results it is very evident that boiling fixing baths are very injurious, a fact already well known to practical men. The explanation hitherto accepted is that at 100°C the alumina hydrate loses water, and that the dehydrated alumina remaining on the fibre is inactive and unsuited for the formation of the colour-lake. The authors' experiments show that this idea is false, and that really alumina hydrate itself is removed from the fibre. Experiment shows that alumina precipitated at 100°C , and boiled for a long time with water, loses only one molecule of water; total dehydration of alumina hydrate only takes place at very high temperatures. Noteworthy conclusions arrived at are, that besides the sulphate acetates already used in practice, the basic sulphates and sulphate acetates deserve attention; that the excellence of sodium phosphate and chalk as fixing agents, as already employed in special cases, is fully confirmed; and that ammonium carbonate, if the price allowed, would also rank with them as one of the best fixing agents for alumina.—W. R.

On the Influence of Steaming on the Fastness of Colour-lakes after Dyeing. E. Kutschera and A. Utz. Mittheilungen des Tech. Gew.-Museums, August, 1886

HAVING frequently made the observation that when dyed patterns are dried and steamed they are faster to soaping than those which are not steamed, an explanation of the cause was sought for. The observation was made with aniline colours dyed on antimony tannate or on catechu grounds, further with alizarin and other colours dyed on aluminium, iron or chromium mordants. The greatest improvement is always noticed when the dye-baths are exhausted at a low temperature. Two suppositions for such a change may be offered. First, that the mordant itself, or the colour-lake already fully formed in the dye-bath, is simply better fixed upon the fibre; or, secondly, that during the dyeing operation the colour-lake is incompletely formed, and only completed during the subsequent steaming. If the first supposition is correct, then the amount, both of mordant and colouring matter present in the fibre, would be larger after steaming than before; if the second supposition is correct, then the amount of mordant on the fibre would be the same both before and after steaming, and the deeper colour would be simply due to a larger quantity of colouring matter having been taken up. A trial was made by mordanting cloth with three different amounts of chromium mordant and dyeing with alizarin. The cloth was then divided into two parts, one was dried and steamed, the other not. Finally both were soaped, and the chromium estimated in equal portions of the two patterns. In two cases the steamed patterns contained an increase of chromium, but the shades of the patterns were proportionately much deeper than could be ascribed simply to the increase of chromium, and in a third case where the steamed pattern contained less chromium the tone of the dyed colour was nevertheless deeper, hence the authors concluded that the second supposition is the most likely one—viz., that the steaming renders the colour faster to soaping by completing the formation of the colour-lake initiated in the dye-bath.—W. R.

Chrysamin as a Mordant. M. G. Galland. Bull. Soc. Ind. Mulhouse, 1886, 272.

CHRYSAMIN, which is obtained by the action of salicylic acid on diazotised benzidine—its formula is $(\text{COOH})(\text{OH})\text{C}_6\text{H}_3\text{N}_2\text{C}_6\text{H}_4\text{N}_2\text{C}_6\text{H}_3\text{N}_2\text{C}_6\text{H}_3(\text{OH})(\text{COOH})$ —not only dyes cotton without a mordant, but may, according to Knecht (Bradford), even serve as a mordant for methylene blue, safranin and aniline green. The author has used chrysamin and similar colours, such as benzo-purpurin and azo-blue, as mordants for various dyes with the following results:—Two minutes' immersion in a bath containing 1 grm. chrysamin, 2.5 litres water, and 25 grms. sodium phosphate for each square meter of the fabric, gave a canary-yellow shade. The best results

were obtained with triphenylcarbinol derivatives, particularly with Victoria blue, its dark-blue shades resisting better than the others a soap bath for 1½ hours at 70° C. The shades obtained with aniline violet do not resist a soap bath so well, and if produced by magenta, methylene blue, malachite green, Bismark brown, or safranin, they are entirely decomposed by a soap bath at 70°. Other colours, such as Coupier's grey, the phthalein derivatives—eosin, erythrosin, coerulein; anthraquinone derivatives—alizarin, nitroalizarin; anthraquinoline derivatives—alizarin blue and the natural colours—logwood, Lima-extract, cochineal, etc., are not fixed so well, or not at all, and are all entirely destroyed by soap. Benzo-purpurin and azo-blue behave towards aniline and anthracene colours, as also to the natural colours, like chrysamin, but the shades produced by the latter are faster.—A. R.

Improvements in Apparatus for use in Dyeing or Treating Woven Fabrics. Titus Salt, Saltaire, Yorkshire. Eng. Pat. 13,029, Oct. 29, 1885. 8d.

IN the usual apparatus for dyeing plush velvet or other pieces, a winch frame is pushed along the top of the dye-vat and the winch turned on its axis by hand power. In the improved apparatus these movements are automatically produced by belting driven by steam or water power. Four claims are made with regard to the arrangement of different parts.—T. L. B.

Improvements relating to the Dyeing of Silk, Wool and other Substances. W. R. Lake, Middlesex. From Madame Veuve Gaillot, Lyon, France. Eng. Pat. 13,214, November 2, 1885. 6d.

A DYE-BATH is prepared by boiling roasted chicory in water, the proportions given being "one glass" of chicory powder to the litre. The goods are dyed at the boil, fast shades varying from pale straw to chestnut brown, being produced without any mordants. The residue can be used as a blacking or polish.—T. L. B.

Improvements in Bleaching Cotton, and Apparatus therefor. John C. Clayton. From La Société Leblois, Piceni et Compagnie, Paris. Eng. Pat. 14,637, Nov. 23, 1885. 8d.

INSTEAD of bleaching spun cotton in the form of thread in skeins or on cops, the unspun cotton is treated in the state of carded sliver. The various operations are conducted in a specially constructed vacuum chamber, the sliver being carefully packed in open-work boxes; drawings are given of the various apparatus. The bleaching is completed in two days, the operations being as follows:—

The cotton is exposed to the action of:—I. A bath containing 1 per cent. of quillaria saponaria and ½ per cent. of oxalic acid. II. A special lye made as follows: To 90 litres of "lye" marking 30–32° Bé., add 10 litres of chloride of lime solution of 10 chlorometric degrees, and about 3 grms. potassium permanganate. III. To a bath of hypochlorite, preferably a neutral one. IV. To a washing bath containing 1 to 2 per thousand of ammonia. V. To clean water.—T. L. B.

A Novel Process of Dyeing Wool and other Textile Materials in Spools or Bobbins and other Forms, and Apparatus in connection therewith. W. E. Gedge, London. Eng. Pat. 8317, June 23, 1886. 8d.

IN special apparatus, drawings of which are fully given, the dyeing is effected under the pressure of a column of the dye liquor above the goods being treated. The construction of the apparatus permits the liquid to circulate methodically, the direction of the flow being changed at the desired moment by a simple play of cocks, thus ensuring equal and perfect penetration of all the spools or bobbins, etc. Four claims are made.

—T. L. B.

Improvements in Machines for Washing Wool and other similar Materials. Alexandre Deletombe and Amédée Prouvost, Ronbaix, France. Eng. Pat. 9635, July 26, 1886. 8d.

FORKS of the kind used in ordinary circular washing rakes, are so adapted to two endless chains passing over two pairs of wheels, and through guides from end to end of the bath, that having seized the wool, they remain in an upright position until they reach the end of the bath, when they raise the wool and deposit it on the feeding cloth of the wringing press, returning then to recommence work. As the movement of the forks is rectilinear, the change of the surfaces in contact is greater than in ordinary machines, a better scouring takes place, whilst the wool is less "fatigued" and twisted. Drawings are given.—T. L. B.

VII.—ACIDS, ALKALIS, AND SALTS.

Improvements in the Manufacture of Soda by the Ammonia Process. H. Schreib, Salzuflen. Dingl. Polyt. J. 261, 349–351.

IN the usual mode of working the ammonia soda process only 60 per cent. of the sodium chloride is converted into sodium bicarbonate. A portion of the ammonia present escapes the reaction with sodium chloride, and is precipitated as ammonium bicarbonate. In order to better utilise the sodium chloride, and also the apparatus, sodium chloride in a solid form is brought into the carboniser, while the ammoniacal brine is treated with carbonic dioxide. The chloride dissolves in the proportion as the bicarbonate is precipitated, decomposing ammonium bicarbonate and forming another quantity of sodium bicarbonate. To introduce the sodium chloride

a vessel B, holding the salt, is in connection with the carboniser A. By shutting off *c*, and blowing air into B, the liquor in B is forced back into A, and after closing *c*, B can be charged afresh with salt without interrupting the process. The sodium bicarbonate precipitate in the carboniser is separated in the usual manner, whereas the mother-liquor, which chiefly contains sodium and ammonium chloride, is saturated with ammonium carbonate, solid sodium chloride being present. The latter dissolves, whereas ammonium chloride is precipitated and removed by filtering. The mother-liquor now running off contains from 20 to 25 per cent. ammonium carbonate, 24 per cent. sodium chloride, and 9 per cent. ammonium chloride, and re-enters the cycle of operations by being treated with carbonic dioxide in the carboniser, and so forth. The ammonium carbonate required in this process is prepared from the ammonium chloride precipitate and ground limestone.—S. H.

On the Conditions necessary for obtaining Hydrochloric Acid absolutely free from Arsenic by means of Hydrogen Sulphide. Robert Otto. Chem. Zeit. Rep. 10, 169-170.

THE author describes more at length a method for preparing hydrochloric acid perfectly free from arsenic, which he has already given in the 6th edition of F. T. Otto's "Anleitung zur Ermittlung der Gifte, etc." The author and his pupils have found the assumption to be erroneous, that otherwise perfectly pure hydrochloric acid (sp. gr. 1.10-1.12), if treated repeatedly with sulphuretted hydrogen, may be freed entirely from arsenic. But Dr. Bannow has observed that crude spirits of salt may be obtained free from arsenic, by careful treatment with sulphuretted hydrogen, and the author has ascertained the additional fact that the last traces of arsenic, which are not precipitated in pure commercial acid by sulphuretted hydrogen, readily separate as sulphide, if the acid be previously mixed with a certain quantity of any substance which reacts with H_2S , and forms an insoluble body with it. Such substances being invariably contained in crude acid, this is the reason why the latter is so easily purified. Washed sulphuretted hydrogen gas is passed into the crude acid, after, if necessary, diluting to a sp. gr. of 1.12, the latter being continually agitated. When the acid smells distinctly of the gas, it is left in a closed vessel for 24 hours at a temperature of 30-40°, and this treatment repeated until the acid contains an excess of sulphuretted hydrogen. When perfectly clear, the solution is decanted and filtered, and the acid distilled to remove other impurities. The first portion of the distillate, which still contains sulphuretted hydrogen, is collected separately. Then perfectly pure hydrochloric acid comes over, until only $\frac{1}{5}$ of the original fluid remains in the retort. In 5 litres of crude hydrochloric acid, to which 0.1 gram arsenious acid was purposely added, the author could not detect traces of arsenic, after treating in the above way. Under certain circumstances, then, minute traces of arsenic cannot be detected with sulphuretted hydrogen. On the other hand, it must not be forgotten that in judicial examinations a fluid is obtained by the destruction of organic matter with hydrochloric acid and potassium chlorate, which contains substances giving insoluble precipitates with sulphuretted hydrogen, and it may consequently be taken for granted that all arsenic is separated. The author believes that all traces of arsenic contained in otherwise pure sulphuric acid cannot be removed, but that this might occur if a larger amount of arsenious acid or other body which would be precipitated by sulphuretted hydrogen, were added.

—A. R.

Manufacture of Mercury and Sulphurous Acid from Zinc-blende at Oberhausen. F. Bellingrodt. Chem. Zeit. 10, 1039.

THE blende containing 0.02 per cent. mercury is roasted, and the sulphurous acid given off converted into sulphuric acid. It was found that the dust deposited in the flues from the kilns to the towers and chambers contained 6 to 7 per cent. Hg_2 , and that the sludge of lead sulphate at the bottom of the chambers contained 4 per cent. Hg . The mercury is extracted from both flue-dust and lead sulphate. A portion of the gases from the roasted ore is applied to the manufacture of anhydrous sulphurous acid and sulphur. The gases are made to ascend a coke-tower, which is supplied with water. A solution, containing from 12 to 12½ kg. SO_2 per cubic metre of water is obtained, which is deprived of its sulphurous acid by heating. After condensing the steam and drying the gas in a tower filled with solid calcium chloride, it is compressed in a pump to liquid sulphurous acid. The decomposition of sulphurous acid into sulphur is performed in two retorts, one of which is filled with coke and the other with fire-brick. Both are placed side by side and surrounded by fire-gases. The sulphurous acid is decomposed chiefly into carbon dioxide and sulphur, which is conveyed into large condensing chambers.

—S. H.

Preparation of Hydrochloric Acid free from Arsenic. H. Hager. Pharm. Zeit. 1886, 31, 401.

BECKURTS recommends an addition of ferrous chloride to the crude acid; then by distilling fractionally he separates first 30 per cent. containing arsenic, and then 60 per cent. acid free from arsenic; the residue in the retort not being used. Now the author found, that $\frac{2}{3}$ ths of the acid which distilled over first contained arsenic, that the following portion contained traces of iron, the presence of the latter being easily accounted for, as ferrie chloride is volatile with hydrochloric acid gas at 110°. The following method is recommended: Crude spirits of salt are treated with tinned plate shavings. Arsenic separates in flakes, and the acid is filtered through glass wool. Or the acid is treated with copper shavings, to which arsenic firmly adheres, so that it is merely necessary to decant the fluid. It is safer to repeat the treatment. 36 hours are necessary to entirely remove the arsenic if the acid is only macerated with the shavings; a few hours suffice, if gentle heat be applied.—A. R.

Removing Arsenic from Hydrochloric Acid. H. Beckurts. Pharm. Zeit. 1886, 31, 439.

THE author replies to some remarks of Hager on the removal of arsenic from hydrochloric acid by means of ferrous chloride. It was not his object to give a method for producing acid free from arsenic suitable for pharmaceutical purposes, but rather a method for the production of an acid suitable for judicial chemical investigations; in such an acid the presence of a little iron is not prejudicial. The author promises to investigate Hager's proposal to purify the acid by digesting strips of copper in it, and will specially seek to ascertain if the acid can thus be obtained sufficiently free from arsenic and copper.—J. T.

Notes on Hydrated Sodium Sulphides. C. Göttig. J. Prakt. Chem. 34, 1886, 229-237.

By mixing a moderately concentrated aqueous sodium hydrate solution, which is saturated with sulphuretted hydrogen, with an equal volume of a sodium hydrate solution of the same strength, crystals are obtained, testing $Na_2S + 9H_2O$. The solution of those crystals is that used for analytical purposes. Böttger produced crystals with $5H_2O$ by treating an alcoholic sodium hydrate solution in the same manner as mentioned above. The author finds that if the conditions of working are varied, crystals of the following compositions can be obtained:— $Na_2S + 5H_2O$; $2Na_2S + 11H_2O$; $Na_2S + 6H_2O$; $Na_2S + 9H_2O$. If sulphuretted hydrogen be passed into an alcoholic sodium hydrate solution of a specific gravity lying between 0.900 and 0.933, and for the preparation of which alcohol of 96 per cent. to 97 per cent. is employed, a copious crystallisation of silky needles is produced. The same is the case if 75 per cent. alcohol be used, and the specific gravity of the solution is above 0.990; or, if 99 per cent. alcohol be used, and the specific gravity varies between 0.908 and 0.910. If the alcohol is too strong (99.8 per cent.) or too weak (65 per cent.), no formation of crystals takes place. The crystals, however, possess no definite character, being chiefly mixtures of two hydrates, which can be separated by fractional crystallisation. The tables on p. 535 show the results and details of several experiments. Table I. contains the tests of the crystals which appeared first—line needles. Table II. contains the tests of the crystals which were deposited after separating the first crop. They were larger and harder, and sometimes granular shaped.

It thus appeared that the specific gravity of the alcohol employed, as well as the strength of the sodium hydrate solution, have an important influence on the hydration of the crystals. A caustic soda solution, for the preparation of which 99 per cent. alcohol was used, gave, with sulphuretted hydrogen, crystals which, after being left in the mother-liquor for 28 days, contained 26.85 per cent. Na, corresponding with the formula $Na_2S + 5H_2O$. A solution made up with 75 per cent. alcohol gave crystals which, left in the mother-liquor for 30 days,

tested 19.12 per cent. Na, corresponding with $\text{Na}_2\text{S} + 9\text{H}_2\text{O}$. All the experiments go to show that on treating a sodium hydrate solution in strong alcohol with sulphuretted hydrogen, crystals of $\text{Na}_2\text{S} + 6\text{H}_2\text{O}$ are

tact with very strong alcohol, they gradually lose water, whereas they take up water from dilute alcohol, forming $\text{Na}_2\text{S} + 9\text{H}_2\text{O}$. Any of these compounds recrystallised from absolute alcohol yields crystals of $\text{Na}_2\text{S} + 5\text{H}_2\text{O}$;

TABLE I.

	PER CENT.			SPECIFIC GRAVITY.		REMARKS.
	Na.	S.	H_2O .	Of Alcoholic NaOH Solution.	Of Alcohol employed.	
1.	21.19	—	—	1.028	0.901	The crystals tested were made from solutions freshly prepared. They were at once separated from the mother-liquor, pressed between filter-paper, and tested without delay.
2.	21.21	—	—	1.028	0.901	
3.	21.68	—	—	0.910	0.795	
4.	21.20	—	—	0.995	0.860	
5.	21.16	—	—	0.908	0.795	
6.	21.62	—	57.8	0.922	0.809	
7.	21.63	—	—	0.922	0.809	
8.	21.8	—	58.48	0.922	0.809	
9.	21.5	—	—	0.995	0.810	The crystals were in the mother-liquor for one hour before they were tested.
The tests correspond pretty well with the formula, $\text{Na}_2\text{S} + 6\text{H}_2\text{O}$, which requires :—						
Per cent.						
Na = 21.73						
S = 17.20						
H_2O = 58.06						

TABLE II.

	PER CENT.			SPECIFIC GRAVITY.		REMARKS.
	Na.	S.	H ₂ O.	Of Alcoholic NaOH Solution.	Of Alcohol employed.	
1.	—	—	66.3	0.995	0.863	Crystals were at once separated from the mother-liquor.
2.	—	—	67.1	0.995	0.858	} Crystals remained in the mother-liquor for 18 hours.
3.	18.91	—	—	0.995	0.858	
4.	19.2	—	—	0.995	0.858	} Crystals were washed with 99.8% alcohol for some time.
5.	—	—	57.1	0.925	0.808	
6.	26.2	17.86	—	0.910	0.808	S was determined as BaSO ₄
7.	—	18.47	—	0.915	0.808	S was determined as CdS } Crystals were at once separated from the mother-liquor.
8.	26.2	—	—	0.930	0.808	Crystals remained in the mother-liquor for several hours.
9.	25.7	—	—	0.910	0.795	Crystals were at once separated from the mother-liquor.
10.	26.65	—	—	0.910	0.795	Crystals remained in the mother-liquor for 8 hours.
11.	25.15	—	—	0.905	0.808	} Crystals were at once separated from mother-liquor, and washed with 96% alcohol for some time.
12.	25.8	—	57.4	0.920	0.809	
13.	25.2	—	55.7	0.998	0.809	

The first four tests correspond with the formula, Na₂S+9H₂O, which requires : —

Per cent.

Na = 19.17
S = 13.33
H₂O = 67.50

The remainder approaches more closely to the formula, 2Na₂S+11H₂O, which requires :—

Per cent.

Na = 25.93
S = 18.09
H = 55.98

forming in the first instance; the solution gradually becoming deprived of its water, then deposits crystals of $2\text{Na}_2\text{S} + 11\text{H}_2\text{O}$, and afterwards crystals of $\text{Na}_2\text{S} + 5\text{H}_2\text{O}$. All these compounds disappear if the action of sulphuretted hydrogen is continued too long. Left in con-

recrystallised from dilute alcohol they form $\text{Na}_2\text{S} + 9\text{H}_2\text{O}$. Sulphuretted hydrogen, acting on a concentrated solution of sodium hydrate in dilute alcohol, forms $\text{Na}_2\text{S} + 6\text{H}_2\text{O}$ in the first instance, and afterwards $\text{Na}_2\text{S} + 9\text{H}_2\text{O}$.

Improvements in Plant or Apparatus to be used in the Treatment of Residuals from Copper Works and Chlorine Manufacture to obtain Pigments and Sulphate of Lime. G. L. Wigg, M. Steele, and W. Wigg, Runcorn. Eng. Pat. 11,129, Sept. 19, 1885. 8d.

BOTH pigments and sulphate of lime are prepared from residuals, such as sulphate of iron liquors from copper and other works, and calcium chloride liquor from the Weldon chlorine process. The first part of the plant consists of precipitating and washing vessels provided with mechanical agitators, so arranged that the contents can be run from one part to another by gravitation. The second part relates to apparatus for oxidising and filtering precipitated iron, and is also provided with a reverberatory furnace to dry the precipitate. Means are then provided for the further treatment of oxidised iron, consisting of a combination of horizontal millstones, a washing vessel, a drying bed, a lixiviator, and a roller mill.—S. H.

Improvements in the Manufacture of Sulphur and Ferric Oxide from Alkali Waste by means of Metallic Chlorides. P. Mawdsley, Flint; and T. Macfarlane, Montreal. Eng. Pat. 11,178, Sept. 19, 1885. 6d.

"YELLOW LIQUORS" of 20° Tw. are prepared by lixiviating partially-oxidised alkali waste. The solution of calcium sulphides thus obtained is treated with iron chloride solution from copper-extracting works, or other sources. A black precipitate is formed consisting of iron proto-sulphide and free sulphur, which is filtered, washed and dried at a low temperature. The result is a coarse black powder containing about 70 per cent. of hydrated iron proto-sulphide, and 30 per cent. of free sulphur. The mass is introduced into a small furnace, heated to low redness and constructed on the same principle as the "blind roaster" used in manufacturing salt-cake. The charging doors are then carefully luted, and the heat being continued, the free sulphur is sublimed and carried over into a condensing chamber. After the free sulphur has been driven off, air is allowed to have access to the furnace, when the sulphur of the iron proto-sulphide ignites, forming sulphur dioxide, which is used for producing sulphuric acid in the ordinary manner. After this calcination the residue consists chiefly of ferric oxide in a very fine state of division, and well suited for use as a pigment. Analogous results may be obtained by the use of other metallic chlorides, such as zinc or manganese chloride.—S. H.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

Improvements in the Process of Gilding Glass. James Pratt, London. Eng. Pat. 12,014, Oct. 9, 1885. 6d.

THE inventor cleans glass surfaces with chloride of tin—pours thereon the gilding solution, the glass being heated and inclined—preferably after the manner described in No. 515 of 1882. The gilding solution is prepared from chloride gold, 3 parts; caustic soda, 1 part; glycerine diluted, and mannite. The film of gold is thickened and preserved by a backing of silver—deposited from the usual silvering solution.—T.

Improvements in the Manufacture of Articles of Glass, Porcelain, Earthenware, and the like. Jean Marie Beurel, Paris. Eng. Pat. 14,462, Nov. 25, 1885. 4d.

THIS invention is a mode of preventing accidents resulting from the breakage of glass, porcelain, and similar articles by introducing wire net-work into the glass while it is in a melted or plastic state.—T.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

On the Manufacture and Testing of Cement. Dingl. Polyt. J. 261, 344—349.

W. JOY, Northfleet, proposes the introduction of the cement mixture, in a pasty state, into the furnace. The

materials, mixed with small coal or coke, are ground up with water, and the moist mixture is thrown on the top of a heated charge, so that the course of the fire-gases is obstructed, thereby causing a change of current with each addition of the mixture. It is thought to produce by this means a more complete calcination of the mass. The same article gives the standard tests adopted by the Association of German Cement Manufacturers for the uniform delivery and examination of Portland cement. The rules, which are too extensive to be suitable for abstraction, deal with (1) packing up and weight, (2) setting-time, (3) constancy of volume, (4) fineness, (5) power of binding, (6) preparation of samples of neat cement and of cement and sand mixtures to determine the power to resist different kinds of stress.—S. H.

Improved Composition or Cement for use in jointing Stoneware, Concrete, &c. W. Hassall, Beeston. Eng. Pat. 11,001, Sept. 16, 1885. 4d.

FOR use in making castings and the like, oxide of iron from gas purifiers is mixed with gas-tar or pitch, commercially pure sulphur, and either quicklime, limestone, or ground slag, as circumstances may require.—E. G. C.

Improvements in the Manufacture of Cement. R. Stone, London. Eng. Pat. 11,098, Sept. 18, 1885. 8d.

THE inventor claims the use of a mixture of oil of vitriol and petroleum or petroleum spirit, or any other highly inflammable liquids, to be added to the wet slurry in place of the customary admixture of ordinary fuel, as coal, coke, or breeze. The slurry can thus be placed directly in the furnaces or kilns, and the drying and burning are conducted in one operation. A better cement is said to be produced, and at less cost. Draught shafts, of brick, wood, or other material, are also erected by the inventor. In some instances he burns the chalk and river mud, as raw material, without washing, either as above or in the ordinary way; the novelty in this case "being the direct application of the raw material, and the saving of washing, drying, and turning thereby effected."—E. G. C.

Improvements in the Manufacture of Cement. E. W. Killick, Northfleet. Eng. Pat. 11,270, Sept. 22, 1885. 4d.

LIME, chalk, and clay are mixed with suitable fuel, by crushing and grinding, so as to form a stiff pug ready for insertion into the kiln for burning; washing, pumping, and drying being thus dispensed with. One fourth part of the mixture may be made of the fuel.—E. G. C.

Improvement in the Manufacture of Cement. H. H. Lake, London. From U. Cummings, U.S.A. Eng. Pat. 7361, June 1, 1886. 4d.

THE object of the invention is to reduce the cost of the cement by the manufacture of sulphuric acid as a by-product. The materials used are clay or siliceous acid and sulphate of lime, instead of the clay and carbonate of lime usually employed.—E. G. C.

Improvement in the Manufacture of Cement. H. Mathey, New York. Eng. Pat. 7675, June 8, 1886. 4d.

THE inventor claims a process of manufacture consisting in "first crushing the natural cement stone to a suitable degree of fineness, then thoroughly mixing crushed clay with the stone, and burning these elements together in a state of agitation and dissemination; next adding, after burning, a pulverised metallic ore, roasted separately to form an oxide, and finally pulverising the stone, clay, and oxide together."—E. G. C.

X.—METALLURGY, Etc.

The Behaviour of Zinc containing Lead on Re-melting.
E. Kraut. Zeits. Anal. Chem. 25, 169—172.

THIS research was undertaken in consequence of the discordant results obtained in the determination of lead in zinc containing lead. It was found that samples from three plates, prepared by melting the metal and pouring it out in three portions, gave 2.32, 2.92, and 1.72 per cent. lead respectively, and a sample obtained by granulation 4.80 per cent. lead. This zinc was used for the experiments, which were made by melting up the metal in a crucible, well stirring, withdrawing a sample and granulating it, then allowing the remainder to cool slowly and analysing the bottom, the next lowest and top layers of the metal. 1819 grms. of zinc were melted, and the results were:—

Granulated metal	1543	lead.
The bottom layer of the regulus, 43 grms. . .	4.121	"
The layer immediately above this, 223 grms. .	2.847	"
The top layer of the regulus.	0.943	"

The further results are given in the following table:—

Melts	1.	2.	3.	4.	5.	6.
Quantity of Zn used in grms.	2000	1819	1395	710	455	388
Granulated portion, % Lead.	1.656	1.543	1.213	0.936	—	—

Lowest Layer:						
Weight in grms.	45	43	9	—	14	—
Percentage of Lead	5.339	4.121	5.472	—	1.754	1.180

Next Lowest Layer:						
Weight in grms.	—	223	207	—	—	—
Percentage of Lead	—	2.847	1.880	—	—	—
Upper portion, % Lead	1.003	0.942	0.744	0.803	0.610	0.561

From these numbers it will be seen that it is impossible to determine the amount of lead in a zinc by preparing a series of plates and taking a sample from each, and the author recommends that when the metal is melted it should be well mixed by stirring, and a small quantity removed with a ladle and the whole of this taken for analysis.—G. H. M.

Improvements in the Treatment of Ores and Materials containing Sulphur for the Extraction of Metals and other Constituents. Robert Oxland, Plymouth; and Charles Oxland, Sydenham. Eng. Pat. 10,024, August 24, 1885. (d.)

THE mixed ore is digested for about half-an-hour at 600° F. with strong sulphuric acid in suitable vessels connected with a vitriol chamber. All the copper and a portion of the iron, together with silver and gold, are thus rendered soluble, and may be washed from the remaining iron pyrites, which is then available for vitriol making, the copper solutions being treated by any known method. The acid may, with advantage, be mixed with ferrous sulphate from a previous charge, before adding to the ore. By prolonged digestion with much acid nearly the whole of the iron pyrites is attacked; at the same time sulphur is separated, and may be collected in depositing chambers as a marketable product. In treating concentrates from auriferous quartz working in this manner, all the pyrites should dissolve and carry with it but little gold, which may be precipitated by iron; the mixture of quartz and free gold may then be readily amalgamated. If the concentrates are roasted before treatment, a larger proportion of the gold will pass into solution. Bisulphates may be substituted for the free acid in any of these processes.

—W. G. M.

The Recovery of Rich Calcium Phosphate in combination with an Improvement of the Thomas-process. C. Scheibler. Ber. 19, 1883—1893.

THE author, referring to his patent (this Journal, 1885, 226) for separating slags from the Thomas-Gilchrist process into two portions, one rich in phosphoric acid, the other rich in iron, points out that the same effect may be produced by fractionation in the converter itself. According to the ordinary method of procedure with this method, 18 to 20 per cent. of caustic lime is added to the charge in the converter, but the author uses only 12 per cent., which is added in two portions. The operation is

carried out by adding two-thirds of the lime before the fusion of the iron, and then using the blast until the slag is saturated with phosphoric acid, without any very great quantity of iron oxide being formed; the first slag is then run off as far as possible. It is impossible to run off the whole of the first slag, so some always remains in the converter and mixes with the second. After running off the first slag rich in phosphoric acid, the second portion of lime, about one-third, is added, and the charge again blown. A slag rich in iron and poor in phosphoric acid is formed. It is claimed that this method possesses the following advantages:—

1. The required quantity of lime is reduced to at least two-thirds of that formerly required.

2. The length of time of the blow is diminished, since the chemical operations are executed more quickly.

3. The weight of raw iron which can be converted in a single charge is greater.

4. The loss is less than formerly.

5. Greater heat of the charge, and consequently very fluid steel.

6. Dephosphorisation is carried much farther than in the former method, without increasing the loss of iron.

7. Two sorts of slag are obtained as by-products, of which the first contains the greater quantity of the separated phosphoric acid, together with only a small quantity of iron, whilst the second slag contains the greater quantity of the oxidised iron, with only very little phosphoric acid.

The following are analyses of the two sorts of slag obtained at the Thomas-Gilchrist Steel Works, of Hörde:—

FIRST SLAG.

P ₂ O ₅ . . .	27.31	28.10	28.95	31.29	31.50	32.59
SiO ₂ . . .	6.25	4.42	5.45	1.16	4.56	5.19
CaO . . .	53.06	52.27	51.52	—	58.88	60.72
MgO . . .	3.76	4.73	4.60	—	2.54	—
Fe	5.75	6.24	3.82	3.56	1.80	—
MnO . . .	3.47	4.16	4.42	—	2.06	2.16
CaS . . .	0.96	1.19	1.24	—	—	—

SECOND SLAG.

P ₂ O ₅	17.79	16.10	17.26
SiO ₂	4.29	4.38	4.68
CaO	44.78	41.60	43.49
MgO	5.44	2.44	5.81
Fe	19.09	21.01	19.75
MnO	4.45	3.26(Mn)	3.85(Mn)
CaS	0.83	—	0.81

FIRST AND SECOND SLAGS OF TWO CHARGES.

P ₂ O ₅	SiO ₂	Fe	P ₂ O ₅	SiO ₂	Fe
27.65	4.89	4.50	17.30	2.96	22.16
29.67	4.45	4.77	16.93	2.74	23.65

By this method a nearly complete removal of the phosphorus is effected (down to 0.015 per cent.). The first slag forms a valuable manure owing to its high percentage of phosphoric acid, whilst the second forms a valuable raw product for smelting works.

The first slag may be either directly applied to the land in a fine powder, or converted into calcium bisphosphate. The latter is formed by dissolving the slag in hydrochloric acid, adding milk of lime to neutralisation, and filtering the resulting precipitate by means of a filter-press. So obtained, it is a soft white precipitate, which is much more soluble in water saturated with carbonic

acid than the finely-powdered slag. The calcium biphosphate contains 33–38 per cent. phosphoric acid.

The following table shows the great difference in composition, especially in the amount of phosphoric acid, in the ordinary Thomas-Gilchrist slag:—

	P ₂ O ₅	SiO ₂	CaO	MgO	FeO	Fe ₂ O ₃	MnO	CaS	Al ₂ O ₃
Slag from Middlesbro' (Bolekov Vaughan)	8.60	17.78	46.62	5.76	16.71	—	1.22	—	2.45
" " " "	14.26	10.00	50.60	4.96	17.14	—	1.80	—	—
" North Eastern Steel Works....	12.92	9.80	—	—	—	18.51Fe	—	—	—
" " " " " "	16.09	7.42	53.30	2.06	11.70	—	5.70	0.62	4.08

—G. H. M.

The Change of Texture of Steel on Heating and Cooling.
J. A. Brinell. Dingl. Polyt. J. 261, 341–344.

STEEL contains carbon either as "cement-carbon" or as "tempering-carbon," and the change of texture of tempered steel is due to the conversion of one state of carbon into the other. Carbon in not-hardened steel is cement-carbon, whereas tempered steel contains tempering-carbon. On examining the changes taking place on heating and cooling heated steel, it was observed that steel cools quicker than iron in the first state of cooling, whereas later on the reverse is the case. This is accounted for by the fact that both iron and steel form crystals on cooling; this formation of crystals is, as it were, so much work performed, which work requires an unequal amount of heat. It is a well-known experience that the same kind of steel often undergoes apparently arbitrary changes of texture on tempering, and experiments were made with a view to detecting these laws, if possible. The Bessemer steel used in these experiments contained: C, 0.52%; Si, 0.13%; P, 0.026%; Mn, 0.48%; S scarcely traces. The author draws the following conclusions from his experiments: If steel loses its coarsely crystalline texture without being hammered, it is owing to the conversion of cement-carbon into tempering-carbon, or *vice versa*. If carbon is to be converted into cement-carbon, steel heated to a white heat must cool slowly to a lower temperature than that to which untempered steel must be heated if its carbon is to be converted into tempering-carbon. The conversion of cement-carbon into tempering-carbon takes place very quickly if the heat is high enough. If tempering-carbon is converted into cement-carbon, heat is always liberated, and it is highly probable that heat is absorbed in the reverse case. If cement-carbon is changed into tempering-carbon—completely or partially—by heating or cooling, a crystallisation is brought about quite suddenly, which is all the more coarsely-crystalline if the steel had already that texture before treatment. By quickly cooling heated steel, the texture is not altered, but the texture, after cooling, is, as a rule, the same as that which the steel possessed immediately before the commencement of cooling. For converting tempering-carbon into cement-carbon not only the right degree of heat is required, but also time, whereas the conversion of cement-carbon into

tempering-carbon only depends upon the right degree of heat. Consequently, quick cooling may prevent the change of tempering-carbon into cement-carbon. The crystallisation of steel also requires the right degree of heat and time, and if the latter condition is not fulfilled

—i.e., by quickly cooling steel—the formation of crystals is diminished or even completely frustrated.—S. H.

Improvements in the Manufacture of Cupels in the Cupellation of Metals and in the Production of other Refractory Apparatus and Materials. F. Maxwell-Lyte, London. Eng. Pat. 10,185, August 27, 1885. 6d.

MAGNESIA, if free from all lime salts other than the phosphate, forms an excellent substitute for bone ash in the manufacture of tests and cupels. The magnesia compound—e.g., magnesite—is highly calcined, and after treatment with dilute hydrochloric acid or magnesium chloride solution, if necessary to remove lime may be re-calcined, crushed, and sifted. It may then be used alone, or mixed with lightly calcined magnesia, or bone ash, or with a metallic oxide or clay to give strength, or sawdust or flour to increase the porosity. After setting, the cupels may be fired or not; whilst setting they should be kept in a moist condition to prevent cracking. A layer of bone ash or bone ash and magnesia should be placed on the top of the cupel.

—W. G. M.

The Utilisation of Waste Tin, Tin Plate, Lead, and Terne Plate. E. R. Blundstone, London. Eng. Pat. 11,624. Sept. 30, 1885. 6d.

THE waste material is to be digested to saturation with hot perchloride of chromium solution, which on cooling will deposit the tin and lead in a crystalline metallic form, the whole operation being conducted in vats in an atmosphere of carbon dioxide.—W. G. M.

Improvements in the Manufacture of Sodium and Potassium. P. M. Justice, London. From H. Y. Castner, New York, U.S.A. Eng. Pat. 7395, June 2, 1886. 6d.

INSTEAD of mixing sodium carbonate with carbon and lime, whereby soda-lime is formed at the high temperature of the retorts, and only about one-third of the sodium contained in the charge is reduced, it is mixed with a metallic carbide. Preferably caustic soda and an

intimate mixture of carbon with metal should be used; the latter is prepared by coking finely-divided iron or oxide saturated with a hydrocarbon, so proportioned as to produce a mass containing 70 per cent. of iron and 30 of carbon. By this reaction, which takes place at a lower temperature than that required in the old process, the whole of the sodium (or potassium) is reduced and distilled, thus:—

and $\text{Na}_2\text{CO}_3 + \text{NaCO} = 3\text{Na} + 2\text{CO}_2$; or, in one equation, $3\text{NaHO} + \text{FeC}_2 = 3\text{Na} + \text{Fe} + 3\text{H} + \text{CO} + \text{CO}_2$. The residual iron and any excess of soda at the conclusion of the process are available for use again.—W. G. M.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

A New Thickening Material for Mineral Lubricating Oils.

L. Marquardt. *Zeits. Anal. Chem.* 25, 159–160.

This new material is the aluminum salt of the higher fatty acids. A ten per cent. solution of it in mineral oil occurs in commerce under the name of “fluid gelatin,” although it does not contain a trace of gelatin. The liquid forms a brown, fairly clear, syrupy, viscous solution, with a tendency to shrink up like gelatin. This “fluid gelatin” is added to mineral lubricating oil to increase its viscosity.

It can be detected in solution in mineral oil by shaking the latter with 95 per cent. alcohol, and then adding ether slowly until the aluminium oleate, etc., separates first in flakes and then in clots; on the addition of more ether it goes into solution again. To determine the amount present quantitatively the following process is recommended:—The oil is heated with dilute hydrochloric acid on a water-bath with frequent stirring. The hydrochloric acid dissolves out the alumina, whilst the fatty acids remain dissolved in the mineral oil. The separated oil is then treated with sodium hydrate solution, which takes up the fatty acids, and the pure mineral oil is then separated from the alkaline solution. The former is then weighed, and the difference between this and the amount taken gives the quantity of aluminium salt present. The result can be controlled by separating the fatty acids from the alkaline liquid with hydrochloric acid and weighing it, and also by determining the amount of aluminium in the same solution in the ordinary way.—G. H. M.

The Elaidin Reaction. Professor Finkener. *Chem. Zeit.* 10, 1039.

EXPERIMENTS are at present going on in the laboratory of the Imperial Board of Trade at Berlin on the testing of pure olive oil. If 10cc. of pure olive oil be treated in a test-tube with 1cc. nitric acid of 1.4 sp. gr. and 0.4 copper filings, a reaction at once takes place, which is finished in half a minute, and is attended by a rise of temperature. On shaking, the red vapours are absorbed, and if the oil be cooled to 12° C. it solidifies in half-an-hour. If nitric acid and copper be replaced by sulphuric acid of 1.53 sp. gr. and a concentrated solution of potassium nitrite, the oil, on shaking and cooling to 10–12° C., does not become solid even after 24 hours have elapsed. Nitric acid of 1.2 sp. gr. and potassium nitrite solidify the oil in 12 hours. Nitric acid of 1.4 sp. gr. and potassium nitrite effect solidification in 3 hours. Nitric acid of 1.4 sp. gr. without any addition does not solidify the oil, whereas equal quantities of fuming nitric acid and water solidify oil in 4 hours. If nitrous vapours are passed through the oil, solidification sets in after a few hours. If copper is replaced by mercury, the action of the acid is delayed. If 0.8 grm. copper is employed instead of half that amount, the phenomena are not altered. If both copper and nitric acid be doubled, the oil requires more time for solidification, and the product of the reaction is softer. If the quantities and proportions between nitric acid and copper are the same, the circum-

stances attending the reaction are always uniform and comparable.—S. H.

On the Chemical Composition of Grease from the Wool of Sheep. A. Buisine. *Compt. Rend.* 103, 66.

THE exudations of sheep, which collect on their wool, are well known to contain substances soluble in water, and substances insoluble in water but soluble in alkalis. The author finds that the substances soluble in pure water contain numerous potassium compounds. He observed the presence of (1) free carbonic acid; (2) ammonium carbonate (by the decomposition of urea); (3) potassium carbonate (due to a peculiar fermentation which goes on at the cost of certain secreted substances); (4) volatile fatty acids—viz., acetic, propionic, butyric, valeric, and capronic acids; (5) higher fatty acids, such as ananthic, capric, oleic, stearic acids, and particularly cerotic acid. These are present as potassium salts, which are formed on the skin or by washing in consequence of saponification by potassium carbonate; (6) fat in the state of an emulsion; (7) phenol as potassium sulphate; (8) lactic acid; (9) benzoic acid; (10) oxalic acid; (11) succinic acid; (12) uric acid; (13) amido acids—viz., glycocyl, leucyl, tyrosyl; (14) colouring matter, the same as in the urine. The aqueous extract of the wool consequently contains all substances (or their decomposition products) generally found in the urine of herbivorous animals. The extracts may become a valuable source for obtaining acetic, propionic, benzoic, lactic, and capronic acids, these being present in considerable quantities. The grease of an Australian wool gave in 100 parts dry residue: 7.1 parts acetic acid, 4 parts propionic acid, 2.6 parts benzoic acid, 2.5 parts lactic acid, and 1 part capronic acid.—A. R.

XII.—PAINTS, VARNISHES, AND RESINS.

Improved Process for Bleaching and Refining Resins and similar Substances. O. Murray, London. From Dr. E. A. Behrens, Bremen. *Eng. Pat.* 11,177, Sept. 19, 1885. *Sd.*

THE resins are treated with benzene, petroleum benzene, bisulphide of carbon, ether, alcohol, etc., so as to obtain complete solution. The solution is then treated with suitable reagents, and separated therefrom. The volatile substances used for dissolving the resins are recovered, and used again.—E. G. C.

Apparatus for the Manufacture of White Lead. J. Haylor, H. S. Read, and H. G. Percival, Middlesex, Herts, and Essex. *Eng. Pat.* 13,115, Oct. 30, 1885. *Sd.*

THE floor of the carbonating chamber is a hot plate, heated by steam or hot water pipes or coils below it, and over this floor is spread a layer of acetic acid. In the middle or other suitable part of the chamber is placed on the floor a box, which receives a supply of air and carbonic acid from without, and the edges of which are immersed in the acetic acid. The sides of the boxes are perforated with numerous small holes, and the gases, mingled with acetic acid vapour, issue from these holes in a diffused condition and distribute themselves over the chamber, in which the pieces of lead are arranged on shelves or frames. The gases pass from the first chamber into a second chamber containing other pieces of lead for conversion. The lead gratings encrusted with carbonate are moved by lifts, travelling bands, or otherwise to the mill in which the carbonate is separated from the metallic lead and prepared for the market.—E. G. C.

An Improved White Pigment. J. B. Freeman, Tottenham. *Eng. Pat.* 13,891, Nov. 13, 1885. *6d.*

THIS invention relates to an improvement in a white pigment already patented by the inventor (*Eng. Pat.*

4879, Oct. 13, 1882), consisting of a mixture of lead sulphate and zinc oxide or sulphide. He now adds barium sulphate, the result being a pigment of greater density, body, and opacity.—E. G. C.

Improvements in "Anti-Fouling" and "Anti-Corrosive" Paints or Compositions. J. Pointon, Liverpool. Eng. Pat. 13,159, Oct. 31, 1886. 6d.

THE inventor claims: "A paint or mixture consisting of ground glass, pulverised slag, or sand, together with linseed oil, a solution of crude turpentine in spirits of turpentine, and a composition, resulting from the combination of the preceding, and possessing the advantages of being practically non-drying, impregnable to water, and 'anti-fouling.'"—E. G. C.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

Improvements in Tanning and Currying Hides and Skins. W. P. Thompson, Liverpool. From John W. Fries, Salem, U.S. Eng. Pat. 7692, June 8, 1886. 6d.

THE hides, previously unhaired by any of the well-known processes, are suspended in a pit containing a solution of carbonate of protoxide of iron. The carbonate of iron solution can be prepared by dissolving 3lb. copperas and 2lb. bicarbonate of soda per cubic foot of water. After about two days in this liquor, the hides are placed in a solution of 25–40lb. copperas and 15–25lb. common salt per cubic foot of water. After from two to three days the hides are hung up to dry, when (the inventor states) the ferrous oxide is oxidised to ferric oxide throughout the hide substance. The currying of this leather may be similar to that of bark-tanned leather, but the inventor states that a mixture of castor oil and alcohol gives the best result. There are six claims to the patent.—B. H.

XIV.—AGRICULTURE, MANURES, Etc.

Abstract from the Report of the Committee of French and Belgian Chemists on the Methods for Testing Artificial Manures. Chem. Zeit. 10, 875.

Estimation of Nitrogen.—1. If the nitrogen is in the state of nitric acid, Schloesing's method is to be used. The purity of the nitric oxide evolved must be ascertained by its being completely absorbed by acid ferrous sulphate solution. The nitrates must be in aqueous solution. Mixed manures, containing organic matter, are first treated with lime, then extracted with 50 per cent. alcohol. After driving off the latter, the residue is taken up with water and tested for nitric acid. 2. Nitrogen, in the form of ammonia, is estimated by distillation with magnesia. Potassium or sodium hydrate is inadmissible. 3. Nitrogen, in the form of organic compounds, is determined by Will and Varrentrapp's method. 4. Mixed manures, containing ammoniacal and organic nitrogen, are first distilled with magnesia, and then by Will and Varrentrapp's process. 5. Mixed manures, containing nitrates and ammonia, are tested by Schloesing's method and distillation with magnesia. 6. Mixed manures, containing nitrates and organic nitrogen, are tested by Schloesing's method, and, after destroying in a separate operation the nitrates by means of ferrous chloride or oxalic acid, the organic nitrogen is determined by Will and Varrentrapp's process. 7. The total nitrogen is estimated by Dumas' method. Rufflé's process may be used, but only after driving off ammonia. Kjeldahl's method cannot be generally applied, as the presence of nitrates liberates chlorine from any chlorides present which would act upon ammonia.

Estimation of Potassium.—Crude potassium chloride is tested with platinum chloride; in mixed manures, the percentage of potassium must be determined by Corenwinder's method. After calcining the sample before the analysis, the aqueous solution is strongly acidified, treated with an excess of platinum chloride, and evapo-

rated nearly to dryness. The cold residue is taken up with ether-alcohol, filtered, and the crystals on the filter washed with the same mixture. The crystals are then dissolved in boiling water, and the boiling solution is decomposed with sodium formiate, metallic platinum being deposited, which is washed with hydrochloric acid and dried. From it the amount of potassium is calculated.

Estimation of Phosphoric Acid.—The total phosphoric acid is estimated by dissolving the sample of manure in hydrochloric acid, and precipitating the phosphoric acid in a measured portion by means of magnesia citrate and ammonia. The precipitate is filtered after twelve hours' standing, washed, dissolved in dilute nitric acid (1:10), treated with sodium acetate, and titrated with uranium nitrate. Soluble phosphoric acid is determined in the aqueous extract, whereas the reverted phosphoric acid in the residue is made soluble by digestion with ammonium citrate.—S. H.

On the Distribution of the Nitrifying Organism in the Soil. R. Warington.

PREVIOUS experiments conducted at Rothamsted on this subject (*Trans. Chem. Soc.* 1884, 645) had led to the conclusion that the nitrifying organism is always to be met with down to 9in. from the surface, and that at 18in. it is sometimes present; but experiments with soil 2–8ft. from the surface failed to yield evidence of the presence of the organism.

Further experiments have been made in 1885, and during the present year, both in the field with the stiff clay subsoil previously worked on, and in another field having a loamy subsoil; in all, sixty-nine new experiments have been made. The soil in the previous experiments was removed, with suitable precautions, from a freshly-cut surface, and placed in sterilised solutions, consisting of diluted urine—0.4 per cent. It having since been found that the facility with which urine nitrifies is greatly increased by the presence of gypsum (*Trans. Chem. Soc.* 1885, 758), an addition of a small quantity of gypsum was made to the solutions employed in all the recent experiments; rather larger quantities of soil were also employed. The results may be summarised as follows:—

Depth of Soil.	Number of Experiments.	Number of Solutions Nitrifying.	Number Nitrifying out of 10 Trials.
Less than 2ft.	17	17	10.0
2ft.	11	11	10.0
3ft.	11	10	9.1
4ft.	11	7	6.4
5ft.	2	1	5.0
6ft.	9	4	4.4
7ft.	2	0	0.0
8ft.	6	0	0.0

Six of the above experiments were made with chalk, which underlies the Rothamsted subsoil; the chalk was from depths of 5, 6, 7, and 8ft. None of the samples of chalk produced nitrification.

The new results show a far deeper distribution of the nitrifying organism than was concluded from the earlier experiments. The power of producing nitrification is now found to exist generally down to 3ft. from the surface. Below this point, the occurrence of the organism becomes less frequent, though at 5ft. and 6ft. about half the trials resulted in nitrification. With soil from 7ft. and 8ft. no nitrification was obtained. The considerable difference between the earlier and later results is to be attributed to the employment of gypsum in the later solutions. The nitrifying organism in the subsoil is, indeed, less abundant, and probably much more feeble, than in the surface-soil, and is apparently unable to start

nitrification in the decidedly alkaline solution which urine produces in the absence of gypsum.

Although it appears that the nitrifying organism may exist at considerable depths, nitrification is practically confined to the surface-soil. The quantity of nitrogen as nitric acid annually obtained in the drainage-water from soils of different depths in the drain-gauges at Rothamsted is on an average of nine years :—

Soil 20in. deep	40·2lb. per acre
" 40in. "	35·6lb. "
" 60in. "	38·8lb. "

There is no evidence here of a greater production of nitrates when the subsoil is included in the experiment.

Nitrates are always found most abundantly in the surface-soil, unless heavy rain has occurred to wash them downwards. Two fallow soils at Rothamsted were found to contain the following quantities of nitrogen as nitrates in pounds per acre :—

1st 9in.	28·5	40·1
2nd "	5·2	14·3
3rd "	—	5·5
Total	33·7	59·9

Action of Ferrous Iron on Vegetation. O. Kellner Bied. Centr. 15, 442—445.

THE author's experiments with ferrous sulphate on cereals confirm those of Griffiths (*J. Chem. Soc. (Trans.)*, 1884, 71; 1885, 46), that it is without action on these plants. Unlike Griffiths, he considers its beneficial action on leguminous plants is due to indirect, not direct action. The presence of ferrous matter in a soil, although not considered absolutely injurious, is regarded as bad, inasmuch as it indicates imperfect oxidation, which is the constant concomitant of acid humus.—D. A. L.

Stable Manure. A. Audouynaud and E. Zacharewicz. Bied. Centr. 15, 513—519.

IN order to determine to what extent stable manure varies in composition, the authors have investigated the composition of the excreta of cows, receiving the usual seasonable variations in fodder during spring and summer; and of horses rested and more or less worked, receiving oats and lucerne hay in April and May. The results per 1000, compared with those of Boussingault, are as follows :—

	THE AUTHORS.			BOUSSINGAULT.		
	N.	K ₂ O.	P ₂ O ₅ .	N.	K ₂ O.	P ₂ O ₅ .
Cow urine.....	11·20	13·94	—	9·69	12·19	trace
" solid excre- ment.....	4·35	0·43	1·39	4·20	very little	1·0
Horse urine....	15·63	10·56	trace	14·80	8·03	trace
" solid ex- crement.....	5·67	1·32	4·03	5·50	very little	3·0

The animals used by the authors were different from those of Boussingault, and came from a more southerly district. The authors estimate, as a general average, the yield in kilos. per cow per annum to be:—In urine, N 31·5, K₂O 40·8; in dung, N 42—43, K₂O 4·2, P₂O₅ 12; whilst the excreta of one horse will give 37·8 kilos. N, 13·1 of K₂O, and 14·4 of P₂O₅ per annum. To account for the potash in the solid excreta, it is suggested that the organic salts of potassium pass away with the urine, whilst the inorganic potassium salts accompany the solid matter. The authors have, moreover, observed that a considerable proportion of the nitrogen and potash supplied in the fodder does not reappear in the excreta and, in the case of cows, the milk. The nitrogen serves to renew, etc., horns, hair, hoofs, etc., and the potash seems to escape through the skin, inasmuch as in currying cows and horses, from 2 to 2·2 per cent. of potash is found in the dust from the former; and 7·4 to 9·7 per cent. in the brushings from the latter.—D. A. L.

Manuring Experiments with different Phosphates. J. Fittbogen. Bied. Centr. 15, 520—523.

THESE experiments were instituted to test the efficiency of Thomas-slag (containing 19·04 per cent. P₂O₅), Scheibler's precipitate (31·42 per cent. P₂O₅), and Nienburger precipitate (21·66 per cent. P₂O₅). Young barley

plants were sown in pots containing ignited sand, a mixture of potassium chloride, magnesium sulphate, calcium sulphate, ferric oxide, and either mono- or dicalcium phosphate, or one of the above. Harvest results are given in detail and tabulated, from which it is seen that these phosphates can supply barley with sufficient phosphoric acid to produce a normal harvest, provided they are used in quantities double that required of mono- or dicalcium phosphate to produce the same effect; in fact, rather more than double is necessary in the case of Nienburger precipitate; the presence of humus or calcium humate, however, greatly increases the efficiency of these phosphates. It is noteworthy that the Thomas-slag, probably owing to its finely-pulverised condition, is not less active than the precipitates prepared from it. Field experiments were also made with oats on a slightly humic, sandy soil, and with potatoes on a slightly loamy, humic sand. Some lots were unmanured, some received nitrate of soda only, some nitrate and Mejillo's superphosphate, or one of the above. All the phosphates gave nearly the same result, but the Thomas-slag possessed the additional advantage of greater cheapness. Detailed results are given, also directions for sowing the slag.—D. A. L.

Comparative Experiments on Marsh-land with Precipitated Phosphates and Thomas-slag. H. Schöenemark, Berger, R. Rimpau, and Fleischer. Bied. Centr. 15, 524—534.

EXPERIMENTS were made on land newly cultivated and on land which had been in cultivation some time. All plots were manured alike with kainite, and some received in addition varying quantities of the phosphates. On the new land, with oats and barley, when all corrections and allowances were made, the slag and precipitate were found quite equal in action; with potatoes, however, the slag was, to some extent, inferior. A dressing of 25 pounds per morgen (0·63 of an acre) of the phosphatic manure was quite sufficient. On the old land the phosphates produced no effect. An examination of the soil revealed the fact that the "old land" was much richer at the surface than the "new land;" in fact, an examination of the surface sand, taken to a depth of 10cm. from marsh-land, after being respectively 2, 3, 12, 14, 17, 22 years under cultivation, showed that it increased in richness every year of cultivation—at first very rapidly, but afterwards the increase became less marked. This is due to cultivation, aération, production of large crops, and consequent accumulation of crop residue, coupled with the more perfectly decomposed state of the "old" as compared with the "new" soil; and, therefore, the existence of plant-food in an assimilable form for the immediate use of the plant.—D. A. L.

Influence of Light and Heavy Dressings of Nitrogenous Manures on Peas. v. Eckenbrecher. Bied. Centr. 15, 570.

IN continuation of experiments which have been demonstrated, that peas were either indifferent to nitrogenous manuring or were even injured by heavy dressings, it is now shown that the nitrogenous manure applied last year has in no single case produced an effect.—D. A. L.

Formation of Oxalic Acid in Vegetation. Berthelot and André. Compt. Rend. 102, 995—1001; 1043—1049.

THESE experiments were conducted in the manner described (*Bied. Centr.* 15, 261). *Rumex acetosa*, *Amaranthus caudatus*, *Mesembrianthemum crystallinum*, and *Chenopodium quinoa* were the plants selected, and these were examined at all stages of growth for oxalic acid. The juice of *R. acetosa* is always acid; that of *M. cristallinum* is very watery, and at first neutral, but as the plant develops the juice becomes acid; in *A. caudatus* and *C. quinoa*, on the other hand, the juice is either neutral or but faintly acid. In like manner the distribution of soluble and insoluble oxalates varies. For instance, in *A. caudatus* the insoluble form predominates, whilst in the mature *Mesembrianthemum* the oxalic acid is almost wholly soluble.

Rumex acetosa (The Common Sorrel).—The dry seed contains 0.05 per cent. of oxalic acid. Young shoots (June 5) contain 13.9 per cent. oxalic acid, 5.1 per cent. soluble, the remainder in insoluble. The bases in the ash are not sufficient to satisfy all this acid; therefore, some of the oxalic acid is present in the free state. When the plant is in active growth (July 26) it is strongly acid, the acidity (calculated as oxalic acid) amounting to 3.6 per cent. of the dry plant.

Amaranthus caudatus (Loves Lies bleeding).—The juice from this plant contains both nitrates and oxalates, and as these two acids cannot exist together unless both are neutralised, the former is found in combination with potash, the latter combined with lime; and, therefore, the juice is neutral.

Chenopodium quinoa.—The juice is neutral, almost free from nitrates, but rich in oxalates.

Mesembrianthemum crystallinum (The common ice plant).—The seeds do not contain oxalic acid. During earlier periods of growth, the juice is neutral (May 18) or slightly acid (June 9). The percentage of oxalic acid is 7.9 soluble, 1.6 insoluble. Alkalis are abundant in the ash, and lime is present in quantity far in excess of that required for the 1.6 of insoluble oxalates. On the 8th July, the juice from the roots is not acid, but that from the stems and leaves is distinctly so. The soluble oxalic acid amounts to 4.4 percent., the insoluble to 2.0. Soluble oxalates and free oxalic acid preponderate in the leaves. On the 23rd September, when flowering has commenced, the root juice is still not acid, whilst the stems are distinctly so, and the leaves strongly acid. The contrast between *amaranthus caudatus* and *Mesembrianthemum crystallinum*, plants of different habits, is very striking.—D. A. L.

XV.—SUGAR, GUMS, STARCHES, Etc.

Chemical Composition of the Precipitate from a Settling-tank in a Sugar Factory. F. Farsky. Bied. Centr. 15, 436.

THE precipitate was the product of the purification of the refuse water by the addition of lime. It was a fine grained magma, with alkaline reaction. After long exposure to the air it became covered with mould, and emitted an odour of hydrogen sulphide. Its composition was as follows:—Water, 43.584 per cent. Per cent. on the dry matter— K_2SO_4 , 0.1742; CaO , 0.0616; MgO , 0.0043; KCl and $NaCl$, 0.0424; $CaCO_3$, 7.1032; $MgCO_3$, 1.8369; FeS , 0.4833; $Ca_3(PO_4)_2$, 3.8558; SiO_2 , soluble in HCl , 18.5492, insoluble, 40.4342; organic matter, 5.8595; sand, 21.6202. The dry substance contained—N, 0.0324; P_2O_5 , 1.7667; K_2O , 0.0631.—D. A. L.

XVI.—BREWING, WINES, SPIRITS, Etc.

Composition of Brandy. C. Ordineau. Bied. Centr. 15, 562–564 (Compt. Rend. 102, 217–219).

THE author regards the kind of yeast employed for fermentation as the only cause of the difference in flavour of brandy prepared from wine, as compared with brandy obtained from other sources. By repeated fractionation, the following substances were separated from a cognac 25 years old. The numbers are grms. per hectolitre:—Acetic aldehyde, 3.0; ethyl acetate 35.0; acetal 35.0; normal propyl alcohol, 40.0; normal butyl alcohol, 218.6; amyl alcohol, 83.8; hexyl alcohol, 0.6; heptyl alcohol, 1.5; ethyl propionate, butyrate, etc., 3.0; ethyl cenanthyate, about 4.0; amines, 4.0; probably also pyridine. Brandy prepared from potatoes, maize, and sugarbeet, in the ordinary way, by means of beer-yeast, contained propyl alcohol, active and inactive amyl alcohol, pyridine, and alkaloid b.p. 180° to 200°, and isobutyl alcohol; no normal butyl alcohol. In an experiment made with wine yeast, 100 kilos. of refined molasses yielded 19 litres of 92 per cent. spirit, from which a pleasant smelling oil was distilled, containing normal butyl and amyl alcohols, and resembling the oil distilled from new wine. Excellent alcohol was obtained in a similar manner from other saccharine substances.

Wine yeast develops speedily at 28° to 32°, and does not appear to degenerate by repeated cultivation. The bouquet of wines and brandy is due to a terpene, with a b.p. 178°, which is present in large quantities in white wine, and whose oxidation products are so characteristic of old cognac.—D. A. L.

An Apparatus for Testing Brewing Materials. C. R. Bonne, Manchester. Eng. Pat. 9956, August 22, 1885. 4d.

THIS consists of a corrugated metal vessel, which can be heated by immersion in a larger pan containing water. The material to be tested is weighed into the vessel, which is previously tared, and a known quantity of liquor added. The whole is heated for a sufficient time, and the loss by evaporation made up by the addition of fresh liquor. The material is then strained, and the strength of the liquor ascertained with the hydrometer, the readings of which are converted into practical modes of expressing the quality of the material by means of tables.—G. H. M.

Improvements in the Manufacture of Yeast. W. S. Squire, Middlesex. Eng. Pat. 11,935, Oct. 7, 1885. 4d.

Improvements in the Manufacture of Yeast. W. S. Squire, Middlesex. Eng. Pat. 12,058, Oct. 10, 1885. 4d.

Improvements in the Manufacture of Yeast. W. S. Squire, Middlesex. Eng. Pat. 12,463, Oct. 19, 1885. 4d.

THESE consist in growing yeast in saccharine solutions, prepared by mashing either malt alone or malt mixed with raw grain, allowing the mash to sour, straining it bright, and fermenting this wort with yeast, either with or without the addition of spent wash.—G. H. M.

Improvements in the Utilisation of the Refuse or Slops of Breweries, Distilleries, Starch Factories and the like. H. W. Lafferty, Gloucester, U.S.A. Eng. Pat. 9431, July 20, 1886. 8d.

AN apparatus for desiccating brewers' and distillers' grains, etc., for cattle food, without any loss of alimentary constituents, by means of centrifugal separating machines.—G. H. M.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

Rancidity of Butter. E. Daclaux. Compt. Rend. 102 1077–1079.

FRESH BUTTER contains a small quantity of free butyric acid, but rancid butter contains a considerable quantity. It is generally supposed that this rancidity owes its origin to a butyric fermentation, resulting from the action of microbes on the nitrogenous matter of the butter. The author, however, has examined a very old butter—it had been to Brazil—and found the nitrogenous matter was still unaltered casein; the liquid expressed from the butter, owing to the salt present, was destitute of microbes; nevertheless, the free acid had increased to 10 or 20 times the original quantity. Evidently this change was not due to the action of microbes, and the author regards rancidity as the result of the inevitable and spontaneous decomposition of the glycerides in butter. All the ethereal salts are, however, not equally susceptible to these attacks; the first to go is butyric, then caproic, and finally the glycerides of the fixed acids. Unaided, the decomposition proceeds but slowly; the presence of water and free acid aid it to a certain extent, but it is chiefly accelerated by the action of microbes, air and light. The action of the last two is accompanied by absorption of oxygen; carbonic anhydride is also evolved, but in volume less than the volume of oxygen absorbed, and various oxidation products are formed, of which the principal is formic acid. The oxidation, however feeble, attacks first of all those substances which give the butter

its odour and taste; and when oxidation has far advanced a taste of tallow is developed. Hence, in making butter, it is advantageous to use cream slightly fermented, therefore free from oxygen, or water charged with carbonic anhydride, etc. With regard to the action of microbes and cryptogamic vegetation, especially the latter, which permeate the butter with their loose, scarcely visible mycelia, they hasten considerably the saponification of butyric, of the glycerides of the volatile acids, and subsequently even the fats and nitrogenous substances. The colour of the butter remains unaltered, except where it is in contact with the mycelia. If the mass is alkaline the fat blackens, owing to the formation of a resin, which is soluble in alcohol and in alkaline solutions. The resin is also formed by the action of sunlight and alkalis. It is an oxidation product. The blackish discolouring of old cheese is due to the same cause.—D. A. L.

Separation of Albumen from Peptones. H. Weiske. Landw. Vers.-Stat. 1886, 33, 147.

SYZMANSKI found that hydrated copper oxide did not precipitate peptone from neutral aqueous solutions, and proposed the employment of this reaction for the separation of albumen from peptones. The author's experiments do not confirm the foregoing. Albumen estimations by boiling with metallic oxide precipitates in presence of peptones, are always too high, and the error increases with the amount of the precipitate and the quantity of the peptones present. Hence, peptone always goes down with the precipitate.—J. T.

(B) SANITARY CHEMISTRY.

Purification of Refuse Water from Factories. A. Müller and Bodenbender. Bied. Centr. 15, 433–435.

THE following experiments were made to investigate the question of self-purification, by means of fermentation of waters containing large quantities of carbo-hydrates, as, for instance, refuse water from sugar factories:—Solutions were prepared with distilled water mixed with 0.5 per thousand of cane-sugar, milk-sugar, or rice-starch; they were impregnated with a nitrifying solution, and put in bottles, some without further admixture, others with the addition of 100 millionths of ammonia as ammonium carbonate, or of ammonia and wood ashes, or of wood ashes, 0.5 per 1000. Two other solutions contained 360 millionths acetic acid, one with ammonia, the other with ammonia and wood ashes. Mould appeared in all cases; least in the pure solutions, most in the ammoniacal. The acetic acid solutions were not favourable to mould formations; they were, however, under favourable conditions, the first to nitrify, and that without loss of nitrogen. After two years at the temperature of the room, there was no ammonia in the solutions containing ashes; whilst the others had lost a good half of their ammonia. With regard to the organic matter, in the pure solutions the cane-sugar showed great power of resistance, both to fermentative and chemical attack, which was less evident in the case of milk sugar; and least of all in the rice-starch. The presence of wood-ash, however, aided the destruction of the cane-sugar considerably; less so the milk-sugar, and even preserved the starch. Ammonium carbonate aided considerably the disappearance of the organic matter in all four cases, with nitrification; considerable in the case of milk-sugar, moderate in the starch, and not at all in acetic and cane-sugar solutions. There was a loss of nitrogen in all except the milk-sugar. Ammonia and wood-ash proved even more active than the ammonium carbonate alone, in working the destruction of the organic matter, which took place with active nitrification, embracing the whole of the nitrogen in the acetic solutions, two-thirds of the nitrogen in the cane-sugar and starch, and half of the nitrogen in the milk-sugar; whilst in spite of the total disappearance of the organic matter in the acetic and milk-sugar solutions, the whole of the nitrogen remained. On the other hand, in all the other cases there was great loss of nitrogen. It is noteworthy that these carbo-hydrates checked nitrification perceptibly, whereas the

mould growth does not interfere with it—perhaps even aids it by clearing the way. The authors conclude that the best mode of purifying such refuse waters, like those from sugar factories, is by means of energetic fermentation, aided by the addition of lime and urine, and supplemented by subsequent irrigation. They remark especially that dressing land under cultivation heavily with carbo-hydrates will cause injurious acidity.—D. A. L.

The Air of Dwellings and Schools, and its Relation to Disease.

THE following is an abstract of the paper on the above subject by Professor Carnelly, D.Sc., Dr. Haldaue, University College, and Dr. Anderson, Medical Officer of Health, Dundee, read before the British Association meeting in Birmingham, in September, 1886.

It is not within the scope of the paper to discuss at length the methods which should be employed for maintaining a reasonably pure atmosphere in schools and in dwellings, but the following suggestions as the result of experience may not be without some value.

(1) As our results show, the state of the air in the Board schools in Dundee is extremely bad and urgently needs improvement. Doubtless the schools in other towns are in a similar condition. Most, if not all, the symptoms ascribed to over pressure which has been complained of so extensively of late, must be largely due to the defective ventilation of the schools. A defective ventilation weakens and depresses the energies, so that a child cannot certainly gain the full advantage of its education under a bad system of ventilation. It therefore behoves School Boards to pay much more attention to the ventilation of their schools than has hitherto been the case. A sufficiently pure air in schools appears to be attainable only by mechanical ventilation. It is true the necessary condition of purity may also be got by the use of open window ventilation, but then, in winter at least, the ill effects of draughts is probably greater than that due to insufficient ventilation. Of the systems of mechanical ventilation it is better to blow air into the room, and allow it to find its own way out (preferably up special shafts), than to ventilate by extraction. Draughts are more easily avoided by the former method. But the great objection to the suction method is that a partial vacuum tends to be produced, which would greatly accelerate the entry of sewer gas into the room from any defective drains, whereas the “blow-in” method has the positive advantage of producing the opposite effect. By blowing warm air into a room a much more uniform and higher temperature may be attained during winter, and this method also is independent of the state of the weather. All parts of the room are more thoroughly heated and ventilated than under the natural system. The air should be blown in under a low velocity through sufficiently large upright shafts in order to avoid draughts. (2) In regard to houses, mechanical ventilation is, of course, out of the question, but very satisfactory results may be obtained in the case of a large block of buildings let out on flats in single or double-roomed houses, as is largely the case in Scotch towns, by having a large open air space or landing on each flat, and provided with open wire-grated windows without glass, so that a good current of fresh air may be maintained along the passages and staircases, whereby a pure, instead of an already vitiated air, enters and supplies the various rooms. (3) The practice adopted in almost all small houses of keeping a lamp burning during the night is one to be deprecated, as it must add very considerably to the contamination of the air, especially in one-roomed houses, in which the cubic space per person is so small. (4) Cleanliness both of person, and more particularly of the dwelling or school, is of the very utmost importance in maintaining the purity of the air as regards micro-organisms, and one which, from this point of view, has not been previously advocated. (5) Though far from deprecating the beneficial effect of abundant air space, yet we think that the frequency with which the air in a room is changed is a far more important point to be attended to in providing a pure atmosphere. (6) Ventilation by mere diffusion should never be depended on alone, for though it may remove a considerable portion of the carbonic acid, it has but little effect

in reducing the organic matter and micro-organisms. (7) It is most important that the windows in houses and schools should be made to open widely, so that at intervals, when the room is not occupied, a good current of air may be sent through the room. This would be very effective in removing the organic matter and micro-organisms.

Micro-Organisms in Drinking Water. Prof. Odling, F.R.S. Brit. Assoc., in Birmingham, 1886.

THE above paper was read by Dr. Odling, as joint author with Drs. Crookes and Tidy. The investigation was undertaken to ascertain the connection between the infection of water and the spreading of disease. He did not deny that certain very clear cases of choleraic or typhoidal outbreak had occurred, which were clearly traceable to drinking water. But still, such instances were very rare, and how is it that so many persons continually drink water to which the excreta of towns has excess without suffering from such diseases? Twenty-five years ago, the sewage of Oxford, of Reading, and of many other places on the Thames, went directly into the river without any pretence of treatment. At that time there was always a percentage of the population of the riparian towns suffering from zymotic diseases, and, therefore, it might have been expected to follow, as a matter of course, that London, which drank the water, would show a higher death rate from these diseases. Yet this was not the case. How is it, then, that although water can be the medium of infection, so little effect follows from drinking, as the people of London then did, a water taken direct from a river polluted and infected at its sources? He considered the theory of germs, or micro-organisms, to be practically established; but, admitting this, it seemed clear that these infectious organisms possessed little power of propagating themselves when removed from their proper nutrient fluids. No doubt it is possible they, for a time, retain vitality; but there are causes interfering with their powers of propagation. The experiments were made with the virus of splenic fever, the well-known wool-sorters' disease. The virus was dissolved in either sterilised distilled or sterilised river water, to form a dilute infected water. After standing a certain number of hours, portions of this water were added to an animal fluid; the virus being thus diluted, and allowed to remain in this condition for some time before being placed under circumstances in which it could possibly reproduce the organisms to which it owes its infectious properties. Micro-organisms thus treated preserve sufficient vitality to allow of their propagating themselves for five or six hours, but propagation does not take place after eighteen hours. It, therefore, appears that dilution effectually protects us from these organisms, by either impairing their vitality or destroying it altogether. Admitting this, it is easy to see how London escaped contamination from the sewage of Oxford and the other towns up the river. To infect the water supply of London with the same proportion of virus as was employed in Dr. Odling's experiments, one million gallons would be required every day, or, considering only that portion of the supply drawn from the Thames, half a million gallons would be required. But the water supply taken from the Thames as it passes over Teddington Lock, is only about one-tenth of the water so passing, which is itself so small, as compared with the whole stream, that its withdrawal causes no sensible diminution of level. Computing this, however, at one-tenth of the whole, it will be seen that 50,000,000 gallons of infection would be required to pollute the Thames water to the extent of the pollution employed in the author's experiments. And even if this enormous and practically impossible quantity of infection could be imparted to the water, the experiments show that the dilution would render it innocuous. Seeing, however, how trifling the real infection must be, compared with this supposition, it would appear that there is little cause for alarm, as far as the Thames is concerned. From calculations he had made, it would appear that if 1,000,000 spores were added to the Thames, there would only be one spore in 50,000 gallons. Spores, of course, opened up a new field

of inquiry, which the authors were now engaged upon. The experiments described were made with the bacillus, not the spore. Spores certainly live longer in water than the bacilli, but they do not propagate. Single spores, moreover, were not necessarily or practically pathogenic. This was seen in vaccination. To perform this satisfactorily, it is not sufficient to introduce the smallest possible quantity of vaccine matter into a single puncture; but, as is well known, it is necessary to make three effective punctures, and even then propagation is not invariable.

Dr. TIDY said he would not, as the time was so short, speak for more than a minute. But he would like to point out that London at the present moment is supplied, to about an equal extent, from the River Lea and from deep wells in the chalk. We should certainly not look for infection from the chalk, but rather from the Lea, which is a stream liable to contamination. As a matter of fact, however, those parts of London supplied from the Lea suffer to no greater extent from zymotic diseases than do those districts supplied from the deep well water of the chalk.

Congo-Red as a Reagent for Free Acid. Prof. H. Schulz, Centr. Bl. f. d. med. Wissenschaft. 1886, 449.

CONGO-RED was used to ascertain whether free acid is formed in lower organisms. The colouring matter is readily soluble in water, and has the advantage of being no hindrance to the organic functions in these animals. In the case of rotatorias the digestive organs were coloured distinctly blue, other parts remaining white. The presence of free acids is thus proved.—A. R.

XVIII.—ELECTRO-CHEMISTRY.

Improvements in Secondary Batteries, Accumulators, or Magazines of Electricity. H. Thame and J. R. Thame, London. Eng. Pat. 12,288, Oct. 15, 1885. 8d.

IN this invention the electrodes consist of tubes of lead, strengthened if necessary by rods or tubes of glass, in which spiral grooves are formed either in the metal itself or by winding on strips or tubes of lead of a suitable section. In these grooves are placed the spongy lead, etc. The electrodes are packed as closely as is possible without touching each other, in frames of suitable material, which are made easily removable. Warping of the electrodes is in this way prevented.—E. T.

Improvements in Galvanic or Primary Batteries. J. E. Liardet, London. Eng. Pat. 12,724, Oct. 23, 1885. 6d.

TO prevent waste of zinc in chromate and bichromate of potash cells, the author proposes a new solution in which sea or salt water and white sulphate of mercury are ingredients.—E. T.

Improvements in the Manufacture of Incandescence Electric Lamps. L. S. Powell and R. P. Sellon, London. Eng. Pat. 1726, Feb. 5, 1886. 8d.

THIS consists of a method for obtaining uniformity of incandescence of lamps under constant conditions of electro-motive force or current. Into each of two vessels containing mercury, but insulated from one another, one end of the filament and a wire from the source of electricity dip; by means of these wires a current at a constant electrical pressure is sent through the filament, and the length of filament outside the mercury is varied, by altering the height of the mercury in some suitable way, until the required degree of incandescence is obtained. The operation is carried on in vacuo or in hydro-carbon gas.—B. T.

Improvements in Incandescent Electric Lamps. Alex. Bernstein, London. Eng. Pat. 3149, March 5, 1886. 8d.

THE improvements relate to that type of lamp in which the light-giving carbon is straight, the conducting wires

being led in at opposite ends of a glass bulb. Each conducting wire is made in two pieces, one piece of platinum wire being sealed into the glass, and another connected to the carbon; these two wires are then joined together by a U-shaped flexible piece of copper at right angles to the direction of the wires. This piece of copper, by its flexibility, prevents any strain caused by the alteration in length of the materials of the lamp, due to changes of temperature, being put upon the carbon filament.

—B. T.

Improvements in the Manufacture of Carbons for Electrical Purposes. J. Kirby, Belgium. Eng. Pat. 8151, June 19, 1886. 6d.

IN tar there is a fine powder held in suspension consisting of 90 to 99 per cent. pure carbon. This carbon is separated from the tar by mixing with one part of tar, two parts of tar-naphtha, creosote or any suitable solvent, and filtered through linen bags; the carbon remains as a black paste, which is pressed to get rid of all tarry matter, and then carbonised in a retort. The product is the material from which the carbons for electrical purposes are made, and is used either by itself or, for cheapness, mixed with graphite from gas retorts. For positive carbons a hollow cylinder is formed of this carbon, and at the time of formation the hollow is filled with plumbago.—B. T.

Improvements in Portable Galvanic Batteries. W. L. Gates, New Jersey, U.S.A. Eng. Pat. 8501, June 29, 1886. 8d.

TO a hollow cylindrical vessel, closed at one end, a similar cylinder of carbon, deeply notched at opposite sides, is fastened at the closed end. In the open end of the vessel is fastened a tightly-fitting plug, supporting a rod of zinc inside the carbon cylinder. The vessel, which is supported in a horizontal position by four legs, has a hopper with a small orifice in the middle of the top. The liquid, which is a solution of bisulphate of mercury and sal-ammoniac, is unable to escape, even when the vessel is inverted, by reason of the pressure of the atmosphere at the small orifice.—E. T.

Improvements in the Treatment of Waste Tin Cuttings to recover Tin and also Iron in a State fit for Re-manufacture, also in Apparatus to be employed in this Treatment. T. Fenwick, London. Eng. Pat. 8988, July 9, 1886. 6d.

THE scrap is suspended in a wicker basket as the anode in a stannous chloride electrolyte, with tin cathodes coated with plumbago, to prevent adhesion of the deposited tin. The tin falls into earthenware troughs beneath the cathodes. The electrolysis, which is performed by a suitable dynamo machine, is not pushed to the complete stripping of the iron, as this would cause solution of some of the latter metal. The partially treated cuttings are therefore next attacked with strong hydrochloric acid, from which the dissolved tin afterwards recovered by electrolysis, the cleaned iron being sold as scrap and available for further manufacture.

—W. G. M.

Improvements in Galvanic Batteries. A. J. Boulton, London. From Dr. O. Lugo, New York. Eng. Pat. 9403, July 20, 1886. 4d.

A CARBON ELECTRODE is placed with the solution of a metallic chloride, such as chloride of copper, in a porous cell, outside which is placed a caustic alkali, such as soda, and a zinc electrode. The deposit of copper on the carbon is obviated by adding hydrochloric acid in the porous cell; the copper is dissolved as soon as formed, and reconverted into chloride. This cell, it is claimed, gives out a constant volt-ampère.—E. T.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Treatment of Hops. L. Boulé. Bied. Centr. 15, 575.

ADHERING LUPULIN is removed mechanically, the hops are then steeped in boiling water, the extract evaporated at a low temperature in a vacuum, dried, powdered, and mixed with the lupulin. The mixture is kept in tin cans, in which the air is replaced by carbonic anhydride. In this way the oil containing the lupulin is not changed into valerianic acid, the hops can be kept any length of time, and can be moreover greatly economised.

—D. A. L.

Phosphoric Anhydride. J. Walter. J. Prakt. Chem. 1886, 34, 133.

PHOSPHORIC ANHYDRIDE in its bulky form can be made much more convenient to handle by compression as follows:—The containing vessel is closed with a caoutchouc cap through which passes a rod with a flattened head. This rod is used to press the anhydride into a cake, out of which small cylinders can be cut by means of a cork-borer or similar instrument. Any metal that may be taken up by the anhydride by this treatment will usually be of no importance.—J. T.

On the Volatile Fatty Acids occurring in the Lupulin of Commerce. J. Ossipow. J. Prakt. Chem. 34, 1886, 238—240.

IF lupulin be distilled with water, volatile acids are found in the distillate, one of which, at least, was supposed to be isomeric with valerianic acid, since oil of hops oxidised with chromic acid gives an acid of the formula $C_5H_{10}O_2$. The acid distillate was therefore saturated with potassium carbonate, decomposed with very dilute sulphuric acid and distilled. The distillate was extracted with ether, and after driving off the ether, the residue was fractionated. The fractions most likely to contain the valerianic acid—viz., those from 170 to 174°—were joined, and a new fraction distilling between 171 and 173° was collected, to be tested for one of the two valerianic acids—methyl-ethyl or isopropyl-acetic acid. Since these two are distinguished by their barium salts, this was prepared from the distillate and examined, as well as the silver salt, but the result does not warrant the author to pronounce an opinion on the constitution of the acid. He intends to try if etherification of the acid will be more successful.

—S. H.

Synthesis of Thalline. Chem. Zeit. 10, 1038.

PHENOL treated with strong nitric acid gives a mixture of ortho- and paranitrophenol. The former is separated by distillation in a current of steam, whilst the latter is converted into the sodium salt and treated with methyl-chloride, forming paranitromethylphenol or paranitro-anisole. The nitro-group is reduced, whereby para-amido-methyl-phenol or para-anisidine is obtained. This is treated with glycerol and sulphuric acid, paramethoxy-quinoline or paraquinanisole being produced (Skraup's reaction), the hydrochloride of which, heated with tin and hydrochloric acid, gives, by the addition of four atoms of hydrogen, the new base tetrahydroparamethoxyquinoline or thalline, which name it received owing to the green colour its most dilute solutions give with chlorine, ferric chloride and potassium bichromate.

—S. H.

Sparteine and its Salts. Grandval and Valser. J. Pharm. Chem. 14, 65, 1886.

ON adding a little sparteine or one of its salts to a drop of ammonium hydrosulphide on a watch glass, a persistent orange-red colouration appears. This reaction is very sensitive. The normal sulphate $C_{15}H_{26}N_2.H_2SO_4$ is easily obtained by adding the calcu-

lated amount of sulphuric acid to an alcoholic solution of sparteine. The salt crystallises out in the form of large rhombohedra with 8 mols. of water of crystallisation on allowing the solution to evaporate spontaneously in an exsiccator. The salt can also be obtained by evaporating its aqueous solution. On adding an alcoholic solution of sulphuric acid to a solution of sparteine in ether, a very hygroscopic white salt is precipitated of the composition $\text{C}_{15}\text{H}_{26}\text{N}_2 \cdot 2\text{H}_2\text{SO}_4$. In the drying oven it decomposes and takes a red colour. It is usually assumed that the halogen salts of sparteine do not crystallise. The author, however, has obtained a well-crystallised basic hydriodide $\text{C}_{15}\text{H}_{26}\text{N}_2 \cdot \text{HI}$ by treating a warm 5 per cent. solution of sparteine sulphate with an excess of potassium iodide, and allowing the cold solution to evaporate spontaneously. By dissolving these crystals in boiling water, cooling slowly and allowing to evaporate freely in the air, very large crystals of the hydriodide are obtained, which are permanent in the air and light. This salt is not very soluble in water, and is precipitated from concentrated solutions of sparteine salts on adding potassium iodide, a reaction of value in purifying sparteine. The hydrobromide can also be obtained by double decomposition, although it is more soluble. It crystallises in prismatic needles. Similarly the much more soluble hydrochloride can be obtained in the crystalline form.—J. T.

XXI.—EXPLOSIVES, MATCHES, Etc.

An Explosive Mixture. A. Cavazzi. Gazz. Chim. 16, 172.

THE author found that sodium hypophosphite heated with sodium nitrate violently exploded. The greatest effect was produced with a mixture of equal parts of the salts. The author supposes the following equation to represent the reaction—

—J. T.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

Properties of Oxycellulose, applied to the Determination of Vanadium. G. Witz. and F. Osmund. Bull. Soc. Chim. 45, 309—315.

WITZ first used vanadium for developing aniline-black in calico printing. Cotton-wool slightly altered by oxidation, as it is obtained, for instance, by steeping in chloride of lime solution (cf. 2^e Bé. for one hour at the ordinary temperature, is able to fix vanadium from very dilute solutions—according to Witz if the solution contains 1 gm. vanadium in 1000 cc. water—and prove its presence by developing aniline-black. The authors propose to test solutions for vanadium by soaking a cotton material partly converted into oxycellulose in the solution, washing and drying the material, and then printing with an aniline-black mixture free from metals and developing the black. Vanadium baths, which contain from 0.1—0.000001 mg. vanadium in a litre, give this reaction distinctly, and the weakest bath gives a result very different from a bath free from vanadium. The reaction is most delicate with vanadium dichloride in the absence of other salts. With the aid of this reaction it is possible to find vanadium in different well-waters. It has not yet been found in animal bodies.

—G. H. M.

Determination of Glycerol. William Fox and J. A. Wanklyn. Chem. News, 53, 15.

THE authors determine glycerol by oxidising with permanganate and titrating the oxalic acid which is obtained according to the equation, $\text{C}_3\text{H}_8\text{O}_3 + \text{O}_6 = \text{C}_2\text{H}_2\text{O}_4 + \text{CO}_2 + 3\text{H}_2\text{O}$. The aqueous solution of glycerol, which should not contain more than 0.25 gm., is made alkaline with 5 grms. of caustic potash, and boiled for half-an-hour with an excess of permanganate. Excess of the latter

is then removed with sulphurous acid. After acidifying with acetic acid, calcium chloride is added, and the precipitated oxalate determined in the usual way by titration with permanganate.—A. R.

Detection of the so-called "Saccharine." Reischauer. Bied. Centr. 15, 492—493.

THE concentrated solution of the sugar, (if alkaline, slightly acidified with phosphoric acid), is extracted with ether. If saccharine is present, the residue from the ether melts at about 200°, and when fused with a mixture of nitre and sodium carbonate the fused mass contains sulphuric acid, which may be determined in the usual way. The weight of BaSO_4 obtained in this manner from 100 grms. of sugar, multiplied by 0.785, gives the weight of the saccharine extracted.—D. A. L.

Estimation of Fusel Oil in Brandies and Liqueurs. J. Traube. Bied. Centr. 15, 559—560.

ONE-FIFTIETH per cent. of fusel oil in a brandy can be detected by the following method:—A thin-walled, very fine capillary tube is attached to an adjustable scale divided in half-millimetres. The brandy or liqueur to be examined is distilled, and the distillate diluted with distilled water until the sp. gr. corresponds to 20 per cent. alcohol; this liquid is sucked up the capillary tube two or three times, and a few hours after the liquid has come to rest, the height of the column in the capillary tube is read off and compared with a standard. An error of a half per cent. in sp. gr. is of no importance, and a very slight correction is required for variations of temperature. The height of the column is lowered by fusel oil, and to a less extent by other alcohols and aldehydes present in brandy, etc.—D. A. L.

Practical Experience with the Diphenylamine Reaction in Milk and Wine Analysis. Joseph Herz. Rep. Anal. Chem. 6, 360.

ON the occasion of the dairy exhibition at Munich, in 1884, Soxhlet altered Uffelmann's method in the following way: 100 cc. milk are boiled with 1½ cc. of a 20 per cent. calcium chloride solution, a few drops of a 2 per cent. solution of diphenylamine in conc. sulphuric acid added to the filtrate, and a layer of about 2 cc. of the now turbid mixture carefully poured on to conc. sulphuric acid, so that the fluids do not mix. In presence of nitrous or nitric acid a blue zone becomes at once apparent, but if 1 mgm. in 100 cc. is present, the colour is observed after the lapse of a few hours only. With still smaller quantities it is necessary to coagulate 450 cc. milk with 6—7 cc. calcium chloride solution, and after adding 2 cc. conc. sulphuric acid to the filtrate, to distil off 120—150 cc. The distillate is made slightly alkaline, evaporated in a platinum dish to about 5 cc., and now examined as above. All reagents and the distilled water must be previously tested for nitric acid.

This method is not employed at Würzburg, as the water there does not contain less than 25 mgms. nitric acid in the litre. Those who examine the milk there have to rinse the vessels used with the milk about to be examined. Coagulation is effected on the water-bath, and, in the case of a positive result, the experiment repeated with some of the distilled water used. A negative result does not necessarily prove that water has not been added; even more so is this the case with wine, for it was not possible to prove the presence of nitric acid in old wine which had undoubtedly once been mixed with water.—A. R.

On the Quantitative Determination of Phenol as Tribromophenol. H. Beckurts. Arch. Pharm., 1886, 24, 561.

THE product of the action of bromine on phenol, tribromophenol, was examined and found to have an admixture of tribromophenolbromide $\text{C}_6\text{H}_2\text{Br}_3\text{OBr}$. It is due to the formation of the latter compound that the quantity of phenol is frequently found too high, since for

the production of tribromophenolbromide, 8 atoms of bromine are used for one mol. of phenol, whereas in the formation of tribromophenol only 6 atoms of bromine are required.

Tribromophenolbromide is decomposed, according to Koppeschaar, as shown in the following equation: $C_6H_2Br_3OBr + 2KI = C_6H_2Br_3OK + KBr + I_2$, i.e., 2 atoms of iodine separate which are equivalent to 2 atoms of bromine, and are retitrated with thio-sulphate, so that only 6, not 8, atoms of bromine are used for 1 mol. of phenol. Addition of potassium iodide, consequently, is of much greater importance than is assumed by Koppeschaar, who only desired to replace bromine by iodine, which is more readily determined. Titration is best effected with $\frac{1}{10}$ normal potassium bromide solution, $\frac{1}{75}$ normal potassium bromate solution, $\frac{1}{10}$ normal sodium thiosulphate solution and a solution of potassium iodide, which contains 125 grms. in the litre. Into a bottle furnished with a well-fitting glass stopper, 25—35cc. of the phenol solution (1:1000) are introduced, 50cc. each of the potassium bromide and bromate solution and 5cc. conc. sulphuric acid added and the mixture well shaken. After 10—15 minutes the bottle is opened, 10cc. of the potassium iodide solution added, and after a few minutes the separated iodine is titrated with $\frac{1}{10}$ normal thio-sulphate solution. The calculation is simple: in a mixture of 50cc. each of potassium bromide and bromate solution, sulphuric acid sets 0.2393 grm. bromide at liberty, according to the equation: $5KBr + KBrO_3 + 3H_2SO_4 = 3K_2SO_4 + 3H_2O + 6Br$. This quantity of bromine would convert 0.0463 grm. of phenol into tribromophenol. One cc. of one-tenth normal thio-sulphate solution corresponds to 0.0082 grm. bromine, and this combines with 0.00156 grm. of phenol. By subtracting for each cc. of $\frac{1}{10}$ normal thio-sulphate solution, which has been used for estimating the iodine set free by the bromine, 0.00156 from 0.0463, the quantity of phenol is found, which was present in the volume of the phenol solution originally employed. The method gives very good results.—A. R.

Determination of Phenol in Crude Carbolic Acid. II. Beckurts. Arch. Pharm. 24, 572.

KOPPESCHAAR'S method for determining phenol (see previous abstract) cannot be used for crude carbolic acid, as considerable quantities of cresols and other homologous phenols are contained in it, and these form different compounds with bromine, so that the quantity of phenol is always found too small. As a general rule, the method is of course sufficiently exact for ascertaining the quantity of phenols in the crude acid, irrespective of the kind of phenols it contains. The author uses a method which is a modification of Crookes'. A certain volume of crude carbolic acid is mixed with the same volume of petroleum ether, and shaken with a sufficient quantity of a 10 per cent. caustic soda solution in a graduated cylinder. After ten minutes, a perfect separation of the alkaline fluid and of the hydrocarbons has taken place. By subtracting the known volume of petroleum ether from the portion insoluble in caustic soda, the amount of neutral oils and resinous substances contained in the acid is found. A portion of the alkaline fluid is mixed with excess of conc. hydrochloric acid, and the volume of phenol which separates out, noted. No corrections are necessary, as the phenols dissolve as much water as the hydrochloric acid dissolves of the phenols. The method gives good results.—A. R.

A Modification of Lundin's Method for Determining Arsenic in Iron and Iron Ores. V. Gröndahl. Jernkontorets Annalen, 41, 149.

THE author finds fault with Lundin's method for determining arsenic acid, because it is difficult to remove the sulphuric acid used for dissolving the iron, in consequence of which wrong results are obtained, for on addition of hydrochloric acid, chlorine is evolved, which, in its turn, separates sulphur from sulphuretted hydrogen. In order to avoid these mistakes, the following modifica-

tion is recommended:—6 grms. pig-iron, steel, or cast-iron are dissolved in 60cc. nitric acid (sp. gr. 1.2) in a beaker holding at least 300cc., and the solution evaporated to dryness in a porcelain dish holding 150cc. The residue is powdered, transferred to a porcelain crucible, and fused until nitrons fumes cease to be evolved. The ignited mass is returned to the dish, 10cc. sulphuric acid (sp. gr. 1.83) added, and excess of sulphuric acid evaporated. The dry mass is then rinsed into a 300cc. flask with 60cc. hydrochloric acid (sp. gr. 1.19). The distillation, which is the next operation, and precipitation with sulphuretted hydrogen, is again carried out according to Lundin. It is needless to pass carbonic acid into the distillate, unless the precipitate produced by sulphuretted hydrogen is to be filtered with all possible speed through a weighed filter. After washing with warm water, the filter and precipitate are dried at 100—110° and weighed.

In determining arsenic in iron ores, it is advisable, after dissolving in nitric acid, to digest with hydrochloric acid (sp. gr. 1.19), and not, as Lundin recommends, with nitric acid.—A. R.

Determination of Invert Sugar. Deutsche Zuckerindustrie, 11, 1229.

WITH regard to Wolf's modification of Biggart's method, Brauns and Volpert find that, by using a $\frac{1}{2}$ per cent. solution of invert sugar and 50cc. copper solution, inaccurate results are obtained, if the amount of sugar is small. According to Volpert, 10cc. of Soxhlet's copper solution, diluted with 40cc. water, require, if boiled for two minutes, 25 Sec. of a $\frac{1}{10}$ per cent. solution of invert sugar. If the 40cc. water contain pure cane sugar (e.g., 2, 4, 40 grms.), a smaller number of cc.'s are used—namely, 23 S, 22 S, 20 S—the decrease not being a regular one, however.

11 grms. crude sugar are dissolved in about 100cc. of water, precipitated with a little lead acetate, and made up to 110cc. 100cc. (10 grms.) are filtered off, the lead precipitated with Glauber's salt, the solution diluted to 200cc., and again filtered. Each 40cc., containing 2 grms. sugar, are boiled with 10cc. copper solution (according to Herzfeld) for half-a-minute. A small portion is then tested with acetic acid and ferrocyanide, a further quantity of copper solution introduced, again tested, etc. Generally, three tests suffice. Under these circumstances, and for 2 grms. of sugar in 40cc., 0.1cc., more or less, represents 0.01 per cent. invert sugar; each whole cc., therefore, representing 0.1 per cent.—A. R.

Acidimetric Determination of Sulphurous Acid. Ch. Blarez. Compt. Rend. 103, 69.

SULPHUROUS ACID behaves differently towards the various indicators. Thus, its basicity seems to be twice as great when phenol-phthalein is used than when cochineal and helianthin are employed as indicators. Sulphomagenta, litmus, and Porrier-blue C4B cannot be used. Each cc. of a $\frac{1}{10}$ normal alkali solution is equivalent to 0.0032 grm. SO_2 , if working with phenol-phthalein, and equivalent to 0.0064 grm. SO_2 if with cochineal or helianthin. The acidimetric determination of free sulphurous acid in presence of other free acids is only possible if the mono- or polybasic acid is so strong as to show its absolute basicity towards cochineal or helianthin. In this case, a determination is made, using one of the latter indicators, and another with phenol-phthalein. The difference expressed in cc. $\frac{1}{10}$ normal alkali solution, if multiplied by 0.0064, gives the weight of anhydrous sulphurous acid contained in the volume of the solution experimented upon. Good results were obtained in presence of nitric, hydrochloric, sulphuric, and oxalic acids.

With regard to sulphites, the following holds good:—Acid sulphites, with an excess of sulphurous acid, seem acid towards cochineal and helianthin, and by means of these indicators and alkali the excess of sulphurous acid may be determined. Acid sulphites are neutral to the last-mentioned indicators, acid to phenol-phthalein; they moreover absorb the same quantity of alkali as

they already contain before the red colour of the former becomes apparent. The neutral sulphites, alkaline to cochineal and helianthin, neutral to phenolphthalein, are converted into acid sulphites by addition of the same quantity of sulphurous acid as they already contain, and their quantity can be thus determined; only it is better to take $\frac{1}{10}$ normal hydrochloric acid solution instead of sulphurous acid. A small excess of the former is added, cochineal or helianthin are used as indicators, and the change of colour is effected by $\frac{1}{10}$ normal alkali solution.

If a sulphite is under examination, which for 1mol. of sulphurous acid contains more than 1mol. and less than 2mols. of alkali, the exact composition may be determined in the following way:—(a) A certain volume of the solution is titrated with alkali until a change of colour in the phthalein appears. (b) The same volume of the same solution is treated with an excess of $\frac{1}{10}$ normal hydrochloric acid, and excess of the latter found by means of $\frac{1}{10}$ normal alkali solution. The sum of the volume of alkali used in a, and the volume of acid actually required in b, calculated for sulphurous acid, gives the quantity of this acid in the volume of fluid examined. If the weight of the sulphurous acid be known, and also the amount of alkali necessary for transformation into neutral sulphite, then the difference represents the weight of combined alkali, and the exact composition of the body is thus ascertained.—A. R.

Estimation of Silver in Burnt Pyrites. E. Thilo. Chem. Zeit. 10, 822, 1065—1066.

THE amount of silver present in burnt pyrites is usually 0.003—0.008 per cent. To obtain accurate results it is desirable to deal with a quantity of pyrites containing 0.01grm. of silver, say 300—500grms. For so much material, scorification and cupellation are not suitable. Methods involving the solution of the whole of this material, hold out no promise of success. Attempts were made to devise a process by which the whole of the silver could be dissolved without taking up the rest of the material. Nitric acid was hardly suitable as a solvent owing to the possible presence of chlorides. Chlorination and subsequent extraction of the silver chloride was tried. Digestion with chlorine water proved better than passing chlorine over the heated material, but bromine water was much more convenient than chlorine water, and attacks silver, arsenic and sulphur compounds more readily than most reagents. Bromine and bromine water have already been proposed for the extraction of the precious metals, both for manufacturing and analytical purposes. The author found the analytical method given by Fresenius to be very troublesome. He finally devised the following process:—1. Brominating the burnt pyrites with bromine water containing excess of bromine. 2. Removal of the excess of bromine by means of free ammonia. 3. Solution of the resulting silver bromide by means of concentrated ammonium chloride solution. 4. Precipitation of the silver (and other dissolved metals) by means of zinc. 5. Estimation of the silver in the precipitate.

1. *Operation.*—An iron dish, with acid-proof lining, 30cm. diameter, receives 300—500grms. of the burnt pyrites, which passes through a sieve of 0.25mm. meshes. The powder is well covered with water, and bromine is added with constant stirring, care being taken to have excess of bromine finally. After allowing to stand for 24 hours, the mass is heated for an hour on the water-bath with constant stirring, supersaturated with ammonia, and after the addition of 500grms. ammonium chloride with a litre of water, is boiled for an hour and filtered. The residue is returned to the dish, without washing, and dried, then ignited in a Hessian crucible, and boiled again with ammoniacal ammonium chloride solution. After ignition the residue can be easily washed, and is now quite free from silver. If the burnt pyrites contained 5 per cent. of copper, this will be reduced to less than 0.1 per cent. in the residue, and as the copper is as difficult to extract with bromine as the silver, the removal of the copper indicates the removal of

the silver also, and it may be assumed in practice that the process is satisfactory as soon as the copper is reduced to 0.1 per cent. The silver solution obtained, about 4 litres in volume, is perfectly stable in the light, so that no darkening of the laboratory is necessary. The liquid is acidified with hydrochloric acid, warmed on a sand-bath, and the silver is precipitated by means of chemically pure zinc. After 1 to 2 hours, all is precipitated (in the presence of cobalt the solution becomes red) and the solution does not turn blue on adding ammonia. After careful decantation, the precipitate is washed with dilute hydrochloric acid, and finally with hot water. It contains frequently small amounts of chlorine and bromine compounds, and a little iron oxide which has passed the filter previously. This precipitate is heated in a clay crucible, with a little potassium cyanide, to reduce chlorides and bromides, then borax-glass is added, and the temperature raised to fuse the copper. The button so obtained is dissolved in nitric acid, and the silver is precipitated by means of a few drops of hydrochloric acid, and weighed.

In pyrites, the silver is estimated by first carefully roasting, and then proceeding as above. The method also gives good results in the case of roasted copper schists, and spathose iron ore containing fall ore and pyrites. The process can be completed in three days.

—J. T.

New Methods for Distinguishing Artificially-coloured Red Wines. Joseph Herz. Chem. Zeit. 10, 968—9.

THE following is the method employed for examining the colouring matter of wines in the Würzburg Laboratory:—30—50cc. of the wine to be tested are mixed in a porcelain dish with about 20—30cc. of a saturated solution of magnesium sulphate and 10—20cc. sodium hydrate solution added with constant stirring; all natural and artificial colouring matters, with the exception of the sulphonic acids, are thrown down with the magnesium hydroxide. A small quantity of the liquid is filtered off, and if the filtrate is not colourless, or only slightly yellow, further quantities of magnesium sulphate and sodium hydrate are added. Concentrated solutions are used in order to avoid too great dilution of the liquid. If very small quantities have to be tested for it is necessary to take 100cc. or more of wine, and evaporate down to 30cc. on the water-bath before adding magnesium sulphate.

The colourless filtrate is decomposed with excess of dilute sulphuric acid (1:3), which restores the red colour if sulphonic acids are present. *Acid magenta (rosaniline sulphonic acid)* is the most commonly used member of this group, and gives a violet-red colour with sulphuric acid; 1mg. per litre can be detected in 30cc. wine. If *orselle* colours have been also used in colouring the wine, the filtrate is blue, and becomes litmus-red on addition of acid. In this case it is necessary to test for acid magenta by Blarez' method (this Journal, 1886, 178) by treatment with lead dioxide, which destroys the orselle and natural colouring matters. The author cannot recommend Cazeneuve's method (this Journal, 1886, 178) for the same purpose.

In order to test the magnesium hydroxide for other colouring matters, the precipitate is stirred into hot water, roughly separated by decantation, then drained on a filter-pump, mixed with sand and dried on a water-bath. Extraction of the residue with ether separates ordinary magenta and "cassissin." The former is recognised by giving the well-known colour on evaporation of the ether; the latter yields a yellowish-brown residue and dyes wool a reddish-brown. With strong hydrochloric acid the wool becomes yellow, with ammonia colourless.

The alkaline filtrate obtained on treating the magnesium hydroxide precipitate with hot water as above, is coloured yellowish-brown by pure wine or wine coloured by whortle berries, dark-violet by *orselle*, red by *paucau*, light-red to dark-yellow by *cassissin*, yellowed to yellow-brown by *vinicoline bordeaux*; the last gives a violet zone by contact with sulphuric acid. The aqueous filtrate shaken with amyl-alcohol gives a red

residue with *ponceau*, dark-brown with *vinicoline*, unchanged with reagents, whilst with *cassissin* it is dirty-green with a violet edge, and is changed to yellowish-brown with hydrochloric acid. The magnesium hydroxide is dark-grey with pure wine, or wine coloured with vegetable colours; with *orseille*, violet; *magenta* or *acid magenta*, dirty-white; *cassissin*, dirty yellowish-brown; *vinicoline*, crimson-red.

Wine shaken with amyl-alcohol, and the coloured layer evaporated in a porcelain dish, gives a residue which is coloured by:—

		With Conc. H_2SO_4	With Conc. HCl	With NaHO
Orseille	Violet-red	Blue	Red	Blue
Bordeaux B	Carmine	Carmine	Carmine	Carmine
Ponceau RRR	Dark-red	Crimson	Crimson	Brown
Cassissin	Violet-purple	Yellow	Yellowish-brown	Red
Vinicoline Bordelaise	Cherry-red	Brown	Red	Brown

The author points out the great difficulty there is in distinguishing between the natural colouring matters, and especially between the natural colouring substance of the grape and that of whortle berries, and he now uses tartar-emetic as a reagent for these colouring substances. This substance is not only a test for artificially-coloured white wine, but also for red wine to which colouring matters have been added. The test is carried out as follows: 10–15cc. of the wine to be tested is shaken in a small cylinder with about 5cc. of a concentrated solution of tartar emetic, and then examined by transmitted and reflected light. If no change of colour takes place, the cylinder is placed on one side for some time, when a coloured precipitate separates out. Pure red wine from different sources always gives a cherry-red colour, whilst all other red vegetable colouring matters give varying shades of violet.

The colours given with tartar-emetic by—

Red wine pure is	Cherry-red.
Red poppy (Papav. Rhoeas)	Dark cherry-red.
Cherry	Violet.
Elder colouring matter (Sambucus) commerc.	Reddish-violet.
Whortle berry (Vaccin. Myrtill)	Bluish-violet.
Privet berries	Pure violet.

With red wine mixed with 10 per cent. foreign colouring matter, these colours are less intense, but by long standing and comparison with pure red wine they can be determined with certainty. The tartar-emetic appears to form an antimony-lake with the colours.—G. H. M.

On the Detection of an Artificial Colour in Claret.

Samelson. Chem. Zeit. 10, 998.

A SURE METHOD for detecting any artificial colouring in claret does not exist up to the present. The following may, however, lead to it. A test-tube filled three-quarters full with wine, to which an aqueous sodium nitrite solution is added, gives the following reactions with different wines: 1. White wine grows a little darker, but the liquid remains clear. 2. Red wine gives a precipitate, which settles after some time. The supernatant liquor must be yellow or yellowish-brown. Artificially coloured wines do not show that yellow colour. 3. A mixture of white and red wine gives a precipitate, which is inversely proportional with the addition of white wine. 4. White wines coloured red with a vegetable dyestuff—the decoction of bilberries, mallow, orchil and red poppy were especially examined—give no precipitate. If genuine clarets be mixed with white wines coloured red, the following may be noticed on adding sodium nitrite: 1. If bilberries or mallow are present, the supernatant liquor is violet; if orchil is present, the liquor is cherry-red; if red poppy be used, the supernatant liquor is light-red. The addition of cider to white wine can also be detected by sodium nitrite, cider being coloured dark-brown by that reagent, and yielding a small precipitate after some time.—S. H.

Remarks on Detecting Artificially-coloured Clarets.

J. Herz. Chem. Zeit. 10, 998.

AMBUHL and ELSNER employ a hot solution of tartar-emetic for testing the red colour of claret. The author finds that this reagent acts a great deal better in the cold.—S. H.

Tannin Estimation.

H. Dieudonné. Chem. Zeit. 10, 1067.

WHEN carefully followed, the author's method gives accurate results. It merely consists in taking the

density of the tannin solution, by means of a sensitive hydrometer, before and after treatment with skin-powder. A special hydrometer is employed, showing only one degree Baumé, but this one degree is divided into hundredths. The density observation is carefully made at a temperature of 22° C., and distilled water must be used in preparing the solution. As standard, the tannin of gall-nuts must be taken. The following table shows the gradation at 22° C. of 0.1–10grms. tannin dissolved in a half litre of water, the readings being given to the nearest half centesimal degree:—

Tannin.	Cent.	Tannin.	Cent.
Grms.	Baumé.	Grms.	Baumé.
0.1	1½	5.1	56
0.2	3	5.2	57
0.3	4½	5.3	58
0.4	6	5.4	59
0.5	7½	5.5	60
0.6	9	5.6	61
0.7	10½	5.7	62
0.8	11½	5.8	63
0.9	12½	5.9	64
1.0	13½	6.0	65
1.1	15	6.1	66
1.2	16	6.2	67
1.3	17	6.3	68
1.4	18	6.4	69
1.5	19½	6.5	70
1.6	20½	6.6	71
1.7	21½	6.7	72
1.8	22½	6.8	73
1.9	23½	6.9	74
2.0	25	7.0	75
2.1	26	7.1	76
2.2	27	7.2	77
2.3	28	7.3	78
2.4	29	7.4	79
2.5	30	7.5	80
2.6	31	7.6	81
2.7	32	7.7	82
2.8	33	7.8	83
2.9	34	7.9	84
3.0	35	8.0	85
3.1	36	8.1	86
3.2	37	8.2	87
3.3	38	8.3	88
3.4	39	8.4	89
3.5	40	8.5	90
3.6	41	8.6	91
3.7	42	8.7	92
3.8	43	8.8	93
3.9	44	8.9	94
4.0	45	9.0	95
4.1	46	9.1	96
4.2	47	9.2	97
4.3	48	9.3	98
4.4	49	9.4	99
4.5	50	9.5	100
4.6	51	9.6	101
4.7	52	9.7	102
4.8	53	9.8	103
4.9	54	9.9	104
5.0	55	10.0	105

The process is thus conducted:—Of the sample to be tested, 20grms. are boiled four times with water and pressed; the liquid is made up to half litre, and if of a higher density than 1° Baumé must be diluted to that

density or lower, note being taken of the amount of dilution. 100grms. of the solution are frequently shaken with 5grms. of powdered skin, and next day filtered off and pressed. If 95° be the reading before, and 43° after treatment with skin, the difference (52°) corresponds to 4·7grms. of tannin according to the table, and if there were no dilution of the original half litre, this would consequently indicate 23·5 per cent. of tannin. To get a good reading of the hydrometer, the stem may be smeared with fat oil and well wiped. Dried skin should be used, as the amount of water retained by the undried would introduce appreciable error, as can be easily shown by direct experiment. Further, the thermometer, and especially the hydrometer, must be very carefully made.

—J. T.

The Determination of Nitrogen by Kjeldahl's Method. A. Rindell and F. Hannin. *Zeits. Anal. Chem.* 25, 155—156.

IN the *Zeits. Anal. Chem.* 24, 388 (see this Journal, 1886, 180), Pfeiffer and Lehmann recommended the use of a tube with a perforated platinum cone surmounted by glass beads, in order to retain small quantities of sodium hydrate, which are liable to be thrown up from the distillation flask. The authors have examined this improvement, and find that even when it is used small quantities of soda are still carried over by rapid distillation, owing to the beads becoming wet with condensed water, and, in consequence, spitting taking place. A greater length of beads did not rectify this, and it was found necessary to employ relatively dry beads, by

surrounding the bead-tube with a steam-jacket. The form of tube used is shown in the accompanying figure. The outer tube has a diameter of 25mm., and the inner tube with beads, which is closed at the bottom by a wire-gauze (nickel), is 10—12mm. wide. The column of beads should be at least 8cm. high. This tube was tested by the distillation of sodium hydrate and zinc, as in a nitrogen determination, and proved quite satisfactory. The authors use a much more dilute standard acid (1cc. $\text{H}_2\text{SO}_4 = 0.0006862\text{grm. N}$) than Pfeiffer and Lehmann, and consider this necessary with the small amount of substance employed. Litmus, by treatment with lime, according to Schlösing's method, furnishes an extremely good indicator.—G. H. M.

Estimation of Alumina in Aluminates. E. B. *Zeits. Anal. Chem.* 25, 183—186.

THE author has used for about three years the method described by Bayer (*Zeits. Anal. Chem.* 24, 542; this

Journal, 1886, 41), for the determination of alumina. The solution employed must be very dilute, and not contain more than 0·1 per cent. alumina. The alkalinity has been determined by adding an excess of ammonium salt, distilling, and determining the ammonia in the distillate.—G. H. M.

New Books.

FORTSCHRITTE UND VERBESSERUNGEN DER WOLLEN-STUCKFÄRBEREI. Seit 1877. Ein Praktisches Hilfs- und Lehrbuch für Färberei-techniker, Tuch-, Flanell-, Plüsch-, Filz- und Wollwarenfabrikanten und solche die es werden wollen. Unter Mitwirkung mehrerer Freunde herausgegeben. Von E. H. ANGARYD, Färberei-dirigent. Mit gegen 120 Farbmustern. Leipzig: Verlag von Gustav Weigel. London: H. Grevel & Co., 33, King Street, Covent Garden.

THIS is an 8vo volume, in the usual loose paper cover. Price 15s. It contains Preface, Introduction, and Table of Contents, with 206 pages of subject matter, and a Remark in Conclusion. With the text are interspersed about 120 specimens and dyed samples. The technical names of the colours are maintained throughout, and no reference is made to scientific nomenclature or formulæ; the book is clearly designed, however, for practical dyers. The arrangement of the subject is gathered from the following arrangement of the contents:—The tar colours and their use in general; (1) thoroughly fast dyes; (2) fast dyes; and (3) half-fast dyes. The technical nomenclature of the tar colours. The investigation of the tar colours occurring in the trade. The method of woollen piece dyeing with the tar colours. The use of the alizarin colours of gallein and cœrulein in the woollen piece dyeing (with 11 dye-patterns). Scarlet- and ponceau-red dyes (with 5 patterns). Orange dyes (with 3 patterns). Rose-coloured dyes (with 6 patterns). Carmine- and amaranth-red dyes (with 6 patterns). Bordeaux- and madder-red dyes (with 9 patterns). Yellow dyes (with 6 patterns). Green dyes (with 3 patterns). Olive-green dyes. Blue dyes (with 10 patterns). Violet dyes (with 5 patterns). Brown dyes (with 10 patterns). Black dyes. Fashionable dyes (with 33 patterns). On the usual mordants employed in dyeing with aniline colours alone or in combination with the natural colours. The washing of dyed woollen cloth. The removal of spots and stains from cloth. New materials for vat dyeing, proved by practice. Table for dyeing with tar colours, silks, wool, and cotton. Table for the detection of some tar colours by means of sulphuric acid. The greatest difficulties of the piece dyer; or, the errors that may be incurred in dyeing woollen piece goods. The loss of dye ("bleeding") in the case of dyed goods or washing and mangling, with reasons, together with hints for avoiding such accidents.

DIE FORTSCHRITTE DER LOSEN WOLLEN- UND WOLLENGARN-FÄRBEREI (unecht und walkecht). Seit 1881. Von R. SACHSE, E. H. ANGARYD und E. HARZANGER. Mit 39 Farbproben auf 5 Tafeln, deren Farbtöne mit den gegebenen Vorschriften übereinstimmen. Leipzig: Verlag von Gustav Weigel, 1886. London: H. Grevel & Co., 33, King Street, Covent Garden.

8vo-SIZED VOLUME, or rather pamphlet, containing Introduction and 99 pages of subject matter, and two pages of tables showing the maximum temperatures for dyeing goods (1) with certain coal-tar colours, and (2) with certain natural colours, and giving the percentage weights, etc., of mordants to be used. The

price of the work is 9s. 6d. The following treatment of the subject is adopted:—The washing of the loose wool. The washing of fine yarn, such as combed yarn. The dyeing of the yarns and loose wool generally. Bleaching by means of peroxide of hydrogen. Then follow methods of dyeing all the different colours, and recipes for the purpose. Fashionable dyes. Dyeing with alizarin colours that are fast against light and washing, on woollen yarn, combed yarn, and loose wool. Rinsing and drying of dyed yarns. Technical nomenclature of the tar colours. The patented dyeing system and apparatus of Obermaier; for wool, for spun yarn in cops, and for loose cotton. Different tested recipes for the woad and carbonate of soda vats.

DIE PRAXIS DER BLEICHEREI UND APPRETUR. Baumwolle, Leinen, Jute im Rohzustande, sowie als Garn, Zwirn und Gewebe. Von R. CENTNER. (Mit 4 Bleichmustern.) Leipzig: Verlag von Gustav Weigel, 1886. London: H. Grevel & Co., 33, King Street, Covent Garden.

SMALL 8VO PAMPHLET containing Preface, Table of Contents, and 123 pages of subject matter, and four pages of tabulated matter. Price 3s. 6d. The contents are headed as follows:—Bleaching process for linen or flax yarns. Practical process for bleaching with potassium and sodium permanganates. Practical introduction to the bleaching of vegetable fibres by means of chlorine and potassium permanganate (with 4 patterns). Bleaching with chlorine in the dry way. The bleaching of cotton yarn and cotton piece goods, especially in the small way. The modern style of bleaching and blue-dyeing of cotton yarn, of hosiery, and of cotton wool, as also of goods with Turkey-red stripes. Good method of bleaching for linen threads, sewing cottons, and worsteds. The bleaching of cotton yarns for the cotton-dyer. The bleaching of cotton wool. The bleaching of cotton fabrics for the calico-printer. Bleaching under the ordinary pressure. Bleaching under high pressure. The finishing of moleskin goods. The bleaching and finishing of English curtains in original width. The principles of the Mather-Thompson bleaching process. Improvement in the bleaching of vegetable fibres with chloride of lime, by G. Lunge. On bleach-spots, by Georges Witz. On the best method of bleaching jute fibres. On the bleaching of jute by means of sulphur. The finishing of cotton fabrics. Finishing of blue printed goods, etc.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

11973 A. Budenberg, Manchester—From Schäffer and Budenberg, Germany. Improvements in pressure gauges. September 21
12014 R. J. Friswell and A. Myall, London. Improvements in filter presses. September 21
12018 A. M. Clark, London—From V. A. Pillond, France. Apparatus for automatically compressing air. September 21
12077 J. R. Alsing, London. Improvements in the construction of titrating cylinders. Complete specification. September 22
12078 H. H. Lake, London—From C. Bianchi, Italy. Improvements relating to means for promoting combustion in boiler and other furnaces. September 22
12091 C. A. Clapham, Bradford. Improvements in filters. September 23

12108 C. A. Knight, Glasgow. Improvements in sectional steam generators. Complete specification. September 23
12166 H. J. Allison, London—From J. Richards, United States. Improvements in centrifugal pumps. September 24
12182 R. N. Boyd, London. Improvements in safety and signal apparatus for steam boilers. September 25
12196 L. Gienre and E. Ofstedahl, Newcastle-on-Tyne. Improved apparatus for accelerating the generation of steam in boilers during and after firing. September 25
12282 E. S. T. Kennedy, London. Flame deflectors upright boilers. Complete specification. September 28
12301 P. Fanta, A. Cohen, and E. Cohen, London. Improvements in the construction or arrangement of parts of furnaces. September 28
12347 G. Harding, Preston. A steam or water valve that does not require any packing. September 29
12352 J. L. Wade, Glasgow. An improved composition for preventing incrustation in steam boilers. September 29
12371 H. Lane and R. H. Taunton, London. Improvements in the manufacture of metallic vessels, suitable for containing gases and volatile liquids under pressure, and for other useful purposes. September 29
12381 J. Gilmore, J. F. Gilmore, and W. R. Clark, London. Improvements in steam generating apparatus. September 29
12410 J. S. Booth, London. Improvements in the construction of boiler and other furnaces. September 30
12412 W. P. Hoblyn, St. Columb. Improvements in smoke consuming stoves and furnaces. Complete specification. September 30
12418 G. Best, London. Improvements in apparatus for condensing steam. September 30
12419 A. L. Normandy, London. Improvements in machinery for producing distilled water from sea or other impure water. September 30
12426 G. Downing, London. From E. Brouillet, France. An improved safety apparatus for steam generators. September 30
12467 R. Thompson, Liverpool. Improvements in or appertaining to furnaces in which the materials operated upon are mechanically stirred under heat. October 1
12475 J. Y. Johnson, London—From L. Labeyrie, France. An automatic valve for steam or other pipes, or conduits conveying fluids under pressure. October 1
12498 J. Brookbanks, Newcastle-on-Tyne. Composition for removing scale or other incrustations from the inside or other parts of steam boilers. October 2
12508 J. Turns, South Shields. An improved apparatus for purifying the feed-water of steam boilers. October 2
12526 W. G. Little and C. W. G. Little, Rotherham. Supplying steam boilers automatically with water, and regulating the height of the water. October 5
12546 W. Shaw and J. Cran, Glasgow. Improvements in apparatus for increasing the draught in boiler furnaces, and funnels or chimneys. October 5
12724 J. T. Key, Sheffield. Improvements in apparatus for supplying tar and other liquid fuel to furnaces and other like fires. October 6
12758 A. Black, jun., London. Improvements in water softening apparatus, applicable also for clearing or clarifying other liquids. October 6
12774 T. F. Hind and R. Lund, London. Improvements in machinery or apparatus for grinding paints, inks, starch, chocolate, and other like materials. October 7
12808 F. W. Hart, London. Improvements in gas fires, stoves, or furnaces for chemical, domestic, and manufacturing uses. October 8
12867 J. W. Lovibond, Salisbury. Improvements in apparatus for standardising and measuring intensity of colour in transparent bodies. October 9
12944 A. A. Joy, London. Improvements in and connected with gauges for indicating and controlling the pressure of gas. October 11
12975 F. H. Stacey and H. Wilkinson, Sheffield. Improvements in apparatus for blowing exhausting, and pumping. October 12
12986 H. C. F. Stoimer, London. Improvements in the construction of apparatus for washing and absorbing gases, and for evaporating or concentrating liquors. Complete specification. October 12
13015 A. Brin and L. Q. Brin, London. Improvements in means and apparatus for effecting the heating of water or liquids for raising steam, or for other purposes. October 12
13012 G. L. Scott, Manchester. Improvements in filters. October 13
13133 H. H. Lake, London—From S. Jönsson, Denmark. Improvements relating to regulating mechanism for use in connection with intermediate belt gear, chiefly designed for limiting the speed of centrifugal apparatus. Complete specification. October 14
13310 J. Murrie, Glasgow. Improvements in boilers for generating steam and other vapours. October 19
13336 A. J. Boulit, London—From W. A. O. Hegeman, United States. Improvements in fluid pressure regulators. Complete specification. October 19
13341 W. Anderson, London. Improvements in centrifugal pumps. October 19
13417 E. Kemp, Glasgow. Improvements in compound boilers or apparatus for heating water and generating steam. October 21
13441 W. P. Thompson, Liverpool—From A. J. McBride, United States. Improved filtering and cooling apparatus. October 21

V.—TEXTILES: COTTON, WOOL, SILK, ETC.

APPLICATIONS.

- 12212 T. S. Brigg, Leeds. An improved printed coating or cloth. September 25
 12213 T. S. Brigg, Leeds. An improved cloth. September 25
 12319 H. E. Newton, London—From O. Chemin, France. Improvements in the treatment of raw or manufactured animal fibres for the purpose of separating vegetable matters therefrom. September 28
 12710 T. Pickles, Manchester. Improvements in the treatment or preparation of grey or unbleached cotton or linen warps or warp yarns prior to weaving. October 6
 13051 T. Honeywood, London. Improvements in the preparation of fibre for textile and other purposes. October 13
 13429 J. A. Hart and Dr. C. Baynes, London. Improvements in machines for blowing and beating cotton or other textile materials. October 11

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11892 H. J. Haddan—From J. Breuer. Decorticating ramio and other textiles, and apparatus therefor. October 8
 13380 F. Sutcliffe. Apparatus for treating cotton, wool, etc., in process of manufacture. September 21
 13782 T. Pickles. Treatment of grey or unbleached warps or yarns prior to weaving. October 12
 15070 J. McNaught and W. McNaught. Machinery for drying wool, etc., and separating foreign matters therefrom. October 19
 15313 C. Till. Improved fabric suitable for the manufacture of blankets, mattresses, wearing apparel, etc., and apparatus for its production. October 12
 15717 W. R. Lake—From F. E. J. Dubar. An improved textile fabric. October 1

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

- 11981 A. Hodgkinson, Ballyclare. Cleansing composition for linen or cotton fabrics or yarns, for use in the process of bleaching same. September 21

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

- 12216 J. Kirkpatrick. See Class XI.
 12286 J. Worrall, Dukinfield. Sewing together the ends of calico or other fabrics intended for calendering, bleaching, and other purposes. September 28.
 12312 J. Hildesheim and The Patent Decorative Washable Sanitary and Waterproof Paper Company, by L. H. Watson, London. Improvements in machinery for sizing or varnishing and applying colours to paper and other fabrics. September 28.
 12362 F. A. Gatty, Manchester. Improvements in dyeing cotton, cotton yarns, and cotton fabrics. October 20.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11810 W. E. Akroyd and W. W. L. Lishman. Apparatus for dyeing and sizing warps. October 1.
 11975 A. S. Young. Printing on calico, etc. October 19.
 15438 G. Watson, jun. Obtaining baths of chloride of antimony for use in dyeing and calico printing. October 12.

1886.

- 38 B. F. Cresson. Dyeing and printing aniline black, and solutions used therefor. October 12.
 7083 T. R. Shillito—From The Zittauer Maschinenfabrik and Elsengeesserei (früher A. Kiester & Co.). Apparatus for oxidising aniline black on woven fabrics. October 15.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

- 12070 A. Brin and L. Q. Brin. See Class X.
 12110 J. J. Hood and A. G. Salaam, London. Improvements in the manufacture of meta-stannic acid, and in the purification of meta-stannic acid. September 23.
 12255 T. Raynaud, Greenwich. Producing hyposulphite of soda, for antichlor, photography, etc. Complete specification. September 27.
 12480 F. H. Gossage, T. T. Mathieson, and J. Hawliczek, London. Improvements in and apparatus for the treatment of sulphide of sodium for the manufacture of sulphide of sodium therefrom (*sic*). October 1.
 13001 J. I. Watts and W. A. Richards, Liverpool. A new or improved sodium product and method or methods of manufacturing the same. October 12.
 13173 A. Packard, London. Improvements in the fabrication of compounds of bisulphate and biphosphate of the alkalis from the neutralised sulphates and concentrated phosphoric acid. October 15.
 13236 A. Frank, London. Improvements relating to the treatment of the spent lyes used in the manufacture of cellulose, by means of sulphites, for the recovery of sulphurous acid therefrom, and to the utilisation of the said lyes after such treatment. October 18.
 13389 E. Solvay, London. A new or improved continuous furnace for the production of chlorine. October 20.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 12035 G. G. Pickling, W. Hopkins, J. Dore and J. Dore, London. Manufacture of vinegar. September 24.
 13099 J. G. Chapman and R. Foote. Apparatus for generating carbonic acid gas. October 12.
 13108 J. G. Johnson. From C. Dubois. See Class II.
 13162 J. B. Spence. Manufacture of sulphide of zinc. September 28.
 11279 G. H. Bolton and J. Leathwood. Lids applicable to caustic soda drum heads, etc. October 3.
 14361 E. W. Parnell and J. Simpson. Production of sulphur and sulphuric acid. October 19.
 15386 N. M. Henderson. Apparatus for distilling ammonia. October 5.

1886.

- 46 E. W. Parnell and J. Simpson. Production of pure carbonic acid gas. October 15.
 715 W. B. Giles and A. Shearer. Manufacture of phosphoric acid. October 22.
 10798 H. J. P. Sprengel. Production of sulphuric acid. October 5.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

- 12076 T. Cooper J. Thomas, London. Improvements in the manufacture of glass. September 22.
 12148 E. H. Pearce and H. Besson, Birmingham. Improvements in machinery for working glasses. September 24.
 12388 F. D. Bradley and H. Snow, Longport. An improvement in the method of piercing or perforating pottery, porcelain, etc. September 29.
 12196 W. Horn and R. Bell, Sunderland. Improved shears used in the manufacture of glass bottles. October 2.
 12542 E. R. Blundstone. See Class IX.
 12793 H. L. Boulton and W. P. Rix, London. Improvements in the production of ornamental pottery ware. October 7.
 12868 W. Breffit, London. Improvements in the manufacture of glass bottles and other like vessels or utensils. October 9.

- 12990 J. Armstrong, London. Improvements in the manufacture of glass, opal, crystal, porcelain, and like substances, and machinery and appliances therefor. October 12.

- 13132 E. Moore, London. Improvements in rockers for use in connection with the annealing hear, or hear, of a flint glass house. Complete specification. October 11.
 13209 W. Lutwyche, London—From A. Ceresa, Italy. Producing mosaic by means of enamelling substances and coloured glass. October 16.
 13233 J. G. Macintyre and F. Vodrey, London. Improvements in the method of decorating ceramic ware. October 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 13561 F. D. Bradley and H. Snow. Manufacture of ornamental pottery, porcelain and glass. October 12.
 13392. L. J. Murray. Manufacture of glass-ware. October 22.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

- 12421 W. D. Curzon, C. R. Williams, and the Patent Paving and Construction Co., Limited, London. An improved manufacture of cementitious slabs and the like for structural and other purposes. September 30.
 12470 E. Long, London. Improvements in concrete blocks for building purposes, and in the means or apparatus employed for manufacturing them. October 1.
 12542 E. R. Blundstone, London. Improvements in the manufacture of plaster of Paris. October 2.
 13242 F. W. Floring and K. J. Meyer, Barmen, Germany. Improvements in making fireproof ceilings, partition walls, and complete buildings; applicable also for making tubes, etc. October 18.
 13278 C. Straub, London. An improved composition or building material for architectural purposes. October 18.
 13291 H. H. S. Pearce, London. Improvements in structural appliances and other fittings, formed by a combination of ordinary building materials with indiarubber and other elastic substances. October 19.
 13306 R. G. Scrivener, Newcastle, Staff. Brick and tile facing. October 19.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 13328 T. Smith. Combination of materials for making cements, etc. October 22.
 15751 W. Joy. Charging cement kilns. October 22.

1886.

- 10631 J. Mobberley and H. Perry. Manufacture of bricks. October 12.
 11027 J. Sutherland. Construction and ornamentation of walls, ceilings, etc. October 12.

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

- 11971 J. Park, Glasgow. Improvements in recovering tin from tinned plate and other materials. September 21.
 11972 B. H. Thwaite, Liverpool. The purification of iron ores and fluid iron metal, and apparatus therefor. September 21.
 12053 D. McKechnie, Liverpool. Improvements in or relating to furnaces for the smelting or refining of copper. September 22.
 12055 M. Vesenmayer, London. Improvements in the method of collecting finely-divided gold and float gold, and in apparatus therefor.
 12070 L. Brin and L. Q. Brin, London. Improvements in the treatment of copper and iron pyrites for the manufacture therefrom of sulphuric acid and oxides of copper and iron, and in the treatment of the said oxides for the production therefrom of metallic copper and the higher oxides of iron. September 22.
 12117 W. Maxwell. See Class XVIII.
 12128 R. Poole, Handsworth. An improved "annealing cover" for sheet-iron or other purposes. September 21.
 12147 J. Ridge, Sheffield. An improved metallic composition or alloy. September 24.
 12157 J. Dale, London. Improvements in tinned copper goods. September 24.
 12202 J. Whitley, Leeds. Improvements in the construction of bronze guns and other ordnance. Complete specification. September 25.
 12227 W. Fairclough and W. Warburton, Manchester. Improvements in reflecting appliances for use in miners' safety lamps. September 27.
 12249 W. S. Squire and S. C. C. Currie, London. Obtaining zinc in a metallic form from alkaline solutions of zinc oxide. September 27.
 12271 W. H. Fallett, London. Improvements in plant for casting steel ingots. Complete specification. September 27.
 12295 G. J. Atkins, London. New or improved means and apparatus for the separation of gold and other metals from their ores. September 28.

- 12326 H. H. Lake, London.—From J. Illingworth, United States. Improvements in moulds chiefly designed for use in the manufacture of armour plates. Complete specification. September 28.
- 12355 A. Brin and L. Q. Brin, London. Improvements in the manufacture of iron and steel. September 29.
- 12364 C. J. Sandahl, J. Birchall and J. Musson, Liverpool. Improvements in the manufacture of iron and steel. September 29.
- 12362 C. J. Sandahl, J. Birchall and J. Musson. Improvements in the manufacture of iron and steel, and in blast furnaces employed therein. September 29.
- 12363 C. J. Sandahl, J. Birchall and J. Musson. Improvements in and in connection with the manufacture of iron and steel, partly applicable to other purposes. September 29.
- 12428 E. R. Cummins, London.—From G. P. Schweder, Portugal. Improved process for extracting gold and antimony-regulus from auriferous antimony ore. September 30.
- 12487 G. A. Goodwin and W. F. How, London. Improvements in the method of and process for utilising tin plate waste. October 1.
- 12541 R. Miller and N. E. McCallum, Glasgow. Improvements in furnaces for the manufacture of steel. Complete specification. October 2.
- 12559 H. Kellerman, London. Improvements in the manufacture of pipes or tubes of sheet metal. October 2.
- 12592 A. N. Hopkins, London. Improved means for restoring the surface of "raised" articles of tin plate. October 4.
- 12623 M. Settle, Manchester. Improvements in electric safety lamps for use in mines. October 5.
- 12630 W. S. Squire and S. C. Cuthbert, London. Obtaining metallic zinc from its ores. October 5.
- 12636 B. J. B. Mills, London.—From N. W. Perry, United States. Improvements in detectors for marsh gas and other hydrocarbon gases. Complete specification. October 5.
- 12651 J. W. Swan, London. Improvements in electric safety lamps, and in the means of detecting and measuring fire-damp or explosive gases. October 5.
- 12675 W. D. Allen, London. Improvements in machinery or apparatus for forging by hydraulic pressure. October 5.
- 12684 A. Gutensohn and J. W. Bushe, London. Improvements in metallic alloys. October 5.
- 12692 H. W. Bessemer, London. Improvements in the manufacture of malleable iron and steel, and in apparatus employed for that purpose. October 5.
- 12720 C. Hensler, London. Improvements in producing silicious copper, and utilising the same for metallurgical purposes. October 6.
- 12727 C. Blagburn, London. Improvements in apparatus for pumping water from mines. October 6.
- 12729 G. M. Edwards, London. Improvements in machinery and appliances for treating, dressing, and cleaning tin and other mineral ores, and in modes, means, and processes connected therewith, and for other useful purposes. October 6.
- 12835 A. T. D. Berrington, London. The manufacture of certain alloys of iron. October 8.
- 12861 J. Warick, Newcastle-on-Tyne. Improvements in the treatment of fume in lead works. October 9.
- 12866 J. Gilchrist and D. Ballardie, Glasgow. Improvements in miners' lamps. October 9.
- 13073 A. Parkes, London. Improvements in extracting gold, silver, and other metals from ores or compounds containing the same. October 13.
- 13151 F. Siemens and J. G. Gardon, London. An improvement in the manufacture of steel. October 15.
- 13162 E. Packard, London.—From E. C. Griffin, United States. Improvements in machinery for pulverising ores or other hard substances. Complete specification. October 15.
- 13185 G. Baron de Overbeck, London. Improvements in the manufacture of aluminium. October 15.
- 13189 H. J. Kirkman, London. Improvements in the process of cleansing metals or alloys previous to their being coated with other metals or alloys. October 15.
- 13223 S. Godfrey, London. Improvements in machinery or apparatus for drilling or boring hard substances, such as rock or stone, for blasting and other purposes. October 16.
- 13230 J. B. Clark and The Panther Lead Company, Limited, London. Improvements in smelting lead ores. October 16.
- 13238 J. Ravenhand, Sheffield. Improvements in ingot moulds, consisting of interchangeable and replaceable projections for nicking ingots to facilitate topping or breaking the ingot. The projections to be fitted in dovetailed recesses and triangular holes through the sides of the mould. Oct. 18.
- 13239 G. H. Lloyd, Sutton Coldfield; A. L. Lloyd, Leamington; and H. Bewlay, Mosley. Improvements in pipes of malleable metal and their mode of manufacture. October 18.
- 13266 E. Walsh, Jun., London. Improvements in blast furnaces. Complete specification. October 18.
- 13476 R. H. W. Biggs, London.—From C. Malin, Paris. Extracting industrially the tin from the iron in tin scraps. October 20.
- 13460 K. Heathfield, London. Improvements in apparatus used for coating sheets of iron and steel and articles of iron and steel with zinc or alloys of zinc or other coating metal or alloy. October 21.
- 13628 J. A. Crane. Production of iron and steel tubes. October 12.
- 14426 G. F. Simonds, London. Manufacturing rolled metal articles, and apparatus therefor. September 24.
- 15170 J. D. Grey. Rolling steel and iron bars or plates for the manufacture of tin orterne plates. October 12.
- 15215 T. Brown and J. G. Gordon. Machinery for rolling steel and iron. October 8.

1886.

918 A. Bobrownicki. Treatment of phosphoretic slag. October 5.

1827 G. A. Goodwin and W. F. How. Foundry ladles and crucibles. October 5.

3138 G. T. Lewis. Smelting tin ore and recovering tin from tinned sheet-iron scraps. October 15.

10011 H. H. Lake.—From R. de Montgelas. Manufacture of chloride of aluminium and double chloride of aluminium and sodium. September 28.

10013 H. H. Lake.—From R. de Montgelas. Apparatus for manufacture of chloride of aluminium and double chloride of aluminium and sodium. October 1.

10306 H. Tabor. Making foundry moulds. October 8.

10607 W. R. Lake.—From R. de Montgelas. The electro-deposition of aluminium. September 24.

11385 F. E. Hainley. Utilising the expansion and contraction of metals due to changes of temperature. October 12.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

12216 J. Kirkpatrick, Glasgow. Improvements in the manufacture of oil for Turkey-red dyeing, calico printing and such like purposes. September 25.

12652 A. Brin and L. Q. Brin, London. Improvements in the oxidation of oils for use in the manufacture of paints or varnishes, or for other purposes to which oxidised oils are applicable. October 5.

12709 C. Schill and C. Seilacher, London. A new or improved process for oxidising oils and fats and other organic substances. October 7.

13387 R. B. Tennant, Glasgow. Improvements in and connected with the refining or purifying of mineral and other oils, and in the recovery of by-products therefrom. Oct. 20.

13402 G. Linget J. Viaudely, London. Improvements relating to the manufacture of soap. October 20.

COMPLETE SPECIFICATION ACCEPTED.

1885.

14957 C. D. Abel.—From The Fabrik Chemischer Produkte Actien Gesellschaft. Separation and treatment of fatty matter from compounds containing wool-fat. October 5.

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

12499 J. B. Hannay, Glasgow. Improvements in preservative coatings for ships' bottoms. October 2.

12632 A. Brin and L. Q. Brin. See Class XI.

12712 W. R. Hodgkinson and A. Wingham, London. Improvements in the treatment of amber and other like fossil gums in the manufacture of varnish, or for other use. October 6.

13284 F. M. Lyte, London. Improvements in the manufacture of pigments. October 18.

13416 J. B. Hannay, Glasgow. Improvements in the manufacture and treatment of lead pigments and compounds, and in apparatus therefor; in part applicable for condensing or collecting various fumes or similar matters. October 21.

COMPLETE SPECIFICATION ACCEPTED.

1886.

606 C. F. Rousset. A new varnish, and method of applying the same. September 21.

XIII.—TANNING, LEATHER, GLUE AND SIZE.

APPLICATIONS.

12681 E. P. Nesbit, London. A process for clearing hides, skins, hair, wool or fur from lime. October 5.

13283 A. M. Clark, London. From J. B. West, United States. Improvements in tanning and stuffing leather. October 18.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

11111 E. Edwards.—From C. Kollico, Cornelle. Process and apparatus for tanning leather. September 21.

1886.

5344 J. W. Vaughn. Machines for putting and otherwise treating hides and skins. September 24.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

12140 K. Küpper. Process and compound for welding cast or wrought steel in bars, and for regenerating the welded steel. October 8.

12981 N. de Bernardos and S. Olzewski. See Class XVIII.

XIV.—AGRICULTURE, MANURES, ETC.

APPLICATIONS.

- 12772 W. S. Squire, London. Obtaining manure from distillers' spent wash. October 7
 13170 C. D. Abel, London. From P. Coupry, France. Improvements in the treatment of fecal matter for conversion into manure, and in apparatus therefor. October 21

COMPLETE SPECIFICATION ACCEPTED.

1886.

- 11883 J. H. Barry. Treatment of excreta and sewage sludge for production of manure. October 19

XV.—SUGAR, GUMS, STARCHES, ETC.

APPLICATIONS.

- 12012 H. H. Lake, London. From T. F. Krajewski, United States. Improvements relating to the treatment of sugar cane for the extraction of sugar therefrom, and to apparatus therefor. September 21
 12302 A. M. Wood, London. Improvements in the manufacture of indiarubber, gutta-percha, and analogous gums. September 28.
 12520 E. M. Knight, Halifax. Improvements in the manufacture of liquid gum. October 2
 12535 A. Brin and L. Q. Brin, London. Improvements in the manufacture of sugar. October 2
 13128 F. Swales, London. From H. Swales, Brazil. Improvements in sugar-cane mills. October 14
 13168 E. M. Knight and A. H. Hobson, Halifax. Improvements in the manufacture of liquid cement or gum. October 15
 13337 W. Ryder, London. Manufacturing "Ryder's silicated rubber composition." October 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 15897 M. P. W. Boulton, B. E. R. Newlands and E. Perrett. Revivifying spent charcoal.

1886.

- 3116 M. F. Heddle, D. C. Glen and D. Stewart. Filtering and decolourising sugar, syrups, etc., and preparing material therefor. October 5
 5735 J. Guardiola. Evaporating apparatus for saccharine juices. September 28

XVI.—BREWING, WINES, SPIRITS, ETC.

APPLICATIONS.

- 12071 F. Foster, London. Supplying the gasometer of continuous action liquid aerating machines automatically from a reservoir of compressed or liquefied carbonic acid gas. September 22
 12291 E. Manbré, Liverpool. Improvements in or appertaining to compounds applicable for the manufacture therefrom of ale, stout, porter, lager, and other like liquors, and in apparatus for making said compounds. September 28
 12560 H. Stockheim, London. Improvements in apparatus for preventing the formation of froth upon beer when introducing the same into casks, and for similar purposes. Oct. 2
 12611 F. A. Reihlen, London. Improvements relating to the preparation and bottling of carbonated beverages, and to apparatus therefor. October 4
 13222 A. W. Gilman, S. Spencer, E. S. Spencer, and A. Perry, London. Improvements in the preparation of brown or black malt or colouring material for use in brewing, and in apparatus employed therein. October 16
 13276 A. G. Fraser and G. Epstein, London. Improvements in treating worts in separating yeast therefrom, and in treating yeast. October 18
 13385 H. Grote, London. A process for removing fusel oil and other impurities from crude spirits, or from the wash containing crude spirits. October 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 12036 G. G. Picking, W. Hopkins, J. Dore and J. Dore, Bromley. Manufacture of spirits. September 28
 14868 T. P. Chittenden. Aerating and attenuating worts and other liquors, and securing a pure germless atmosphere wherein to carry on fermentation. October 5
 15063 A. W. Gillman and S. Spencer. Finings for sour beer, waste and returns. October 8
 15168 F. Keeling. Preparation of finings for beers and wine. September 28

1886.

- 6069 S. A. W. Howmann. Manufacturing compressed yeast. September 21

- 9258 F. Faulkner and W. Adlam. Appliance for use in circulating and aerating malt and raw grain worts when producing ordinary malt liquors, distillers' wash, etc. October 8

- 10376 D. W. Hamper and J. H. Howell. Improvements in brewers' coppers and analogous vessels. October 5

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

APPLICATIONS.

A.—CHEMISTRY OF FOODS.

- 11995 W. G. Dunn, London. Improvements in baking powders. September 21
 11999 L. von Wohlforth, A. Tausky and F. von Friedland, London. Improvements in means and apparatus for preserving meat. September 21
 12061 H. R. Lipscombe, London. Manufacture of a composition for softening and purifying water. September 22
 12155 G. Fry, London. An improved apparatus for introducing cold air into refrigerating chambers. September 24
 12156 G. Fry, London. An improved apparatus for thawing frozen meat, or for the refrigeration of animal and vegetable substances. September 24
 12292 E. Phillips, Croydon, and R. Stavely, London. Manufacturing dull coffee finings. September 28
 12408 P. Homero, London. A tea made of a plant, herba homeriana, which is a cure for consumption and other diseases of the chest. September 30
 12608 J. Low, London. Improved mode of preparing food from cereals. October 4
 12890 J. Low, London. Improved mode of preparing food from cereals. October 9
 12951 A. Brin and L. Q. Brin, London. The manufacture of nitrogenated water. October 12

B.—SANITARY CHEMISTRY.

- 12075 G. H. Leane, London. Improvements in apparatus for the continuous or intermittent filtration of sewage, and for like purposes. Complete specification. September 22
 12218 T. Ogden, London. Improvements in furnaces for the desiccation, deodorisation, and combustion of animal and vegetable matters or town's refuse. September 27
 12259 R. de Soldenhoff, London. Improvements in the desiccation, incineration, and carbonisation of precipitates or solids resulting from sludge or other substances liable to putrefy, and in means and apparatus employed therein. September 27
 12882 W. B. Hallett, London. Improvements in the preparation of materials for use in the treatment of sewage and other liquids in order to purify them, and in the method of treating them, and in apparatus for use in their treatment. Sept. 29
 12829 G. W. Brenner, London. Preparing ingredients for treating sewage and other liquids for their purification. October 8
 12850 F. P. Perkins, Exeter. The treatment of sewage by clarification and precipitation. October 9
 13007 J. C. Butterfield and H. H. Mason, London. Improvements in the treatment of sewage and the recovery of valuable products therefrom. October 12
 13313 R. H. Reeves, London. Improvements in the construction of and arrangement of apparatus for the ventilation of drains or sewers, the deodorising of sewage, and disinfecting of gases. October 19

COMPLETE SPECIFICATIONS ACCEPTED.

A.—CHEMISTRY OF FOODS.

1885.

- 14552 B. H. Thwaite. Preserving animal and vegetable foods and liquids. October 22.
 14697 H. Pischow. Apparatus and process for preserving alimentary substances. September 28
 14807 W. F. B. Massey—From Mainwaring and J. Edmunds. Arrangements for oxygenating water contaminated with organic matter. October 5
 15387 J. Hooker. Preservation of condensed milk, and of milk, condensed or not, in admixture with alimental or medicinal matters. October 15
 15399 V. Tribouillet and E. Husson. Preservation of alimentary substances, and apparatus therefor. October 19.
 16071 F. Schmidt. Apparatus for the manufacture of ice. September 28

1886.

- 10170 H. J. Haddan—From M. Blumenthal. Manufacture of rennet. September 28
 10995 H. P. Madsen. Utilising the blood from slaughter houses in preparing food for man and cattle. October 12

B.—SANITARY CHEMISTRY.

1885.

- 13749 W. C. Sillar and The Native Guano Co. Treatment of sewage and other liquid putrescent matters. September 24
 15102 J. A. Drake and K. Muirhead. Means and appliances connected with the separation of liquids from sewage in filter-presses. October 13

1886.

- 11883 J. H. Barry. See Class XIV.

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

- 11997 W. Maxwell London. A method of producing carbon fibres or filaments. September 21
 12001 E. W. Adcock and J. W. Trotman, London. Improvements in primary batteries. September 21
 12111 J. Noad, London. An improved galvanic battery for generating and storing electricity. September 23
 12117 W. Maxwell, London. An electric furnace. Sept. 23
 12165 W. Stanley, jun., London. An improved electric generator. September 24
 12169 G. C. Fricker, Putney. Improvements in dynamo-electric machines. Complete specification. September 24
 12235 G. F. Rose, London. Improvements in primary electric batteries. September 27
 12251 G. Binswanger and C. Pollak, London. Improvements in electric batteries. September 27
 12531 H. Weymersch and R. McKenzie, London. Improvements in primary electric batteries. October 2
 12595 E. Andreoli, London. Improvements in secondary batteries. October 4
 12632 J. W. V. Kent, London. A new method of transmitting and distributing electro-magnetic energy. October 5
 12656 A. J. Boulton, London—From H. B. Cox, United States. Improvements in or relating to batteries. Complete specification. October 5
 12756 R. Dick and R. Kennedy, Glasgow. Improvements in and connected with the transformation and distribution of electric energy, and in apparatus therefor. October 6
 12770 W. Munns, London—From H. Merzbach and S. O. Eisele, Germany. Improvements in galvanic batteries. October 7
 12778 S. F. Walker, Cardiff. Improvements in dynamo-electric machinery or apparatus for generating electric currents by means of motive power, and for converting electrical energy into motive power. October 7
 12818 W. W. Beaumont, London. Secondary batteries. October 8
 12861 W. H. Munns, London—From H. Merzbach and T. O. Eisele, Germany. Improvements in dynamo-electric machines. October 9

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 11.—VOL. V.

NOVEMBER 29, 1886.

Non-Members 30/- per annum; Members
21/- per Set; Single Copies 2 6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S. ..	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S. ..	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.

COUNCIL FOR YEAR ENDING JULY, 1887.

President: David Howard.

Vice-Presidents:

Sir I. Lowthian Bell, Bart., F.R.S.	Sir H. E. Roscoe, M.P., F.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
Dr. Peter Griess, F.R.S.	E. C. C. Stanford.
Dr. Ferdinand Hurter.	J. C. Stevenson, M.P.
E. K. Muspratt.	John Williams.
Dr. W. H. Perkin, F.R.S.	Philip J. Worsley.

Ordinary Members of Council:

John Calderwood, F.R.S.E.	John Pattinson.
Eustace Carey.	S. A. Sadler.
R. Forbes Carpenter.	Sir Bernhard Samuelson, Bart., M.P.
Henry Doulton.	Sir Chas. Tennant, Bart.
Dr. John Evans, F.R.S.	Lewis T. Wright.
S. H. Johnson.	
Ivan Levinstein.	

With Sixteen Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

NOTICES.

The supply of copies of the Journal for January, 1882, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of that number, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the number will be reprinted.

The number of Subscriptions at the old rate which are being received from members for the year 1887, renders it necessary to call attention to the fact that, under the provisions of the Bye-Laws, as revised at the last General Meeting, the Annual Subscription to the Society will be in future 25s., instead of One Guinea as heretofore.

Arrangements are being made whereby those who have given Orders on their Bankers may exchange them for Orders at the new rate. Meanwhile, members wishing to make payments in advance are earnestly requested to note the alteration, and thus save much correspondence.

Authors of communications read before the Society or any of its Local Sections are requested to take notice that, under Bye-Law 43, they cannot receive the prescribed 50 copies of their communications unless they comply with the condition laid down in that Bye-Law—viz., that they give notice of their desire to receive such copies upon their manuscript before sending it to the Editor. Mention should also be made as to whether the Discussion is to be included in the reprint.

CHANGES OF ADDRESS.

A. Learmouth Adam, 10 Robertson Street; 10, Sir Michael Street, Greenock, N.B.
T. E. Ash, 10 London; 4, Saltram Place, Citadel Road, Plymouth.
A. Bouke, 10 Stratford; Highgate, N.

 James Wood, 10 Church; Green's Terrace, Padliham, near Burnky.
 Jas. C. Wright, 10 Manchester; c/o Messrs. Sadler & Co., Middlesbro'-on-Tees.

LIST OF MEMBERS ELECTED, 26th NOVEMBER, 1886.

Robert Bardsley, c/o Jewsbury & Brown, 41, Downing Street, Manchester, manager Mineral Water Factory.
 Bertram Blount, 23, Queen Anne's Gate, Westminster, S.W., analyst.
 Herbert L. Buckridge, 53, Palace Road, Crouch End, N., consulting chemist.
 Jno. Dawson, Kirkheaton Coal-tar Colour Works, Huddersfield, manufacturer of coal-tar colours.
 Wm. Haywood Dawson, British Alizarin Co., Limited, Silvertown, Victoria Dock, E., chemist.
 Wallis Evershed, c/o Whitewell & Co., Limited, Kendal, Westmoreland, brewer's chemist.
 Isidor Frankenburg, Greengate Rubber Works, Salford, Manchester, manufacturer of rubber goods.
 F. A. Glaeser, Carpenter's Road, Stratford, E., varnish manufacturer.
 Agnew Griffith, Daisy Mount, Blundell Sands, Liverpool, chemical student.
 Boston Harley, Laboratory, Carron Works, Falkirk, N.B., analyst.
 G. Crompton Holt, c/o Hugh Hughes, 4, York Buildings, Sweeting Street, Liverpool, analyst.
 J. Cecil Husband, Knowsley Street, and 21, Heywood Street, Cheetham, Manchester, pharmacist.
 William Morgan, Ph.D., Swansea, public analyst.
 T. Burdon Reay, 85, Herrington Street, Sunderland, chemist, Wear Fuel Works.
 James Riley, Laboratory, Brinscall Works, near Chorley, Lancashire, chemist.
 Jno. Taylor, The Belgrave Pharmacy, Torquay, chemist.
 Wm. Turnbull, 14, Wilbertorce Terrace, Gateshead-on-Tyne, manufacturing chemist.
 Thomas Wardle, Leek, Staffordshire, silk dyer, printer, and sericulturist.
 J. B. Wilkinson, Tong Street, Dudley Hill, Bradford, Yorks, chemical manufacturer.
 Jos. Wood, Brinscall, near Chorley, Lancashire, calico printer.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.	R. Messel.
H. F. Armstrong.	R. E. R. Newlands.
W. Lant Carpenter.	B. Redwood.
W. Crowder.	T. Royle.
C. Graham.	John Spiller.
S. Hall.	G. C. Frewby.
A. K. Huntington.	J. Williams.

Hon. Local Sec. and Treasurer: Thos. Tyrer,
 Garden Wharf, Church Road, Battersea, S.W.

The meetings of the London Section will be held on the first Monday in each month.

SESSION 1886-87.

Prospective Arrangements.

Dec. 6.—Mr. E. H. Truesdel, "On Strontium Hydrate."
 " Mr. T. Fairley, "On Various Forms of Filter Pumps and Water Jet Aspirators."
 " Messrs. A. G. Green and F. Evershed, "Note on the Volumetric Estimation of Nitrous Acid."
 Jan. 3.—Mr. Watson Smith, "On the Explosive, 'Kincite.'"
 Feb. 8.—Mr. W. Jago, "On Fermentation in its relation to Bread Making."

Notices of Meetings and Papers will be found in the Scientific Journals.

Notices of papers and communications to be made to the Local Secretary.

WHAT SHALL WE DO WITH OUR TAR?

BY LEWIS T. WRIGHT, C.E.

AMONG the various products of the distillation of coal in gas-works is a black, more or less viscid material known to us as tar. In some other manufactures tars are produced, but they are not discussed in the present paper.

This substance, that in the early history of gas undertakings was a waste product, became, through the discoveries of chemists and the enterprise of manufacturers, a storehouse of wealth and beauty. A few years ago, when the purchasing powers of the world for articles of necessity and luxury alike seemed to be almost without a limit, some of the products obtainable from coal-tar held a very considerable commercial value, and tar reached the price of 65s. per ton; yet, when the diminished demands of the purchasing populations first became evident to the great bulk of larger industries, tar products maintained their prices for a short time as though they were not to be affected as other commodities; but in a little while the channels through which so much had poured now began to evidence signs of choking, and increasing pressure became more and more necessary to get the products to flow away. Rapid then was the fall in prices—the irresistible force of which no efforts could stay.

The first individual to feel this enormous reduction of prices was the tar distiller; but the shadow cast over his shoulder by coming events fell across the threshold of the gas-maker, who suffered all the pangs of alarm before being actually smitten with the full blast of the storm, and then loud and indiscriminate, but quite unjust, complaints were hurled against tar distillers, dealers, and merchants, for what was thought to be their share in the fall of prices. When these were high and certain gas undertakings were receiving large sums for their tar and liquor, much injudicious jubilation was indulged in, and the inflated statements emanating from certain corners of the gas world became distorted and magnified images in the eyes of the public, who regarded gas-works as establishments wherein coal-gas was produced for nothing, and who firmly believed that the selling price of the gas was pure net profit. The enterprises called forth by the desire of capitalists to have a share in these streams of pure unalloyed profit did much to intensify, and even precipitate, the immense depression of gas products we are now so much deploring.

The quantity of tar annually produced in the United Kingdom must be a matter for estimation.

The returns made to the House of Commons relating to the authorised gas undertakings of the United Kingdom give the amount of coal carbonised in the year 1884 as 8,004,518 tons; and in 1883 as 7,631,304 tons. These show that the increased consumption of coal shown by the returns for 1884 over those for 1883 was 4·89 per cent. Assuming that the same percentage of increase obtained in the year

1885, we should have for the coals carbonised by authorised undertakings in that year the quantity of 8,395,940 tons. There are here and there scattered about the country small private works and unauthorised gas undertakings, but the amount of coal they consume in a year must be, as compared with the total, very nominal.

I take the total quantity of coal carbonised for gas-making purpose in the United Kingdom to be now 8,450,000 tons per annum.

For the purpose of arriving at the total quantity of tar produced by the distillation of the above quantity of coal, I shall take as the average yield throughout the United Kingdom the amount of 12.5 gallons of an average specific gravity of 1.185 per ton of coals carbonised. This will give the production of tar in 1885 as 105,625,000 gallons, or 558,780 tons weight. Of the tar produced in the distillation of coal only a certain (large) proportion goes into the hands of the tar distiller, for a certain (small) amount is used direct in the raw condition for tarring, asphalt, and other purposes. I find it very difficult to form an opinion of the extent of this tar thus escaping distillation. In some cases within my knowledge the proportion of local sales, as they are termed, reached 24 per cent., and that, too, when the price was at its highest point; but in view of what I know of the local sales in other towns, and from information generously supplied me by fourteen representative gas undertakings in all parts of the country, I take the quantity not distilled at $7\frac{1}{2}$ per cent. of the total production. There is also no doubt a certain quantity of tar now being employed for retort-firing, but at present I do not believe it much exceeds 1 per cent. This relatively insignificant proportion of tar in use as fuel is likely to be very much augmented if prices remain at their present level, or fall below it.

We may fairly assume that the total quantity of tar going into distillers' hands is 97,175,000 gallons. It would surprise many people if they were told that tar only contains about 5 per cent. of substances having positive value as materials entering into chemical manipulation, and that the great bulk goes for common purposes, such as creosoting, lubrication, and fuel.

Surely the day will arrive when the great bulk, instead of a select portion of the coal-tar hydrocarbons, will have positive chemical uses, and who can doubt but there are immense triumphs yet to be gained by our chemists and manufacturers in this direction?

I regret my inability at present to give definite information regarding two points of considerable interest—viz.: (1.) Variation in the composition of tars with varying qualities of coal distilled; and (2.) influence of temperature of production on the composition of the tar. Such results as I have are not sufficiently confirmed by repeated experiences to admit of publication; but, whilst touching upon this portion of the subject, it will be as well, perhaps, to give some broad information respecting the variation in the yield of tar from coal distilled at various temperatures, especially since G. E. Davis, in a paper read before this section on January 4, 1885, has published statements regarding the variation in the yield of tar that are opposed to my experience. As we increase the distillation temperature of our carbonising process we find the tar slightly decreasing in quantity, but increasing in specific gravity. I shall detail below the results of certain experiments made in this direction, but would now call attention to the fact that it is the tar which limits the distillation temperature we ordinarily employ in our retort-houses, probably more than any other cause. I believe that most large establishments would employ much higher heats than now, if it were not for the trouble

of stopped ascension-pipes and plugged-up hydraulic mains, etc. The moment when this difficulty of stopped pipes, etc., sets in is well-defined for each kind of coal. We know that when a certain yield of gas is being got from a certain coal, we are on a line that cannot be overstepped with the present disposition of gas-making plant. Now, it is all very well for Mr. Davis to call upon every gas-works in the country to reduce their make of tar 30 per cent. by an increase in the distillation temperature. If he were acquainted with the average gas-works he would know that there was very little margin for such an increase as to appreciably affect the production of tar at all.

The experiments given in table on page 560, conducted in clay retorts with the ordinary form of gas plant, will well serve to illustrate the variation in the volume and weight of tar yielded by coals distilled at widely different temperatures.

In the table the expression "normal temperature" means the best practically and continuously possible in a modern gas-works. By "very high temperature" is meant one only practicable by careful nursing, and for a short period.

It will be observed, by the inspection of the table, that with the coking coal differences of temperature represented by a reduction in the yield of gas per ton of 3272 and 3628 cubic feet affected the weight yield of tar 2.4 and 12.7 per cent. respectively, and that with the cannel coal a reduction in the yield of gas of 2727 cubic feet was represented by an increase in the tar of 8.7 per cent.

In the average gas-works the distillation temperature employed is as high as can be conveniently attained with the present forms of gas-making plant. So there is practically no margin for any reduction in the output of tar by the employment of higher "heats." There is, however, a tendency for the improvement of plant in this direction to admit of the employment of higher distillation temperatures.

The present extremely low price offered for tar, after a period of inflation, naturally induces those interested in gas manufacture to seek for some other more profitable means of utilising the tar than that of selling it to tar distillers, and various schemes, mostly *réchauffés*, have been submitted to the notice of gas engineers. These admit of the following classification:—

(a) Those dependent upon a preliminary distillation of the tar, and wherein the gas-works would be dependent on the services of the tar distiller.

- 1.—Utilisation of the lighter hydrocarbons (benzol) for the enrichment of coal gas.
- 2.—Utilisation of certain portions of the tar for manufacture of illuminating gas by their destructive distillation.

(b) Those wherein the tar is used by the gas maker, *en bloc*, without the intervention of the tar distiller.

- 1.—Utilisation of the tar for manufacture of illuminating gas by its destructive distillation.
- 2.—Utilisation of tar as fuel.

However hopeless some of these suggestions may appear to be on close investigation, we are yet bound to give them our attention, and if they serve no other purpose in the end than the promotion of inquiry, we ought, I suppose, to be grateful for that.

The only schemes that can be said to have had any hold at all upon the minds of gas engineers are those for the benzolisation of coal gas, and for the use of tar as a fuel. The idea of gas-making out of oil seems to be opposed to the gas engineer's instincts, so many absurd schemes having been brought out and failed in this connection.

The first scheme to consider is the benzolisation of coal gas, and can be very simply stated. Taking the

percentage by weight of benzol in coal tar as 0.8, the weight percentage of tar on the coal as 6.6, and the quantity of gas to be carburetted per ton of coals as 10,000 cubic feet, we have as the total quantity of coal-tar benzol available per 1000 cubic feet, 0.1183 lb. From laboratory experiment I find that to increase 16 to 17 candle gas a quantity of 19 lb. of benzol must be added to every 1000 cubic feet, so the amount of benzol available is only equal to an enrichment of our coal gas of 6-hundredths of a candle, and the cost, if we take benzol at 1s. 6d. per gallon will be at the rate of about $3\frac{3}{8}$ ths of a penny per candle per 1000 cubic feet enriched.

There is neither practical nor economical advantage here.

I have given some attention to the question of the conversion of the coal tar hydrocarbons into illuminating gas by destructive distillation. It must be remembered that all these bodies have been previously submitted to a high temperature, have been born in the gas retort, and are acclimated, as it were, to such conditions. As a matter of fact it is not easy to convert them into gas of any use.

The various oils I have worked with have been crude naphtha, light oil, and several fractions of creosote. The oil was run into a retort packed with

the great feature with these oils. How they could be got over in practice I cannot say.

Even the present price of crude naphtha, low as it may seem, quite precludes its use as a material for manufacture of illuminating gas. One of the drawbacks of the light and creosote oils was the poor quality of the gas, and even if the difficulties I have spoken of—viz., ubiquitous naphthaline obstructions—could be combated, there is nothing to invite their use for gas making at their present values.

Further, it must be remembered that gas-works are systems wherein the form of each piece of apparatus has been developed in the light of many years' experience for the best performance of its function in dealing with the particular coal and coal gas it is the object of the works to manufacture. I think it would be correct to say that many large gas-works of to day successfully dealing with one class of coal would be at a considerable difficulty if they were called upon to deal with coal of another type. Our gas-works are not designed to deal with gas from tar oils, and even if an apparent advantage could be shown with tar oils, one would hardly care to erect the necessary plant and work out its best form unless the advantage were felt to be of a permanent and not of a temporary

lumps of caustic lime, and the gas there generated passed through another similar retort also packed with lime in pieces. Both retorts were maintained at an orange-red heat. It will suffice here without entering into the details of each individual experiment, to broadly give the practical results obtained. The quantity and quality of the illuminating gases obtained in these trials depended upon the rate at which the oils were fed into the system of retorts.

Gas from Crude Naphtha.—The highest illuminating power obtained was 20½ candles with a yield of 10,130 cubic feet per ton. The highest yield of gas was 27,100 cubic feet per ton, with an illuminating power of 14½ candles; when the make of gas per ton fell as low as 6000 to 8000 cubic feet the illuminating power did not rise above 20 candles.

Gas from Light Oil.—In 16 experiments the make per ton ranged from 18,000 to 30,000 cubic feet per ton, and the illuminating power from 16 to 13½ candles.

Gas from Creosote Oil.—The highest illuminating power I obtained with creosote was 14 candles with a make of 13,300 cubic feet per ton; the highest yield of gas 29,300 cubic feet per ton, with an illuminating power of 8½ candles. To decompose the oils such a temperature has to be applied that low candle power gases are only obtained.

In all these experiments with tar oils continual stoppages took place from obstinate accumulations of dirty naphthaline in the pipes; chronic stoppages are

character. Not any of the schemes above discussed have the merit of dealing with the whole bulk of the tar.

It would be useless here to enter into the history of all the attempts that have been made to work up tar as a gas making material. Every gas maker has tried to make gas out of tar and failed. The obstructions with this material are even more obstinate than with the oils, and no one yet has been found who could deal with them. The results I have obtained with a pair of retorts charged with lumps of caustic lime average 10,700 cubic feet of 12½ candle gas. Tar as a gas-making material is, as every one is aware, dear at a gift.

I consider that it would be most disastrous to the gas industry, resting as it does upon a basis different to any other manufacture, having a monopoly of the supply of gas in return for certain parliamentary restrictions to be subjected to violent changes in its procedure at every change of the market of tar and tar products, disturbing its discipline and its efforts to perfect its processes, and interfering with the regularity of its services to the community. The gas consumer would be injured by the oscillating policies of the gas works, for with them it is not altogether a question of price. Excellence of management in regard to evenness of quality and perfect regularity of supply counts for something. In discussing this part of the question I do not wish it to be supposed that practical gas makers have lately seriously enter-

tained such schemes; on the contrary, I believe that, whilst they all like to know something about them they have not yet settled down to treat them *au sérieux*.

When, however, the engineer considers the question of liquid fuel, he is on pleasant ground, for what can exceed its simplicity and efficiency. Divest this subject of all commercial limitations and regard only the mechanical aspect, and one is charmed and delighted with the easiness of its management and the regularity and intensity of the heat obtained. So neat and perfect is the solution of this problem that the engineer might well wish that he could always have his fuel in the liquid condition.

My experiments with tar and creosote firing have taken many directions, and their application to retort and boiler furnaces has been specially studied.

Tar firing for retorts has been conducted mainly on the three following methods:—

1. Injection into the furnace by means of compressed air, with atomising apparatus.
2. Injection into the furnace by means of steam, with atomising apparatus.
3. Feeding into the furnaces by simple gravitation alone or in combination with coke.

In all the above cases the temperature arrived at was so intense (locally to the furnace) that only the most refractory of fire-bricks, such as the best Welsh silica bricks, could be found to withstand it. Furnaces lined with the best Stourbridge material would not last out 48 hours, whereas, in ordinary work with coke they would last over eight months' continuous firing. Even silica brick does not appear to last so long on tar as with coke, but I cannot speak with certainty on this point. Certainly, the temperature is so high that none but the finest fire material could be successfully employed.

The injection of tar by compressed air is, with regard to retort firing, a refinement. For metallurgical uses it would be of the highest value, as the resulting temperature is immense, but against steam injection in retort firing it is at a disadvantage. Steam injection has occupied many minds of late, but I am convinced that it could not hold its own against the simple feeding of tar into the furnaces by gravitation with special means provided to secure perfect combustion.

Experiments were conducted with a view of determining the relation between tar and other fuels, weight for weight, in a two-flued Lancashire boiler with Galloway tubes of the best modern construction.

The following table shows the pounds of water evaporated per pound of the respective fuels employed:—

Class of Fuel.	Water evaporated per pound of Fuel.
Nottinghamshire top hard cannel	7.40
Yorkshire silkstone coal	8.42
Derbyshire silkstone coal	8.11
Coke from top hard cannel	8.34
Coke from Derbyshire silkstone coal	9.49
Unscreened breeze from silkstone coal	6.44
Tar, steam injected	10.70
Creosote	11.24

The relation in these boiler trials between tar and silkstone coke is as 1 to 1.13. In the case of retort firing the relation between steam injected tar and coke is as 1 to 1.17, and in the case of gravitation feeding as 1 to 1.24.

The gravitation system of tar firing only requires the manipulation of one valve per furnace and possesses the further advantage over the steam injection system of an economy of fuel of 6 per cent., and the cost for apparatus is less. With it the per-

fection of combustion and freedom from smoke leave nothing to be desired. No advantage was found to result from a combined system of coke and tar firing. The action on the furnaces when the tar used was at the rate of about 12 gallons of tar per ton of coals carbonised by the furnace was just as severe as with the other systems.

With suitably lined furnaces there is no difficulty of any importance connected with tar firing, whilst there are some mechanical advantages, such as the saving of the labour attendant upon the charging and cleaning of fires that would amount to from 3d. to 4d. per ton of coals carbonised. In a London stage retort-house, the cost of firing amounts to 3½d. per ton of coals carbonised, and there are works wherein the cost is nearly 5d. per ton.

In studying the question of the price at which it would pay to burn tar, each individual case would have to be dealt with on its merits, since circumstances widely differ with the locality. For instance, there are places where the substitution of tar for coke as fuel would simply place upon the market a coke of excellent quality, fetching 15s. per ton; whereas, in another works, the coke pushed out would be useless for sale, and would command nothing, perhaps not even fetching the price of its removal. If it be desired to know the fuel value of tar per gallon at any place, the following formula may be employed:—Let T = cwt. of tar made per ton of coals carbonised; f = the fuel equivalent in cwt. of coke of 1 cwt. of tar—viz., 1.24; S = saving in wages per ton of coals carbonised; p = selling price of coke per cwt.; g = gallons of tar produced per ton of coals carbonised; F = fuel price of tar per gallon:—

$$\therefore F = \frac{Tfp + S}{g}$$

In London coke may be taken as worth 12s. 6d. per ton net at the works, and the quantity of tar produced per ton of coals carbonised at 1.16 cwt.—viz., 10.75 gallons of a specific gravity of 1.21—equal as a fuel to 1.44 cwt. of coke, and if we concede a saving in labour connected with firing of 3d. per ton of coals carbonised, the fuel value of tar will be (assuming that the price of 12s. 6d. per ton of coke would be maintained in the face of the increased output of coke) 1½ths of a penny per gallon.

In a case where the coke pushed out by tar firing would be worth 1d. per cwt. only, and the production of tar is 1.37 cwt. per ton of coals carbonised—viz., 13 gallons of 1.185 sp. gr., and when a saving of 4d. per ton of coals carbonised might be expected in the labour of firing, the fuel price of tar would be 0.438 of a penny per gallon.

It would appear that tar is at less than fuel price in most places now, and the reason that so little is being burned is to be explained by a natural mental inertia. I think a great many people would like to avoid the contingency if they could, and some perhaps are fearful of the effect upon an already glutted coke market.

If all the tar in the country were burned, the present quantity of gas coke sold, which is presumably 3,168,750 tons, if we consider the coke sold to average 7.5 cwt. per ton of coals carbonised, would be increased by nearly 700,000 tons, an amount that could not be put upon the coke market without serious consequences arising, but such a circumstance as the burning of all the tar could not possibly occur, for the withdrawal of a certain portion would certainly cause the price of tar to rise.

That there has been an over-production of tar, or that the price has been regulated by any other causes than the laws of supply and effective demand, I do not believe. There is no evidence

of serious accumulation of stocks of tar or tar products. All seem to be absorbed in their proper markets. Should it not be a source of gratification to us that in this severe commercial crisis the industries, acting as intermediaries between tar makers and consumers of the finally manufactured forms of tar products, have been able to find purchasers for their articles? There are no signs of an extinction of the uses of these things, and when the present rage of competition passes away, there is every reason to believe that the manufactures in question will again become profitable to all concerned. In order to arrive at a decision, whether or not to burn tar, a gas undertaking can only be influenced by plain business considerations of its economy or otherwise as a fuel. To burn it out of pique, because a certain price cannot be realised for it, or with the idea of forcing up the price by restricting the market, is unworthy of a public body.

I must express my entire dissent from Mr. Livesey's views, as given in the *Journal of Gas Lighting* for March 2, 1886. I feel that the course he advises us to take of burning 30 per cent. of our tar, with the intention of forcing up the price of the remainder to 2d. per gallon, is one that would bring us into discredit with the public, who have a decided objection to trade combinations and monopolies. We have the monopoly of gas supply, and at least we can be content to let the tar and other products be controlled by the natural courses of trade.

If the tar is worth more as a fuel than it will fetch by sale, then it will be proper to burn it; but if it can sell for more than it is worth as a fuel, then it will be bad business not to sell. Interference on the part of the gas industry with the idea of a convention or trade combination for the purpose of fictitiously forcing up the price to arbitrary limits, is to be strongly reprobated, and would certainly have injurious consequences from the crippling and checking of the development of the industries that radiate from the gas works. These things are always better left alone. We have, with regard to the future, every interest in keeping these industries alive, and it is quite possible, that by clumsy interference, we might give some industry such a blow as it could not recover from, and we should finally be sufferers by its extinction.

I am quite sure, however, that there is no need to anticipate that any injudicious tampering with trade will be indulged in. We can safely leave the question to be solved by the clear judgment of our gas makers—the tar producers.

DISCUSSION.

The CHAIRMAN said that the best thanks of the meeting were due to Mr. Wright for his very clear exposition of a practical question. In practical chemistry the question to be solved invariably came to this—was the process *profitably* applicable? There were many processes which were exceedingly beautiful, and even perfect, in theory, which were extravagant beyond words in actual working. They must not be carried away by the enthusiasm of those who would teach them that everything had its value, and that all that was required was science to render that value available. In dealing with gas-tar, however, one must consider the whole bearing of the question, and not merely one side of it. He hoped that some of these gentlemen present who had had practical experience in the matter would now give the meeting the benefit of their views and experiences.

Mr. FRANK LIVESEY (South Metropolitan Gas Co.) was a little disappointed, considering the title of the paper, that Mr. Wright had not given the meeting a somewhat better and fuller answer to the question

involved in it. He had told the meeting what he had done in the way of burning gas as fuel, but the support he gave to that method of dealing with it was by no means hearty. He had told them also of some of the difficulties to be met with, but not how to get over them. One of those difficulties, they were told, was the intense local heat produced in the furnace, and destructive of all materials save the very best Welsh fire-bricks. That experience did not correspond with his own. If tar were injected into a furnace, issuing just under the furnace arch, that arch having a few small nostril holes in it, no doubt the arch would soon be melted down. But if the tar were injected into a deep furnace of the regenerative type, local heat would be kept down, only those portions of the brickwork which were closely laid one on another would be affected, and very little damage would be done. He had seen tar fuel injected by steam, by gravitation, and by various other methods, and knew from actual practice that a furnace would stand tar firing as long as ordinary firing. He heartily agreed that a combination of coke and tar fuel was not advantageous. He would like, in conclusion, to correct Mr. Wright with respect to the construction he had put upon Mr. George Livesey's letter to the *Journal of Gas Lighting*. His brother was the last man who would advocate a trade combination. But here was a residual product which must increase with the continually increasing consumption of gas. As the makers could not combine to restrict the production of tar, they must find some method of disposing of it. At present the only known way was to burn it; and anyone who should suggest an effectual and economical method of doing so, would greatly benefit the gas manufacturers.

Mr. N. H. HUMPHREYS (of Salisbury) could quite endorse Mr. Livesey's statements respecting the burning of tar in furnaces of ordinary fire-brick. He had a furnace which had been in use for five months, and which he found to be in better order than if he had used coke in it. He had used the tar fuel without steam,—simply running it in by gravitation. He had been very particular as to regulating the quantity of tar admitted, and also as to the temperature. He had not had uniform good luck with tar fuel, having once melted a retort down in 48 hours. That misfortune was due to want of attention to the damper. With proper attention, one could have a fire of almost any temperature. It was necessary to maintain a good full-red heat and a sufficient air supply, or the chimney would smoke. At Salisbury gas-works, they were using up all their surplus tar as fuel, as the price obtained for the tar would not pay for its carriage. Moreover, they could obtain a good price for their coke.

Mr. H. E. JONES (Commercial Gas Co.) said that those who knew Mr. Wright knew him to be scientifically competent to sooner or later obtain from gas-tar higher service than that which it could render merely as a fuel, and that he would bring to bear upon the question that commercial instinct which would teach him how best to apply his science. He was glad that Mr. Livesey's motives in recommending an increased combustion of tar had been thoroughly explained. There was also an impression existing that, owing to the rise in the value of tar products some time ago, coke burners had been endeavouring to recover their liquid products, and so there had been introduced into the market a tar supply from a new source; hence the present over-production. The depression in the price of tar would, he believed, eventually lead to many more chemical works being put up in this country for the manufacture of the higher classes of tar products. It seemed barbarous to burn tar at all, it being the source of so great a number of useful products. He knew a contractor

who was using tar largely for paving, and who claimed to have produced a material superior even to French asphalt. As the source of products of the carbo-hydrogen series there was great scope for the profitable use of tar; and he had hoped that Mr. Wright might be able to indicate to the meeting some such new outlet. As it was, the paper bristled with useful information and deductions. He had learnt for the first time the precise ratio between the coke and tar required to heat a furnace. He had previously heard some of the wildest and crudest suggestions as to the possible saving to be effected, but the point was now settled beyond contradiction. When tar was used as fuel it should not be used in combination with coke. To mix up the two things was to utterly prevent the desired economy.

Mr. STEELE (Middlesbro') said that he must re-echo the disappointment of the previous speakers that Mr. Wright had not answered the query contained in the title of his paper. It had been suggested that tar might be profitably utilised in the manufacture of pavement; but this was no new idea, and afforded but cold comfort to tar producers. The gas companies would do well to meet the present conditions of trade in a liberal spirit, and should not hesitate to burn their surplus tar when there was no market for it. There were many companies throwing away tar to-day who could burn it profitably. The gas-makers of Middlesbro' had been pioneers in this matter. They had long used tar fuel in their retorts, and had always found that ordinary bricks—and very common bricks too—would stand the fire both of tar and of creosote. So far as it had a calorific value, therefore, he advised gas companies to burn their surplus tar, in order to relieve themselves of the huge incubus of a losing trade, and help the distillers to develop the higher uses of coal tar.

Mr. J. I. VAUGHAN had been much interested by Mr. Wright's remarks on the high heats obtainable by burning tar. He looked for great advantages from the extended use of liquid fuel in metallurgical operations, and in places where gas fuel could not be readily obtained, and where it would be of great advantage to be able to produce an intense heat without the dirt inseparable from coal. He would be glad to know what system of furnace was found best, and what quantity of air was delivered with the tar or creosote to produce that high heat which was said to have reduced Stourbridge bricks in 48 hours.

Mr. J. MACTEAR did not think that Mr. Wright was called upon to teach them what to do with their tar, but he had, nevertheless, thrown an immense amount of light on the direction in which they should go. He knew that the Glasgow Section had an immense amount of information on this very subject, more particularly in connection with the distillation of coal at various heats. Dr. Wallace had done much work in the subject, and would be able to give information extremely valuable in this connection. In the Dundee Gas Works tar had been burnt under the retorts for many years to great advantage, whenever the price made it suitable so to do, and in a very simple way. The necessary alterations to the furnaces did not take more than an hour or so to make, and cost, probably, only a few shillings; the building up of a bed of brickwork, and the removal of the fire-bars, being all that was required. Such retorts had been used there successfully for many years, and if the Section could get the experience of their working it would throw a great deal of light on the subject.

Mr. G. C. TREWBY (Gas Light and Coke Co.) had had experience in the burning of tar at several works, and found no great difficulty in it, provided

he had a good combustion chamber. There were certain works, however, where it would be ruinous to attempt it. Where the retorts were set running over the furnace, the effect of burning tar would be to enlarge the nostril holes and soon to bring the retorts down. Where the combustion chamber was so arranged as to run the whole length of the retorts, tar might be burnt with great economy as compared with coke at its present price. He was burning tar at four works, and considered it simply a question of the comparative values of tar and coke. He would warn those who had not yet gone into the affair to be very careful in their experiments. He had tried several ways of burning tar, and was in favour of allowing it to fall by gravitation on to a bed of breeze or coke. He had found five gallons of tar to the ton of coke a suitable proportion. He was not sure that there was a saving in labour by burning tar fuel; he feared it was a little the other way, owing to the attention that the men had to give to running the tar in. Sometimes, moreover, time was lost in filtering it, to prevent stoppage of the pipes. He thought, therefore, that nothing could be put down to the credit of tar on that account.

Professor ARMSTRONG congratulated the Society on the appearance of Mr. Wright in the capacity of chemist, since, up to the present, the gas industry had been left almost entirely in the hands of engineers. With regard to Mr. Davis's recent paper, he thought that their experience went to confirm Mr. Wright's view, that a much lower yield of tar could not be obtained by employing higher distillation temperatures; and this was just what might be expected. With respect to the intense local heat produced by tar fuel, it would be very desirable that Mr. Siemens's recent utterances on the subject should be taken more into account than they had been. The importance of having a large space in which combustion should take place had been ably put forward in his paper. It had been suggested that the time would arrive when the great bulk, instead of a selected portion only, of the tar produced would have chemical uses. The author had admitted that tar contained only about 5 per cent. of material capable of being utilised at present in chemical operations; but could they hope for any great increase in that percentage? Surely not! It was high time that chemistry should enter more effectively into the gas industry. Was the gas-maker right in his present method of treating coal? Would it not be better to deal with it so as to produce a larger proportion of residuals and a different class of coke? As now made, tar was of little service except as fuel, and although its quality might be improved in the future, its value for other purposes would be little enhanced thereby. He thought that in future we should aim at in some way improving the quality of our gas. Dr. Percy Frankland had brought forward facts supporting the contention of his father that the quality of gas had deteriorated, and no other conclusion was possible. The increased illuminating power of gas now-a-days was chiefly due to the improvements effected in gas burners. The speaker alluded, in conclusion, to the disadvantages arising from the Act of Parliament fixing the present standard of illuminating power, and to the benefits which would result from its repeal.

Mr. G. ANDERSON had been interested in the production of tar for some thirty or forty years, and had made many experiments, somewhat of the nature of Mr. Wright's, on the utility of making gas from tar and other like substances. He had long ago come to the conclusion that the best material for the commercial manufacture of gas was coal. The figures put before them were very valuable, and indicated results very similar to those obtained roughly by

himself. The calculation of 12·6 gallons of tar per ton of coal was, he considered, too high. That quantity would not be obtained as a rule from Newcastle coals, though it might be from some others. As to the high heats obtained by burning tar, that was simply a question of furnace construction. If the brickwork were brought very low down to the furnace, as some retorts were set, the result would be as Mr. Wright had pointed out. But if one removed the central retort immediately over the furnace, and had a number of retorts radiating from this centre, a large combustion chamber would thus be provided. The combustion would first take place on the furnace bed, and the products would be carried up into this large open space. Under such conditions there would be less wear and tear on the furnace than with coke fuel. Heat was not the only thing which destroyed a furnace; there were other more mechanical circumstances, such as clinker, and the necessity of keeping the door open at times, which led to the cracking of the brickwork. If the furnace were kept almost constantly closed, as when tar was used, there was not only a saving of expense but, as Mr. Wright had said, a saving of labour. He had recently seen a number of letters from gentlemen describing most ingenious methods for getting their tar to run. He had gone through that experience thirty years ago, and had found out at last that there was nothing wrong with the tar. It had simply been allowed to get foul, and thus extraneous substances had stopped up the pipes. If the tar were carefully kept as it was made, there was nothing to fear as to its running freely, provided it were run in at a proper temperature—*e.g.*, at 80 to 100 degrees. In winter time it was harder to run; but even then it only wanted warming. A boy could work a tar fire, whereas a strong man was required to work a coke fire. His own practice had always been to arrange during the spring and summer what quantity of tar would have to be burnt during the next winter, then to put up the necessary proportion of tar furnaces. He had found 70 gallons of tar to give the same heating power as a chaldron of coke, and 70 gallons of tar, at a penny a gallon, would cost only 5s. 10d. He could not credit that an ordinary furnace could be altered into a tar burning furnace at a cost of a few shillings, for he had made the attempt and failed. Working in London, his difficulty had been to get a furnace which should burn tar without creating a nuisance, and in which the stoker could not burn coke and shut off the tar. After many trials, he had succeeded. His furnace was simply an inclined plane, at an angle of 20 to 30 degrees, higher in front, so that the tar would run down. The inclined plane was kept some 6in. from the back of the furnace, and about a foot higher than the usual bed, so that air could enter by the ashpit as well as with the tar in front. The tar soon made enough breeze to fill the ashpit, and the air passing over this became hot before entering the furnace. With such a furnace tar could be burnt without producing smoke; if smoke did result, it was simply due to mismanagement. He had at one time sold nearly all his tar for the purpose of making pavement, first depriving it of some of its naphtha, and thereby rendering it more suitable for the purpose. If crude tar were put into inexperienced hands for the manufacture of paving material, the result must be failure, and thus tar would get a bad name. At another time, finding a difficulty in selling his breeze, he got a machine, and combined the tar and breeze into blocks, and sold it for fuel in that form. He was in Dublin a few months ago, and found the same thing being done there on a large scale. There were a number of things of that sort which gas managers should think about.

Mr. WRIGHT, in reply, said: One or two gentlemen had touched upon the question of the suitability of particular furnaces for tar firing. He would like to ask what was the material of those furnaces?

Mr. LIVESEY said the material in his case was Stourbridge bricks.

Mr. WRIGHT was under the impression that in London fire-bricks of a better material than Stourbridge clay were generally used, and would be glad to know if it were not so. He had been charged with giving no answer to the question contained in the title of his paper. He thought that he had said distinctly that his view was, that when the price offered for tar was below its value as fuel, then, as a mere business consideration, it should be used as fuel. On the other hand, if makers could obtain for their tar a fraction more than it was worth as fuel, then they were bound to sell it. He considered that the question could not be treated on any other lines. He was exceedingly sorry if he had misapprehended Mr. George Livesey's meaning. He had the greatest respect for Mr. Livesey, and would be very sorry if anything he had said should hurt his feelings. But he was certainly under the impression that Mr. Livesey had advised tar producers to burn a certain proportion of their tar with the idea of getting 2d. per gallon for the remainder. Mr. Humphrys had experienced the running down of a furnace. He would like to ask him if he was not now using a better material.

Mr. HUMPHRYS replied that he was using the same sort of bricks now. The cause of the misfortune was too much damper.

Mr. WRIGHT continued: It seemed that experiences differed. In his own case, the only bricks he could get to stand the heat of a tar fire were silica bricks. He could conceive it possible to have a tar fire with ordinary brick, if the fire were kept down, and if the combustion were very imperfect. But such a state of things was not possible with him—he must get a perfect combustion. All his experience was, that if he got a perfect combustion, and burnt a sufficient quantity of tar, then the temperature was very high and the local heat very great. Mr. Jones had spoken of tar pavement. In some cases he had found that makers had sold as much as 24 per cent. of their production for asphaltum purposes; in other cases makers would sell none at all for that purpose, and those who required it had to buy from the tar distiller—which he thought was a better state of things. One thing had struck him very forcibly with respect to this liquid fuel. The temperature of the flame might be as high as one wished. With compressed air, a 1½ inch bar of iron, held in it for a few minutes, ran like water. Whatever the experience of other gentlemen might be, he could say from his own experience, that under the action of good tar flame Stourbridge material ran, not like treacle, but like water. Dr. Armstrong had said that there was very little hope of the great bulk of the tar produced coming into use for chemical manufactures, there being so large a proportion of pitchy matter in it. He believed that on an average there was about 25 per cent. of free carbon in tar, but he could not see why the remaining 75 per cent. should not be utilised in chemical manufactures. Mr. Anderson had said something about smoke. Well, with tar firing, the line of demarcation between perfect and imperfect combustion was very sharp. One should regard tar as a gaseous fuel the moment it was in the furnace, save that proportion of it which was free carbon. And as with gaseous fuel a large excess of air was not necessary to obtain perfect combustion, so he had found that a fraction more tar or less air would produce smoke, and *vice versa*. Perhaps some-

thing might be done in the direction of getting an imperfect combustion in the furnace and burning the smoke in the flues. He had had some little success in that way, but could not speak fully of it at present.

Liverpool Section.

Chairman : Prof. J. Campbell Brown.

Vice-Chairman : Dr. F. Hurter.

Committee :

J. Atleek.
E. G. Ballard.
Ernest Bibby.
H. Brunner.
J. C. Gamble.
D. Herman.

J. W. Kynaston.
E. K. Muspratt.
Jas. Simpson.
A. Norman Tate.
A. Watt.

Local Sec. and Treasurer : W. P. Thompson, 6, Lord Street, Liverpool.

Meetings will be held at the Chemical Laboratory, Brownlow Street, on the following dates (1st Wednesday in the month), at 7 p.m. :—

Dec. 1.—Dr. Gustav Shack-Sommer, "On the Manufacture of Sugar."

Dr. Hurter, "On Pyrometers."

Meetings will also be held on Jan. 5, Feb. 2, March 2, April 6 (Annual Meeting), and May 4, and the following papers have been promised :—

Mr. James W. Westmoreland, "On the Determination and Valuation of Copper in Ores and Products," and "On the Determination of Sulphur in Pyrites."

Mr. V. C. Driffeld, "On Boiler Management."

Dr. George Archbold, "On the Manufacture of Starch."

Mr. G. Watson Gray, "On the Estimation of Tin in Wolfram Ores."

Mr. A. Norman Tate, "On Melting Points."

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

A Meeting of the above Section was held in the Chemical Theatre of the University College, Brownlow Street, on Wednesday evening, November 4, 1886.

PROFESSOR CAMPBELL BROWN PRESIDING.

CHAIRMAN'S ADDRESS.

PREVIOUS discussions at more than one Section of the Society of Chemical Industry have indicated that many members are not satisfied with the state of technical education in this country. If every one who is to be engaged in chemical manufactures were to pass through a course of training such as it is my intention to sketch to-night, from preliminary school-days onwards so far as capacity and means would permit, the waning or lost supremacy of this country in manufacturing industry, of which we hear so much, would, I think, soon reassert itself, and that must be my excuse for bringing the following remarks before this Section of the Society.

The full course I shall sketch is intended for masters, employers, directors and managers, and their professional advisers and assistants. For workmen and foremen I should recommend, not a different kind of education, but that their education should commence in the same way, and differ only in degree from that of managers. Necessity will compel them to stop far short of the full curriculum, but they should go as far as they are able : you cannot give a young workman too wide an education. Combined mental and bodily training will be the best aid to workshop and factory progress, while liberal and scientific culture will be infused into the occupations of the people.

It has been made sufficiently clear by those whose opinions carry most weight, that the special details and the most recent improvements in each branch of

manufacture are only to be learned in the works themselves. What then can the young chemical technologist learn at college beyond the elementary principles of the science and practical details of analysis, with, perhaps, special training in the rapid performance of such forms of analysis as are most employed in the kind of works he is likely to enter? Much has also been said already, at this Section and elsewhere, regarding the imperfections of the Science and Art Department system, and other similar organisations for promoting scientific and technical teaching. I think that while these organisations have done a great deal in the way of spreading the desire for and opportunities of learning something about chemical science, one of their defects is that they have unintentionally fostered the idea that when a student has got to the upper end of their system he is a chemist. He may have learned—as is indeed customary—the general outlines of several branches of manufacture in the course of his attendance on lectures, but it is not until he has mastered the principles of the science and most of the details of analysis that the student is ready to commence in earnest, and with effect, the study of Technical Chemistry.

Unfortunately there is a too common impression amongst students and others that having reached this stage their chemical education is finished, whereas it has only commenced. Young men frequently come to me stating that they have passed such examinations and taken such and such certificates and prizes in the advanced stage, honours stage, etc., in this and that branch, and asking me to employ them or recommend them for employment as chemists. They are very much astonished when I tell them, as gently and kindly as possible, that they are only now ready to commence their strictly professional training, and that they are worth very little in the shape of salary until they really know their profession.

Has not this flooding the country with untrained or partly-trained men, who think they are trained, something to do with the complaints so frequently heard of the employment of Germans instead of Englishmen as chemists in works where intelligent and skilled work is required? I think it has as much to do with these complaints as the readiness of the German to work for less pay than the Englishman. German students are, on the average, better trained, because they persevere longer at school and college, and sometimes work longer and harder for themselves while they are there, and they do this because German manufacturers pay for highly-trained men, and will not have the half-educated class which some people in this country are supposed to be willing to employ.

At a time, then, when the necessity for better technical instruction and training of all children who will have to earn their own livelihood in later life is forcing itself on the attention of the public, while at the same time there is a pretty general feeling that if there is not over-pressure there is at least sufficient pressure upon the intellectual powers of growing children in our Board Schools, it may not be amiss to consider for a moment the relation between theoretical and practical instruction, and how they may be best co-ordinated in the education of those who are to carry on the industries of this country as workmen, foremen and managers.

Those who insist on the fact that the principal aim of ordinary school training should be to open the child's mind and discipline it to think and study, are very apt to believe that all the time in early life must be given up to the attainment of this object, except what is reserved for recreation and rest, and that any technical or special training should be post-

poned to a later period, when the boy or girl is ready to leave school.

On the other side it is urged that few of the boys and girls now in the Board Schools can expect to earn their living by the exercise of their brains alone; most of them must work with their hands, and must learn some handicraft. While the schoolmen of the old stamp maintain that apprenticeship after leaving school is the best method of training workmen, others point out that before the days of compulsory education boys began to learn the use of tools at a very early age, and that to become a good workman it is necessary that a boy should begin to use tools early.

There can be no doubt that much of the inefficiency of modern workmen is due to the neglect of masters and journeymen to teach apprentices in the thorough way which was in former times common; and, in fact, to the too frequent neglect of masters to see that their apprentices are taught at all. Apprentices are allowed to see journeymen working, to carry their tools and utensils—in short, to attend and serve the workman—but they are not taught their trade. The prolongation of school days tends only to increase the evil, unless something further is done to supply the place of the earlier apprenticeship.

Hence has arisen a demand for the erection of workshops for training school-boys in the use of tools, and for the recognition of such training as a compulsory subject, and one which will earn grants under the Education Code.

Now I think that if we look at this subject from a physiological and common-sense point of view, it will be clear that: (1) A sound early mental training is essentially necessary to every child that has afterwards to fight the battle of life in a civilised country. Good school education is therefore the first essential after a sound healthy body. (2) If the hands are to do any kind of work skillfully in after life, they too must begin their training early: and (3) These two kinds of training, instead of clashing, are mutually helpful.

Properly imparted, instruction and practice in handling tools will be not only useful, but still more will be a pleasure to the boy, jaded by his ordinary school routine of lessons, and will be welcomed by him as a relief and an amusement; while the change of work, employing an entirely different set of organs, will, instead of interfering with progress in school work, render it both more efficient and more agreeable. The exercise of one set of functions will be complementary to the other, and the individual receiving the double training will grow up with all his faculties more equally and more fully developed.

The questions then arise: Should the workshops be attached to each Board School, and should each boy attend part of each day at the workshop? Doubtless this would be the ideally perfect system; but it is not practicable, nor is it necessary in order to accomplish what is required.

It would be sufficient, and quite within what is practicable if workshops for different kinds of trades were erected in a few well-chosen districts of a town, and each scholar in every Board School were required to spend a sixth day every week in one or other of those workshops, such day being counted as part of the attendance recognised and required by the Education Department. Thus the boys from different schools could attend the selected workshops on different days of the week, and discipline, regularity of attendance, etc., could be looked after just as in the case of any of the three "R's."

I venture to say that with most boys the workshop day would be looked forward to almost as to a holiday; the physical advantage to him would be nearly, if not quite, as great as if it were a holiday, owing to the regularity of the recurrence of this

change of work, and he would return to his mental work with greater zest. A healthy mind and a healthy body alike crave exercise, and the school or lecture room, and the workshop, if they are properly conducted, and are judiciously mixed, should each be a source of enjoyment. By this system I do not think that the amount of ordinary school work would be lessened; but if it were, the decrease would be very slight, and the reply to objections is, that some provision for training the hands and muscles to work is essential to an embryo workman, is beneficial to an embryo gentleman, and must be had at any sacrifice if we, as a nation, are to maintain our position in the face of other competing nations, and the system I have sketched is that which of practicable methods accomplishes what is required with the least sacrifice.

It is by no means essential that a boy should limit his choice of a handicraft to that or those in which he has received his early training. As any subject well and systematically taught is capable of opening and expanding the intellect—as, for instance, a good classical education is frequently of the greatest value to a young man who, perchance, does not open a Greek or Latin book after he has left school or college—so a boy who has learned to cut and plane timber and carve wood in his early school-days will be a better plumber or engine-fitter when he begins to go out as an assistant or apprentice, than a boy who has never handled a tool, except by chance, until he has reached the age at which he is allowed to leave school. It is the training of the muscles to work habitually in concert with the eye and mind that is wanted, rather than acquaintance with the precise mechanical details of his future life's work.

The only effective training in handicrafts for the immediate purpose of earning a living must be given under conditions which hold in actual everyday life; and this can only be done in workshops conducted on strictly commercial principles. The aim of school training should be to develop and train all the faculties which can be useful in after life, no matter in what lot that life may be cast. If you want a good workman, a quick observer and an intelligent thinker, you must begin to train all the faculties at the earliest period that will not interfere with physical development; you must not give a boy or girl too much study nor too much work, but give them broad general ideas, good habits of mind, habits of observation and activity which will enable them afterwards to appreciate and employ the opportunities of higher instruction which they may have as they advance in years.

In the teaching of science it is a great mistake to aim *specialty* at imparting a knowledge of facts which will be of use in after life. It is the desire to do this which has gone a great way in encouraging the multiplication of science subjects in schools. It would be far better to teach one science subject substantially and well than to teach a smattering of several. Every boy and girl, in whatever sphere of life, should be taught one science as a part of ordinary school training, but the mistake is too frequently made both in science teaching and in ordinary school routine, of forgetting that it is the mental training and discipline, and not the storage of facts, that form the valuable feature of school work—the training of the understanding and the development of the reasoning faculties rather than the exercise of mnemonics.

And here let me remark in passing, that the tendency of the training in those schools in which living or dead languages are the chief characteristic feature, is to produce an exaggerated idea of the importance of words. The highest result of such a training, even when successful, is to produce a command of

words and the power of placing ideas clearly before a listener, valuable faculties certainly, which must not be neglected, but apt to be a bore when the ideas are few or wanting, and positively dangerous when the ideas are not well thought out and founded on truths. The command of language is a valuable tool in the hands of a student or investigator, enabling him to read the thoughts and observations of others both in his own and other countries and times, and to communicate his own thoughts and observations to others; but the mastering of this tool is not, or ought not to be, the sole aim and end of any man or woman's education.

The introduction of science into every stage of school and college life, if it were properly taught with the special view of getting the greatest *educational* (as distinguished from *instructive*) results from it, would be a most valuable corrective of the tendency just alluded to.

While the study of one science should be made a compulsory item in ordinary Board Schools as well as secondary school work, I think that one science at a time is perhaps enough until study begins to be specialised in some direction.

For the purpose of training the powers of observation and classification, the study of natural history (either vegetable or animal) is best adapted, and this should come first. Every boy and girl should be well taught the elements of one branch of natural history.

To train in exact and logical powers of reasoning, Euclid and some of the other branches of mathematics, pure and applied, are most suitable; every boy who can stay at school long enough should be taken as far in mathematics as his time and ability will permit.

To gain carefulness in experiment, watchful humility in seeking evidence before drawing conclusions, to acquire the habit of putting one's opinions to the test, to correct the tendency to vague speculation and to convince one that nature overlooks and forgives no error, there is no training better, and very little as good, as that of the chemical laboratory.

This ought to come at a later stage. To study chemistry with full or even fair profit, the knowledge of language must be far advanced, the habit of observation must be already acquired, and the power of reasoning and calculating must be beyond the elementary stage. At the risk of wearying you by repeating much of what has been again and again said by many speakers and writers, I must insist on the necessity for making the teaching of chemistry practical as well as theoretical from the commencement. Without experimental illustration to connect words with things, words only are taught, and ideas are not understood. Nothing will more certainly disgust a student than to be forced to learn what he does not understand. This is a plea for making even elementary chemistry a somewhat advanced subject, and for teaching it experimentally.

But although a good course of lectures, well illustrated by experiment, is a pleasant exercise of the reason, it partakes too much of the nature of an amusement unless something more is added. To get the educational value which I have mentioned out of the study of chemistry the student must himself work in the laboratory from the beginning. The object of education is to produce a man who not merely knows things, but who can do things. Habits of action are needed as well as habits of thought. The student should be allowed to prepare for himself some of the elementary substances and simple compounds which he sees made or used on the lecture table, and to perform with his own hands some of the experiments illustrating or demonstrating fundamental laws.

Laboratory work of this kind should be simultaneous with the course of elementary lectures, and should

precede the study of analytical chemistry. Such a course as I have indicated is not made compulsory in any of the University or other set curricula of study, either for science students or other students; but it is of great importance, and the college whose rooms we occupy to-night has provided and recommends a voluntary class for those attending the first and most elementary course of lectures. I consider it essential. A student or a teacher does not fully understand an experiment even by seeing it performed; for the full appreciation of it he must perform it for himself, or at least must have performed something of a similar nature.

The effect of scientific training should be not to produce a mind willing to accept statements of which it has no clear conception, not to assume as correct the opinions which have been taught by others, but rather to produce the mental habit of doing all in one's power to test and correct opinions and conclusions by experimental verification, without which the process of inductive reasoning is incomplete.

To commence the serious study of chemistry by accepting the teaching of a lecturer, without at the same time attempting personal verification, is apt to produce an irresponsible, unscientific mind; it is all very well for those who only want to know what are the accepted conclusions of scientific men, but it will not do for those whose future fortunes are to depend on the successful pursuit of chemical industry. Of course, I do not mean that a student must himself prove the truth of all scientific laws and theories which he accepts—the truth can only be ascertained by the combined labours of all scientific men in all generations; but in order to be able to accept the conclusions of others with discrimination, and to judge of the value of the experimental evidence placed before him, he must begin by experimenting for himself.

Having laid a foundation by becoming acquainted with the elementary principles of the science, and having become convinced of the truth of the fundamental laws by an intelligent examination of the experimental evidence of their truth, then, and not till then, can the young technical chemist derive full advantage from a disciplinary course of analytical work, both quantitative and qualitative. The course of qualitative analysis is, in my opinion, capable of being so conducted as to be a valuable discipline in technical, medical, and scientific education generally. Rightly taught, it comes nearer to the discipline obtained by the old training in the writing of Latin versions than anything else I know, with the additional advantage that it exercises the eye and the hand as well as the mental faculties.

But to have this value it must not be merely a course of test-tubing. The mere application of what are called tests is no training, and requires nothing worthy of the name of scientific skill. No one can analyse a natural product or an artificial manure by testing for potash and similar operations. That is not analysis. A course of drill in real qualitative analysis of complex substances by the best methods, is of great value in general scientific, as well as in specially technical education.

I need not say anything here more than has been said already at this Section as to the necessity for including other subjects in a course of preparation for technical chemistry as a pursuit; such as French and German, mechanics, physics, drawing, nature and strength of materials and other engineering details; the necessity for these things is acknowledged by all, and they are provided in the technological curriculum at University College, Liverpool; Owens College, Manchester; University College, London, and elsewhere.

The technical student being now equipped for commencing the study of technical chemistry, he should be taken through the principles which are involved in the processes of some typical kinds of manufactures, his attention should be called to the improvements which have been brought about in manufacturing processes since the foundation of the industry; he should be shown how and why these improvements were made, and should be encouraged to endeavour by his own work and research to make improvements in some branch, or to make some original investigation.

He should be guided through courses of practical work on the examination of technical gases, and should be taught the principles of thermal chemistry, and made to understand how these principles can be used in technical research. He should also be accustomed to make preparations on a larger scale than the few grammes usually dealt with in ordinary laboratory work, so as to enable him to deal with materials in bulk.

In this technical stage of the student's career the method of instruction should be mainly by laboratory work, accompanied by demonstrations and explanations by the teacher, and not by lectures only. It is no doubt necessary to teach and illustrate the first principles of chemistry to large numbers by means of set lectures, supplemented by tutorial revision with sections of the class. But the average student cannot absorb all that is gone over in an hour's lecture, during which no allowance can be made for differences in individual mental inertia, past knowledge, distraction of mind, occasional absence, and so forth; nor can he give expression to his difficulties and get a supplementary explanation unless he comes in closer contact with his teacher than is possible in the lecture-room. Demonstration in the laboratory to small numbers at a time is the most efficient mode of teaching the advanced branches of chemistry.

In these latter days, when organic chemistry advances by such rapid strides, and when practical applications of old laboratory curiosities are pervading our every-day life; when new organic compounds of great complexity and marvellous beauty or striking usefulness are being discovered or brought into use every week; when new substances extracted from plants, or made synthetically in the chemical works, are being introduced for medical use in ever-increasing numbers; when some forms of our old friend nitrocellulose meet us, not merely in the shape of gun-cotton and collodion, but in the binding of books, the coverings of our chairs, and the combs of our toilet tables; when the profits of gas-making have come to depend on the utilisation in an unlimited variety of ways of the formerly despised waste-product, tar;—it is time that every one about to be engaged in chemical industrial pursuits should become acquainted with systematic organic chemistry, learn to carry out with his own hands the leading typical reactions by which one form of organic compound is transformed into others, and learn practically modern forms of organic research.

Organic chemistry is a very tempting pursuit to the advanced student; there is no branch of natural science in which something which has never been seen before can be made or discovered with less expenditure of labour and skill. And accordingly in organic chemistry, even more than in mineral chemistry, we too frequently see a student undertaking a showy but useless immature original research before he has learned his principles or become properly trained in the performance of a goodly number of typical examples of already known transformations. No sooner has he got up in words and formulæ a

tabular arrangement of the classes of organic compounds, or a few of them, than he starts an original research and publishes an account of the preparation and properties of a new substance, to which of course he has to give a long name in accordance with its derivation and supposed structure, the existence of which has been foreshadowed by previous investigators, the mode of whose production any organic chemist could suggest, and which any chemist could produce whenever it might be wanted.

Do not think that I undervalue original research; on the contrary, I fully appreciate its value and the pleasure derived from it, and would have original research kept before the mind and imagination of the student as the goal which he should constantly aim to reach. Nor do I desire to limit research to utilitarian objects in the narrow sense of the term. But I deprecate the substitution of the easy preparation of a new chemical individual for a difficult and somewhat prolonged practical training in work that has already been mastered by previous investigators and in the performance of the leading general reactions for the preparation of typical series of carbon compounds.

The student commencing the study of organic chemistry should be familiarised not so much with the formulæ of series, but with the substances themselves. The last thing, not the first, should be to get the formulæ as short-hand expressions of things and facts which he knows. Care should be taken to avoid allowing him to get the impression that formulæ have any other use or function than this.

Having made the personal acquaintance of organic compounds, and learned the classification into series by reference to the substances themselves, and not from printed tables or blackboard diagrams only, he should be made to chlorinate a paraffin, and separate and distinguish the isomeric products; then to convert a haloid ether into an alcohol, to oxidise an alcohol into an aldehyde and an acid successively. And so on through the more important operations in daily use in organic laboratories. Then and not till then, should he be allowed to work out in detail some special group, and encouraged to take up some line of original research. Thus he will be equipped for whatever work he may be required to do when he goes out into practical life.

It is not altogether the fault of teachers and institutions that practical training in organic chemistry is not carried on with full systematic persistency. It is more the fault of students and their parents, and of employers, who do not allow, or at any rate encourage young men to persist long enough in the unromantic and not directly remunerative detail of advanced pot-hooks. There is a temptation to turn their knowledge to pecuniary account as soon as it is sufficient to secure the smallest return, to the pretty certain sacrifice of future advancement.

I need not remind members of this Society of the close connection between the development of Chemical Science and the progress of Chemical Manufactures. Science is knowledge, and knowledge is power, especially to a manufacturer. Every one now recognises the mutual obligations and the necessity for mutual co-operation between scientific men and manufacturers. The study of the history of chemistry is as instructive as the history of nations. Looking back in the history of chemistry, we see that the most highly-trained mind learns to cultivate science for its own sake, and finds it one of the noblest pursuits; but even from a narrower point of view the thing most worthy of attention is not the direct pursuit of wealth. In ancient times the pursuit of chemistry consisted mainly of the working out of methods for extracting gold and silver; and

later, in the times of the Alchemists, the principal object of research was the philosopher's stone or the means of transforming the baser metals into gold.

During these periods no great progress was made in either chemical science or manufactures. It is true that some interesting and useful substances were discovered—and kept secret; such as, for instance, phosphorus by Brandt and Kunkel. But the knowledge of phosphorus and its preparation and properties not being made widely known, phosphorus was not much wanted, its use did not become general, and its manufacture did not flourish, the study of it was not stimulated, and its sources and the rationale of its manufacture were not investigated; and so on in other cases.

It was not until the knowledge of chemical substances and processes was very widely spread that a great and rapid development, both of science and manufactures, resulted.

The pursuit of truth for its own sake is best both for science and manufactures. Of course, any branch of manufacture, in order to flourish, must pay. Yet, in order to be successful as a manufacturer as well as a student of nature,—to make the most money even, by manufactures,—I venture to say that the consideration of money making must not be the most prominent thing before the mind, should not be the direct aim.

If any one proposes to carry on a new manufacture he first ascertains that the thing to be made will be of use and benefit to some section of mankind. He then learns all he can about it, ascertains its most abundant sources, and seeks to find out by the study of nature's laws the most simple way of transforming the raw material into the manufactured product. The man who has the most perfect knowledge of nature's facts and who works in the most simple obedience to nature's laws, will be the most successful and will make the most money, not the less so that money making was not his direct aim.

No doubt it has often happened that a man, by more or less haphazard attempts or empirical trials, in the direct endeavour to carry on his process in the cheapest way—i.e., to make most money by it—has come ultimately to the method which is most simply in accordance with the laws of nature. But this is not the best way of doing it, and is not the most likely way to succeed.

These considerations bring us to the borders of a great moral law. But as I have already traversed a sufficiently wide field to-night, I must leave the morals of the subject to your own private contemplation.

DISCUSSION.

Mr. E. K. MUSPRATT said the question of technical education was one that was occupying the public mind of England at the present time, and it was very interesting to all of them who were engaged in manufacture by discussion to elicit what they thought was the best method of carrying out such education. He knew there were others present who had been engaged in teaching science in its application to manufacture, and who would be able to give them the result of their experience, for, after all, it was by experience they must learn which was the best method of education, and it was because the Germans and Swiss had so much greater experience that they were far in advance of us in nearly every department of education. They must begin at the bottom, and it was in the elementary schools where the foundation must be laid for the higher technical

training. He was much interested in that portion of the Chairman's address which dealt with this elementary education. They were beginning to recognise that it was not sufficient to educate the children in the three "R's." For a long time they were under the impression in this country that it was going beyond the function of the State to teach further than the three "R's"—that is, reading, writing, and arithmetic. At the earliest possible moment everybody should be trained to use his hands, his eye, and his mind. One advantage they had on the Continent was the co-ordination of the primary, secondary, and the higher education, and they were only beginning to carry this out in Liverpool. He was glad to say that since the passing of the Education Act of 1870 they in Liverpool had fairly got elementary schools to recognise the advantage of teaching elementary science. They had also two or three secondary schools where the claims of science were recognised, and they had now in the institution in which they met the opportunity of studying the higher branches. They had, further, the advantage of science and art classes, with their prizes and grants. A great number of pupils imagined that because they had taken out a certificate and received honours they were then perfectly trained in that particular science to which they had given their attention. This, of course, could not be the case. An education of that kind could not be all that was required, and what they had to look forward to in the future was that those who had passed through science and art classes should go through a course of technical education in an institution of that kind in which they were assembled. He thought that would be the direction which their education would take in future, and he was sure when they had more experience they would be on a par with Germany and Switzerland, with a system of education which would assist in developing the industries of the country. He had much pleasure in moving a vote of thanks to the Chairman for his address.

Dr. HURTER seconded the vote of thanks, and remarked that in Switzerland the necessity of giving boys a training in the use of tools had been recognised, and evening classes had been started at which boys about ten years old could learn the use of a few tools. The trades chosen for this instruction were joinery and bookbinding, or, better, cardboard modelling. The work done by the boys was excellent as regards workmanship. Still, Dr. Hurter was of opinion that the use of tools could only be properly acquired during apprenticeship. Dr. Hurter then referred to the greater length of time which is usually devoted to education on the Continent, particularly in Germany and Switzerland, and hoped that the English nation would soon improve their educational system.

Mr. NORMAN TATE said Mr. Muspratt had referred to the co-ordination of education, and this was most important. In teaching children in primary schools, their probable occupation in after-life should be most carefully considered, and in secondary and other schools this should be even more closely attended to. The training of a lad at school should have intimate connection with the occupation he had to follow when he grew up and had to work to keep himself and his wife and family. He thought that, at present, in this country this was not sufficiently considered. The Chairman had referred to the Science and Art Department. He (Mr. Tate) considered that department had done much to direct and encourage science and art education, but he thought that oftentimes too high a value was attached to the results of the examinations, and that young men were too prone to over-value their certificates and prizes, forgetting that the system of education fostered by this depart-

ment was very much of a primary character, and that the successes obtained should, at any rate as regards technical pursuits, be considered only steps to more thorough education and training. With regard to chemical studies there was now an Institute of Chemistry, but in the prospectus of that Institute, in stating the regulations for admission, too much stress, in his opinion, was laid upon instruction in schools and colleges, and not sufficient note taken of work done in practical laboratories and technical establishments. No artisan could be taught in a school how to work in a thoroughly practical business-like manner, and thoroughly practical, analytical, and technical work could not be so well learnt in school and college laboratories as in laboratories and places where the work had reference to important technical and commercial operations, but in the prospectus of the Institute time occupied in practical work, except in schools and colleges, was not recognised as part of the necessary training for admission.

The CHAIRMAN: Does not the Institute require three years' practice as well as three years' training?

MR. NORMAN TATE: The practice referred to in the prospectus was limited to the schools, and no mention was made of other practical laboratories. The latest prospectus, which he had seen but a few days ago, only mentioned certain schools and colleges.

The CHAIRMAN: The old regulations mentioned three years' practice in addition to three years' college training for the fellowship.

MR. TATE hoped the present regulations would be altered before very long, for practical men would not be satisfied as the regulations now stand.

MR. FITZPATRICK said he was highly delighted with the paper which the Chairman had given them that evening, as there was a vast amount of instruction in it. With regard to the Liverpool School Board, he was one of the denominational members of it, and he must say there was not one of the members of the Board who did not take a most intense interest in the scientific instruction of the children, but their great difficulty at present was how to inaugurate any system of technical education. The principal difficulty they had was in the early age at which children left school, and being in school only five days a-week. If they had one day of technical training, that must necessarily be taken from the teaching in the three "R's," and they were obliged to insist upon the subjects being taught which were stipulated in the code. It was not for School Boards to inaugurate any system, but for Parliament, and if Parliament could see its way to giving a technical education, there would be no people more delighted than the denominational members of the School Board. He thought it was useless to point to Germany or Switzerland, because, as has been stated by one speaker, brought up in Germany, he was 23 years of age before he was taken away from school, whereas in England children were taken away at 12 and 13 years of age. The Germans surpassed them in technical knowledge and skill, they surpassed them in the study of the ancient classics, in the study of Dante, and even in the study of Shakespeare. The English were probably given too much to roast beef and plum pudding, thereby clouding the native brilliance of their intellect, but at any rate in trying to promote technological education let the circumstances of the English people be taken into account; they must learn from foreign nations what was applicable to themselves, and not take what was totally inappropriate to the English people.

ON THE COMPOSITION AND DECOMPOSITION OF REDONDA PHOSPHATE.

BY WALTER TATE, F.C.S.

THE mineral known as redonda phosphate has for many years engaged the attention of numerous technical chemists, especially of those interested in the industry of chemical manures. The fact that it affords one of the richest and cheapest known sources of phosphoric acid has stimulated experimenters to endeavour to obtain from it that compound in an available and useful form. The raw mineral contains phosphoric acid equivalent to about 84 per cent. of tri-calcium phosphate, while the calcined material equals about 107 per cent. Hence, considering the low price at which it is obtainable, the redonda phosphate supplies phosphoric acid at a much lower cost than most other commercial mineral phosphates. But the circumstance that its phosphoric acid is combined in an insoluble state with alumina and iron oxide is the cause of its low commercial value, and its conversion into phosphate of lime economically, is the great desideratum. Containing upwards of 20 per cent. of alumina, it is also available as a source of alum and sulphate of alumina, if the phosphoric acid and iron oxide could be separated from the alumina without too great an expense. The writer has been for the last year or two chiefly occupied in experimenting with this phosphate, and has devoted this paper to a few notes on (1) the composition of the phosphate, and (2) its decomposition or decomposability.

THE COMPOSITION AND FORMULA OF THE MINERAL.

The following represents its average composition:—

• Phosphoric acid (P_2O_5)	38.50
Alumina	22.00
Iron oxide	10.30
Insoluble siliceous matter	6.50
Undetermined, including traces of lime	1.00
Water (loss on ignition)	21.50
	100.00

• Equal to tri-calcium phosphate, 84.04

Its composition is comparatively simple, and shows it to be essentially a hydrated phosphate of alumina and iron. The silica in good specimens is very small in amount, being often less than 1 per cent., and is, I believe, merely an extraneous impurity derived from the surrounding rocks or matrix.

In a paper read before the London Section of the Society (Journal, March, 1885), last year, by W. J. Williams, equations are given which convey an inaccurate idea of the composition and character of the phosphate. No analysis is furnished, but the following formula— $AlPO_4 + 2FePO_4 + SiO_2$, from which it would be inferred to be chiefly a phosphate of iron, with a minor proportion of alumina phosphate.

Now, this is evidently incorrect, the analysis showing that the proper formula for the mineral is:— $3AlPO_4 + FePO_4 + 18H_2O$; or, in other terms, $4P_2O_5, 3Al_2O_3, Fe_2O_3, 18H_2O$. The correctness of this is proved by calculating the figures of the analysis (after deducting the silica for the reason before stated) when the following is the result:—

	Calculated from Analysis (less Silica).	Theory $4P_2O_5, 3Al_2O_3, Fe_2O_3, 18H_2O$.
P_2O_5	11.17	41.73
Al_2O_3	11.23	11.79
Fe_2O_3	23.53	22.70
H_2O	23.00	23.80

The fact that the mineral consists principally of aluminium phosphate rather than of iron phosphate is not unimportant, if it be true, as maintained by H. B. Yardley (Journal, August, 1884) that iron oxide is the chief or sole cause of "reversion" or "going back" of "soluble phosphate" in manures, and not alumina, as was at one time supposed. Whence it appears that a phosphate of aluminium is of much more practical value to the manufacturer of superphosphate and other soluble manures than a phosphate of iron containing the same amount of phosphoric acid. The utility of obtaining a true knowledge of the composition of the phosphate, and of correcting inaccurate impressions, must be sufficiently apparent.

DECOMPOSITION OR DECOMPOSABILITY.

The facility with which the phosphate yields to the action of reagents, both liquid and solid, is remarkable. The reagents employed include, besides sulphuric acid, several sodium salts, such as the chloride, hydrate, carbonate, sulphate and nitrate. It is beyond the scope of this paper to enter into the details of the various processes which have been proposed, and most of which are to be found described in published patents. My chief object is to show by the results of some experiments that I have made that the phosphoric acid in the mineral can be obtained in an available form more economically than was formerly supposed possible.

Hitherto it seems to have been taken for granted by chemists who have previously worked at this phosphate that in order to decompose in the "dry" way the aluminium-iron phosphate, so as to render the phosphoric acid soluble, it was essential to employ such a quantity of sodium salt as would not only suffice to form tri-sodium phosphate, but also sodium aluminate. For instance, on referring to the paper by Williams, quoted above, it will be seen that he used such a proportion of sodium chloride or sulphate. The results of my experiments have proved, however, that the phosphate can be decomposed by much less sodium salt than would be required under the above supposition. In fact, I have found that the mineral is decomposable by such a quantity of sodium salt as supplies sodium in amount just sufficient to combine with the phosphoric acid to form tri-sodium phosphate, allowing none for the alumina. The difference in the quantity of sodium salt in the two cases is very considerable. Thus, since there are in the phosphate four molecules of phosphoric acid to three molecules of alumina, and since a molecule of alumina would combine with the same amount of sodium as a molecule of phosphoric acid, it is clear that the saving of sodium salt is equal to three parts out of seven, or nearly forty-three per cent.

The following is a short summary of a few out of a large number of experiments performed, in all of which the quantity of sodium salt used was only just that required to form tri-sodium phosphate:—

A. Decomposition by Sodium Chloride and Steam.—A mixture of finely-ground phosphate with sodium chloride and sand was moistened, made into cakes, dried, and heated to redness in a furnace through which a current of superheated steam was passed. Copious evolution of hydrochloric acid gas occurred, and the amount of decomposition was, by analysis, found to be as follows, in three experiments:—

P ₂ O ₅ in Original Phosphate Calcd.	P ₂ O ₅ rendered soluble.			Average Decomposition per 100 P ₂ O ₅ .
	I.	II.	III.	
45.0	39.0	40.7	37.9	86.6

Only traces of alumina were rendered soluble.

B. Decomposition by Sodium Sulphate and Carbon.

—The phosphate was mixed with sodium sulphate (salteake), some coal and sand, and made into cakes or "balls," as before, which were then heated to redness for some hours in a closed furnace.

The resulting product gave these figures on analysis, in four experiments:—

P ₂ O ₅ Original Phosphate Raw.	P ₂ O ₅ rendered soluble.				Average Decomposition per 100 P ₂ O ₅ .
	I.	II.	III.	IV.	
38.5	33.3	35.1	31.6	37.2	91.0

Traces only of alumina in solution.

C. Decomposition by Sodium Nitrate.—The mixture of ground phosphate and sodium nitrate was heated in a crucible to redness until nitrous gas ceased to be evolved.

The product examined gave the following figures in four experiments:—

	Original Phosphate	RENDERED SOLUBLE.				Average Decomposition.
		I.	II.	III.	IV.	
P ₂ O ₅	38.5	36.5	37.3	37.3	37.5	96.4
Al ₂ O ₃	22.0	—	8.9	6.3	10.0	38.1
Fe ₂ O ₃	10.5	—	—	—	—	—

Here, over 96 per cent. of the phosphoric acid was made soluble, and over one-third of the alumina.

The result of the lixiviation of the foregoing products is practically a solution of tri-sodium phosphate, which is readily convertible into tri-calcium phosphate by precipitation with milk of lime, or a soluble calcium salt. The tri-calcium phosphate can then be converted into soluble mono-calcium phosphate by the usual method of treatment with sulphuric acid.

Whether the economy effected in the decomposition of the mineral, as indicated in this paper, is sufficient to bring the practical working of the phosphate within the range of commercial success, is a question which I shall not attempt to decide; but it is unquestionably a step in that direction.

In conclusion, it may not be out of place to observe that the redonda phosphate is decomposable by natural agencies, or climatic influences, when applied in a powdered state to the soil.

Field experiments, by the late Dr. Voelcker, proved that the redonda gave results with root crops and cereals superior to those obtained with ground (Cambridge coprolites, also better than precipitated phosphate of lime, and equal to dissolved bones. (*Journal of Roy. Agr. S.* 1882–83). It is probable that its use in the natural state, but powdered finely, might prove of service on many soils. The fact that it supplies phosphoric acid free from lime may be an advantage in its application to those cultivated lands which, by the long-continued treatment with chemical manures containing an excess of lime, have become overstocked with that substance.

DISCUSSION.

Mr. BRUNNER disagreed with the reader of the paper that this phosphate was a cheap material, and the reason of this was, he supposed, that the holders of it were sufficiently wealthy to hold it. He could

quite endorse what the writer said with regard to the experiments he had made, as he had carried out most of them himself, and with much the same results that he had found. Mr. Brunner then described the process which he patented for the manufacture of phosphate. He quite believed that although inventors would be losing their time in taking up this redonda phosphate, he believed it was a good manure in itself, and all they wanted was to secure it at a reasonable price.

Mr. NORMAN TATE said in making redonda phosphate practically useful, the question of price was of considerable importance. He thought there was a deal of nonsense in so dealing with natural phosphates by manufacturing processes as to produce the large percentage of soluble phosphates now asked for by dealers and users. In actual use much of it becomes at once insoluble in the soil, and he believed a good proportion was wasted in the drainage. Instead of pandering to the idiosyncrasies of buyers and users in this respect, he considered it would be far better to grind up the phosphates into a very fine condition and mix it with the soil, and then probably the plants would prove far better chemists than we are, and turn it to profitable account.

The CHAIRMAN said that the paper was one of considerable interest. Some ten years ago a similar phosphate had been a drug in the market, and was offered at 10s. per ton. At that time many chemists had tried to utilise it. One method tried was solution in excess of sulphuric acid, neutralisation by alkali, and separation of the alum from the phosphate by crystallisation; but ammonia and potash had been found too expensive for commercial success, while sodium alum was not sufficiently crystallisable to effect a separation. In Mr. Tate's method it seemed wasteful to first form sodium phosphate and then convert it into the cheaper calcium compound. Would it not be better either to use the sodium phosphate as such, or to endeavour to form a calcium compound direct? For manurial purposes there could be no doubt that redonda phosphate mixed with organic matter would be a valuable manure. He concluded by proposing a vote of thanks to Mr. W. Tate for his paper. This was carried unanimously, and

Mr. WALTER TATE, in reply, said: As regards the cheapness of the redonda phosphates, the price at which it is now obtainable, delivered at Liverpool, affords about 19lb. of phosphoric acid (P_2O_5) for 1s., which is, I believe, a much lower price than any other phosphate in the market. The reason for converting the tri-sodium phosphate into calcium phosphate is that the demand for the former is very limited, and the same is true of potassium phosphate. As to the direct use of the natural phosphate as a manure, the chief obstacle to be overcome is the prejudice of the average agricultural mind. I have tried the calcium chloride method, patented by Mr. Brunner, but found the separation of the calcium phosphate from the alumina and iron oxide, by means of acid, impracticable.

THE ELECTRICAL DEPOSITION OF DUST AND SMOKE, WITH SPECIAL REFERENCE TO THE COLLECTION OF METALLIC FUME, AND TO A POSSIBLE PURIFICATION OF THE ATMOSPHERE.

BY PROF. OLIVER LODGE, DSC.

THE research of which I have the honour to speak to-night, takes its origin in an observation made by Dr. Tyndall, of which he has published an account in

the proceedings of the Royal Institution, London, for 1870.

The phenomenon discovered by Dr. Tyndall was a dark or dust-free space formed over a hot body when held in strongly illuminated dusty air. A flame or hot poker held beneath the concentrated beam of an electric lantern shows it perfectly, and the appearance is as of wreaths of black smoke.

That it is not smoke, but anti-smoke, is perhaps rendered most evident by observing the utterly different appearance of smouldering brown paper held in the same place. In fact it is manifest that what we see in a sunbeam is not the beam itself, but the dust illumined by it. It is somewhat misleading, though customary, to speak of the motes as rendering a sunbeam visible; it is really the beam which renders visible the motes. And the more motes there are, the more there is to see, naturally; hence smoke in the beam greatly increases its luminosity, while anything which removes or expels the dust-particles destroys its luminosity, leaving a clear dark space!

Now what is the cause of this dust-free space? The first idea was that the dust is burned and destroyed by the flame. But this explanation is negatived by using a moderately warm body, say a hot kettle, and noticing that above this also the dark space is perfectly distinct, though narrow.

Dr. Frankland next suggested that much of visible dust consisted of moisture, and that it was dried and rendered visible by warmth. Both explanations can be at once disproved by replacing common miscellaneous dust of unknown origin by a carefully chosen smoke, say that of burnt magnesium, which is certainly neither volatile nor combustible.

Finally, Dr. Tyndall suggested an ingenious mechanical explanation, that the air was dragged up in convection currents faster than its supported dust, which consequently got left behind; and with this he was content.

So the matter rested until 1881, when Lord Rayleigh re-examined the phenomenon, "not feeling satisfied with the explanation given by the discoverer," and conclusively established the inefficiency not only of all ready-made hypotheses concerning it, but also of those which occurred to himself. A most interesting reversal of the experiment was made by Lord Rayleigh, for, instead of holding a warm body under the beam, he held a cold body above it, and witnessed the formation of a down-streaming dark plane of great sharpness, bordered by bright fringes of extra dusty air, which he attributed to the dew-point being passed, and the consequent condensation of moisture upon dust-nuclei.

Three years ago I took up the subject, and, with the active co-operation of the late Mr. J. W. Clark, then acting as Demonstrator, repeated all known experiments with minute care, in order to find out the cause of the singular phenomenon.

The results of this research are numerous; I can do no more than summarise a few of them to-night, though I believe that some of them, if followed up, would lead to results of considerable interest. The first thing we observed was that the ascending dark plane was the extension and upstreaming of a dust-free coat which invested the surface of the warm body, and which was really the essential part of the phenomenon, the dark plane being merely an upstreaming extension of it. From gently warm bodies the upstreaming dark plane, being made by the uniting of two coats, one from either side of the body, is easier to see than the coats themselves, but they are usually quite distinct, and on the average may be taken as about the hundredth of an inch thick.

Appearance of Coat and Plane shown by Diagram

(Figs. 1 and 1A).—Round red-hot bodies the coat is obtrusively evident. We first observed the coat on the concave side of a hemi-cylinder of sheet copper. We tried this shape in order to disprove Lord Rayleigh's suggested explanation that the dust-freeness might be due to the curvature of the stream-lines

FIG. 1.

and centrifugal force. This idea it does disprove most effectively, for the curvature being negative on the inside of the cylinder, dust ought to be thrown towards the body, instead of being kept well away from it, as in fact it is (Fig. 2).

Lantern Slide of Planes.—It is not easy to project the actual dark coat and plane on to a screen, because the light from the dust particles is but feeble; but it is possible to send a beam along the rod, instead of

FIG. 1A.

FIG. 2.

across, and to show that the dust-free space is more transparent than the surrounding smoky air. In this way a projection of thick coat and plane, in light, upon the screen, is easily made.

Experiment.—A platinum wire a few inches long is stretched across a glass box, and arranged to be pulled straight at all temperatures. A parallel beam is sent exactly along the wire, and through a lens, the box is filled with brown paper smoke, and a few Grove cells applied.

In trying this experiment one often finds a copy of the appearance imprinted upon the glass wall of

the box in smoke, and this dust-graph also serves to illustrate the phenomenon.

[Projection on screen of dust-graph formed on a vertical glass plate, where the end of a hot rod is held against it in still dusty air.]

It may be convenient here to state, at least roughly, the line of explanation to which we have ultimately been compelled. We regard it as quite certain that the facts serve as another illustration of the kinetic theory of gases, of the same kind as Mr. Crookes's radiometer. The dust particles are kept out of contact with the warm body by means of a differential molecular bombardment on their surfaces. True, the thickness of the coat is far larger than the mean free path of a molecule at the corresponding pressure; and accordingly no body as big as a radiometer vane could at that distance be acted upon; but Professor Osborne Reynolds has shown that very minute bodies are susceptible to a bombardment at much greater distances; and it is, I think, in accord with his theory that dust particles should be repelled from hot bodies over a measurable distance even at ordinary atmospheric pressure, although radiometer vanes would only be acted upon at a pressure of a thousandth, or something approaching a millionth, of an atmosphere. I do not say that this explanation is yet complete, and I am not aware that anyone has adopted it. It is, however, pretty clear that there will be an outward pressure from the surface of a hot body,* so long as the air near it is getting warmer; and if convection currents are allowed, the air near a hot body is continually in the state of getting warmer.

The main facts which we assured ourselves of may be thus briefly summarised.

1. The dark plane becomes visible over a cylindrical thermometer bulb indicating a temperature only half a degree warmer than the air.
2. The dark coat becomes just visible round a body one degree hotter than the air; at two degrees it is distinct; and at five degrees it is fairly thick.
3. The coat enlarges with diminished pressure, and narrows when the pressure is increased.
4. In hydrogen the coat is thicker, and in carbonic acid thinner, than in air.
5. If volatile smoke like volatilised camphor is used, the coats become thicker, though less sharply defined.
6. Round a rod of camphor in ordinary smoke the dust-free coat is extra thick, owing to the extra bombardment of evaporation.
7. Round cold bodies the coat is practically absent, especially on the top of the body; and if the cold is too great no descending dark plane is formed: only a bright one.
8. Liquids containing solid powder in suspension (e.g., dried ferric oxide in water) form a very narrow dark plane over a moderately warm cylinder. But the thickness of the plane is so slight that it is difficult to observe, and it gets thinner with increase of temperature, instead of thicker, as in the case of gases; hence the experimental rod in a liquid must be only gently warmed.

The formation of a descending dark plane in dusty air below a moderately cool body is singular, for it would not naturally have been expected on the bombardment hypothesis. The dust particles must be driven towards, instead of away from, a cold body; and this fact is obtrusively evident, from the fact that such a body becomes quickly covered with soot

* See for instance some experiments of Mr. Crookes on repulsion by hot surfaces, described in *Nature*, vol. xv. page 301.

in an atmosphere of MgO or other smoke, while a warm body remains clear.

It is easy to illustrate this fact by two black conical flasks, one full of hot water, the other of cold, both put under a bell-jar of thick white smoke. In about five minutes, if they be taken out, it will be found that the hot one is nearly free from soot, the cold one covered as with hoar-frost.

Mr. Aitken, of Edinburgh, has also observed this fact, and has pointed out that it explains the deposition of soot in chimneys, and of lampblack on cold glass. Mr. Aitken's paper in the Transactions of the Royal Society of Edinburgh for 1884, is a most comprehensive and lucid account of all this part of the subject. His work was concurrent with ours, as related in the "Philosophical Magazine" for 1884, and it is better described.

Bodies colder than the air in contact with them have the dust in it bombarded on to them; as is well seen on a wall above hot-water pipes, or on a ceiling above a gas-jet. Smoking of the gas-jet will of course provide more material to be deposited, but the dust and smoke naturally (or unnaturally) in the air are usually ample to effect a sufficient blackening, over even a perfectly clear flame. An incandescent electric lamp hung a foot or so under a white ceiling will similarly cause a small black patch.

In rooms warmed by radiation (open fire or sunlight), objects are warmer than the air and keep much dust off themselves; though the bombardment may not be sufficiently vigorous to overcome the gravitation of the larger dust particles, especially over a flat horizontal surface, where convection is sluggish.

In stove-heated rooms things are liable to be colder than the air, and thus get exceedingly dusty.

The cause of the clearing of smoky air inside a bell-jar by the introduction of a hot platinum wire, or other hot body, as observed by Tyndall, who called it calcining of the dust, is now manifest: the dust is bombarded on to the sides and floor of the vessel by the warmed air. The self-formed picture of dark coat and plane formed on a glass surface when the end of a hot cylinder is held against it is similarly completely explicable.

But, it may be asked, if dust gets driven towards cold bodies instead of away from them, how is it that any dark or dust-free plane forms beneath them? At very low temperatures I believe it does not, but rather a bright or dusty layer forms instead. From a rod a few degrees below the air a fine dark plane is visible, however, edged by two bright ones. I do not know what Lord Rayleigh's view of this descending plane is, but it may be due to the gravitative settling of the dust through the air immediately beneath the cold body; a thing which is shown to occur by the existence of a thin dark half-coat formed underneath, but not above, such a rod, and by the deposit of dust on its upper surface. The rod shelters the air immediately beneath it from the shower, and so a layer of clear air forms and streams downward continuously. If the downward convection currents are too rapid the settling has not time to occur, and no dark plane is visible.

The original plan of experiment included a series of measurements of the thickness of the dark coat at different temperatures (both excess and absolute), at different pressures, and in different kinds of gas. This research Mr. Clark had indeed begun to arrange for, but his untimely death last year cut short this part of the investigation. Another very necessary thing is to see how it varies with size of dust particles. Meanwhile I had devoted myself to developing a branch of the subject which we had accidentally hit upon in the course of testing one hypothesis which had at an early stage occurred to us

as perhaps a clue to the cause of the phenomenon of the dust-free plane. We thought it possible that air in streaming over the surface of the solid might get electrified, and that, from air so electrified, dust might somehow be expelled. To test this hypothesis, we purposely electrified the rod, positively and negatively, to see what happened. A hundred volts or two produced a barely noticeable effect; positive electrification causing a slight widening, negative electrification a slight narrowing of the dust-free coat. But as soon as the potential rose to a few thousand volts, and brush discharge began to be possible, a very violent and remarkable effect was noticed: the dark coat widened enormously and tumultuously, and the whole box was rapidly cleared of smoke.

To specially observe this new phenomenon is very easy. Fill a bell-jar with any kind of smoke: tobacco, camphor, turpentine, magnesia, ammoniac chloride, ammoniac sulphite, brown paper, steam, phosphoric oxide, lead fume, zinc fume, no matter what, and then discharge electricity into it from a point connected with a Voss or Wimshurst machine, the other pole of which is connected with the ground or with the base of the bell-jar.

In a second or two, aggregation of the smoke particles sets in, they form in masses or flakes along the lines of force, and in another instant the jar is clear of smoke; it has all been condensed on the sides and floor of the vessel.* [Experiment.]

The kind of smoke used is quite immaterial, it is all acted upon in the same way, but to make the effect visible to an audience; it is better to use something which does not dirty or render opaque the glass. Burning magnesium ribbon makes a very good and clean smoke. For experiments on a large scale a cheap smoke is obtained by burning sulphur in the neighbourhood of a pan of ammonia. Whether positive or negative electricity be used seems to make no difference.

Instead of a single point, a double set of points may be used, each connected with one pole of the machine. A round knob will act instead of a point, but not so quickly. Brush discharge, or anything that electrifies the air itself, is the most effectual. When a knob or pair of knobs is used, the lines of force are interestingly mapped out by the dust-flakes.

The cause of the phenomenon is manifest enough. The electrified or polarised particles attract each other, and are attracted by the opposite poles, just as iron filings are influenced near a magnet.

In thinking over what manifestations of this aggregating power of electricity were already known, the beautiful observations of Lord Rayleigh on water-jets occurred to me; though the cause in this case is not so clear. The experiment is not so well known as it should be, and, being an extremely simple one, I venture now to show it. A vertical water-jet two feet high, from an opening $\frac{1}{8}$ inch in diameter, scatters into drops and falls as a shower of rain; but hold a piece of rubbed sealing wax a yard or so distant from the place where the jet breaks into drops, and they at once cease to scatter; they fall in large blobs as a thunder-shower.

[Experiment. The rain may be allowed to patter on to paper, when the difference in sound is very distinct. The air should be free from electricity beforehand, as the jet is extremely sensitive.]

Clouds can probably be caused to rain by discharging electricity into them; at any rate a cloud

* Note added July, 1886.—My attention has just been drawn to a paragraph in "The Mechanics Magazine" for November, 1850, wherein it appears that this phenomenon was at that time observed by a Mr. C. F. Guitard; a fact of which I had been quite ignorant.

of steam in a bell-jar rapidly turns into Scotch mist or fine rain, and so disappears.

[Experiment. Insulation in this case is a slight difficulty, but it is easily managed.]

To make a thick mist or fog it is sufficient to introduce a scrap of burning sulphur under the bell-jar; instantly the country mist becomes more like a town fog, but this also is rapidly dispersed by electricity. [Experiment.]

I have ventured to think it possible that the coagulation or combination of oppositely charged dust particles is a gross imitation of the cohering of oppositely charged atoms in a chemical compound. When nitrogen and hydrogen are subjected to sparks they unite gradually into ammonia. When a brush discharge passes into oxygen it aggregates into ozone, as is well known from the smell near an electrical machine in action. Such actions (especially the latter) do seem to me of the same nature as the aggregation of charged smoke particles, though far more refined. The size of a smoke particle is not great, but it is enormous compared with an atom. Each granule of a lycopodium cloud may be taken as containing pretty exactly one trillion molecules. A smoke particle is a good deal smaller than a lycopodium granule, but not incomparably smaller. It is because of the minuteness and the interleaved arrangement of oppositely charged atoms in a compound, that its electrical capacity is so enormous; so that ten billion units of each kind of electricity can be stowed away among the atoms of a milligram of water, without raising the potential of each above a volt or two.*

FIG. 3.

Two bell-jars as used for smoke and fog condensation in lecture experiments. The one with the point let in at top is for any dry smoke; the other is for any damp or acid smoke. Insulation is in this latter case quite outside the chamber, and the rod, swathed in glass or gutta-percha, enters through a wide hole in the base-board. The little flask is only to catch drip. The ivory ball is to be illuminated by a beam of light, and to shine through the fog as it clears.

APPLICATION OF THE COAGULATING POWER OF ELECTRICITY TO PRACTICAL PURPOSES.

In many industries the presence of fine dust or fume suspended in the atmosphere is highly objectionable, sometimes because of the poisonous or dangerous nature of the dust, sometimes because it is valuable and apt to escape and be wasted.

* In connection with this part of the subject, see British Association Report for 1885 (Aberdeen), page 744, where an electrostatic theory of chemistry is discussed.

In flour mills and coal mines the fine dust is dangerously explosive. In lead, copper, and arsenic works it is both poisonous and valuable.

Mr. Alfred Walker, of Walker, Parker & Co., first informed me of the difficulty which lead smelters labour under in condensing the fume which escapes along with the smoke from red-lead smelting furnaces, and he wished to put an electrical process of condensation to the test on a large scale.

The devices which are in use at different works to collect or condense this fume are very numerous, and some of them very cumbersome.

At Bagillt the method used is a large flue two miles long, coiled up in the side of a hill between the furnace and the chimney; much is retained in this flue, but still a visible cloud of white lead fume continually escapes from the top of the chimney.

The only difficulty in the way of depositing fume in the flue by means of a sufficient discharge of electricity, is the violent draught which is liable to exist there, and which would blow away mechanically any deposited dust. In some ways the blast may be helpful, for instance by keeping the electrical points clear and preventing local clogging; but a large chamber must be provided somewhere for the coagulated flakes of dust to settle and remain in calm.

The plan I suggest at present is to line a certain portion of the interior of a flue with spikes, and then to hang in the middle of it wire netting, *well insulated*, and studded all over with ragged edges and points. It may be suspended lengthways in the flue. If the chamber be very large, it may be well to have a number of long prickly nets, arranged parallel to each other, and kept alternately positive and negative.

The insulation of the suspended conductor, whatever its shape, has, of course, most carefully to be arranged; everything depends upon that.

[Experiment showing the action of an electrical point held above a model chimney emitting smoke. Its first effect is to destroy or reverse the draught; but if the chimney be itself provided with points at the top, and an electrified cap be held over it—*e.g.*, a small sheet of prickly wire gauze, the draught is assisted, and the smoke is mainly condensed.]

I do not regard this as a good method of dealing with smoky chimneys. The right way to deal with them is to abolish them—*i.e.*, to make combustion so perfect that no unburnt matter escapes.

The experiment illustrates, however, that smoke can be caught and deposited on the wing.

[Special apparatus for producing and condensing quantities of smoke was next shown in action. It could be kept electrified by a small Voss machine. After a lecture in London I had an opportunity of trying Mr. Wimshurst's 8-plate machine on the smoke chamber, and the rapidity with which it was cleared was surprising. Roughly speaking it might be called instantaneous.]

When such a machine as this of Mr. Wimshurst's comes to be used, one may hope to make an impression on fume produced on a manufacturing scale. But further data in this direction are desirable.

SIR HENRY E. ROSCOE, M.P., F.R.S., IN THE CHAIR.

CHAIRMAN'S ADDRESS.

THE CHAIRMAN : It is a pleasure to me to be able to be amongst you this evening to open the Fourth Session of our Manchester Section of the Society of Chemical Industry, and I must first ask your kind attention to some remarks of a personal char-

acter. I desire to thank the members of this Section and other gentlemen, members of firms in Manchester connected with our chemical industries, for their kindness in presenting, as they recently did, a memorial to the Council of the Owens College, asking that I should continue in some position connected with that institution. I appreciate the confidence thus shown in me. The terms in which

the memorial is couched are too flattering, but I must say that the expressions are not stronger than my desires have been. I have always felt that in this district, where chemical industry occupies so important a place, it is important that the industry should be united with and founded upon science, and the efforts which I have made in co-operation with my colleagues, who have so nobly assisted me in the tuition at the College, have always been in this direction. That the efforts thus put forth have not been wholly unavailing is shown by the very considerable number of our pupils who now occupy positions of trust and importance in the chemical establishments of this district. I need scarcely add that it is with great regret that I find my labours, for nearly thirty years as a teacher of chemistry in this great district, drawing to a close, and I assure you, gentlemen, and my other friends in this city, that my interest in the maintenance of this union of science and practice is, and will remain, as great as ever. It will always be a pleasure, as well as a duty, for me to assist the cause of scientific education here and elsewhere; indeed, it is the confident hope that I may be able to do something in this direction for our common country that has induced me to make, what is to me, a considerable sacrifice in entering public life. Again, I beg heartily to thank all the friends who signed the memorial. I think I may congratulate the Society on what appears to be an improvement in the general trade of the district. I don't know whether that improvement has as yet reached the chemical industries, but I cannot help thinking it will do so soon. In connection with this matter I wish to bring under your notice a subject which I think of great importance to the chemical industries of this district. I refer, as you will easily understand, to the proposed Manchester Jubilee Exhibition. I wish to refer specially to Section III., which is set apart for chemical and allied industries. The worthy vice-chairman of our Society, Mr. Ivan Levinstein, is chairman of the committee, and a more active, painstaking head of a committee of that kind could not have been found. Associated with Mr. Levinstein are many distinguished gentlemen interested in chemistry and its applications. The intention of the committee, I understand, is to have an exhibition of chemical products, chemical apparatus, and chemical processes such as, for extent and perfection of arrangement, has never yet been witnessed. The different stages of manufacture, from the raw material to the finished article, will be carefully shown. I hope the Manchester industrial chemists will put their best foot foremost and assist the Exhibition authorities to show the great strides that have been made by the chemical manufactures of this district during the last fifty years. Some idea of the extent of the section of the Exhibition in which they are particularly interested, may be formed from the fact that the space set apart for it is 48,000 square feet. The section has been divided into seventeen classes, and if a good representation of the various classes can be secured, the Exhibition will be a better one than has ever been seen before. I hope the members of the Society will do what they can to make the Exhibition second to none that has yet been held. Looking at the matter from a pounds, shillings, and pence point of view, I think it will be worth your while to take the matter in hand.

The CHAIRMAN concluded his address with a short description of the Chemical Institute recently built at Zurich at the cost of £70,000, in order to show what might be done in England if the people had the same views as people on the Continent with regard to the applications of science.

NOTES ON A FEW CHEMICAL SUBSTANCES RECENTLY INTRODUCED INTO THE FIELD OF CHEMICAL INDUSTRY.

BY IVAN LEVINSTEIN.

ONE of the principal objects of our Society is that of keeping its members posted up in the progress which is being made, not only in scientific, but more especially in industrial chemistry. With this object in view I desire to direct your attention to the following chemical compounds—viz., salol, lanolin, and antifebrin, which have lately become of industrial and also of medicinal importance.

Commencing with salol—the new antirheumatic *par excellence*—I may just state that I am aware that attention has already been called to it by Mr. Moss, in a paper read before the British Pharmaceutical Conference, held on September 1; that gentleman was, however, under the erroneous impression that the process of its manufacture was a secret, and was not aware that it was the subject of a patent; and this fact will serve as a justification for further referring to this very interesting and valuable substance.

Salol was produced about three years ago, by Professor Nencki, who also investigated its physiological properties. To Dr. H. Sahli, however, is due the credit of having first practically applied it to medicinal purposes; and the results which he obtained were made public by him in the early part of the present year, in a communication to the Société de Médecine et de Pharmacie, at Berne. Nencki and von Heyden's successors patented the process of the industrial manufacture of salol in Germany, England, and other countries about three or four months ago, and transferred the right of manufacture to three continental firms—viz., Messrs. Durand & Huguenin, of Basel; Dr. von Heyden's successors, of Dresden; and E. Schering, of Berlin. The complete specification of the British patent, No. 8018, 1886, has not been filed, and no copy of it is obtainable, while the German specification has not yet been printed. According to the inventors, there are within their knowledge three modes of practically effecting the industrial production of salol—viz.,

1. Heating salicylic acid and phenol or naphthol with phosphorus pentachloride or phosphorus oxychloride.

2. Melting the sodium or other metallic compounds of the salicylic acid and phenol or naphthol together, with phosphorus pentachloride or phosphorus oxychloride.

3. Treating with phosphorus pentachloride or phosphorus oxychloride the crude product of the reaction obtained in the manufacture of salicylic acid.

This last mode is probably the most likely to produce the most economical results. The general reaction may be stated to be as follows:—

When fatty or aromatic acids are heated with phenol or naphthol in presence of a dehydrating agent, such for instance, as phosphorus oxychloride, acid ethers are formed. Thus, if molecular quantities of salicylic acid and phenol are melted together, and this mass heated with phosphorus oxychloride, at from 120° to 130° C., the salicylic phenol ether or phenol salicylate, "salol," $\text{HO.C}_6\text{H}_4\text{CO.O.C}_6\text{H}_5$, is obtained.

Under the same conditions the resorcinol salicylic ether may be obtained, if the phenol is replaced by resorcinol.

The reaction is effected in a simpler manner, and gives a better yield if in place of free salicylic acid and phenol their sodium or other metallic salts are used, as the following equation will explain :—

Instead of phosphorus oxychloride, phosphorus pentachloride may be substituted.

In place, however, of commencing with free salicylic acid, the salicylphenylether (salol) may be produced by taking the crude product of reaction, as obtained in the process of manufacturing salicylic acid according to the following formula :—

This mixture, after being allowed to cool, is treated either with phosphorus oxychloride or phosphorus pentachloride, when the process may be explained by the following equation :—

Finally, the process may be effected by first heating for some time in closed vessels a mixture of phenol carbonate, sodium hydrate, and phenol at 180° to 200° , allowing it to cool a little, and then treating the mass as above described with phosphorus oxychloride or phosphorus pentachloride.

The information available with regard to salol is naturally scanty, as the article itself is comparatively of recent origin, and its manufacture was only commenced within the last few months. All that has been published is more or less an abstract of the communication of Dr. Sahli, who, however, chiefly confined himself to its therapeutic properties. Dr. Sahli's experiments thus far go to prove that salol is a valuable antiseptic antipyretic and antirheumatic. He especially remarks on its great efficacy in rheumatism, and on this point I can confirm his far greater experience by a single instance which happened to fall under my personal observation. A friend had been suffering for a lengthened period, extending over several years, from chronic rheumatism of the joints; and after having spent more than three months of the present year at the best anti-rheumatic watering places on the Continent, returned without having derived the benefit desired. On the contrary, the pains increased, and also the swelling of the knee and finger joints. Having read Dr. Sahli's paper, I induced my friend to try salol, and its beneficial effect on him has certainly been most striking. In the course of a few days the pains were relieved, and the swellings subsided immediately. My friend then discontinued the use of the salol, but was again inconvenienced by the damp and wet weather of the early portion of last month; he again took the salol with equally satisfactory results, and though it has not yet entirely removed his chronic rheumatism of old standing, he is at least in the fortunate position of possessing a remedy which will afford almost immediate relief from pain, and at once reduce the swelling of the joints. The possession of such a remedy is undoubtedly a great boon in this damp climate, so unfavorable for the cure of rheumatism. I may add that my friend had repeatedly tried salicylic acid, but had in every case been compelled to discontinue its use owing to the disturbance of the digestive functions which this remedy unfortunately produces with most persons

Now salol is practically free from this very great disadvantage, and under ordinary circumstances may be taken for weeks twice or thrice daily in doses of thirty grains, without producing any perceptible effect on the digestive organs. As Professor Nencki has shown, salol, being insoluble, passes unaltered through the stomach, and is only decomposed into salicylic acid and phenol in the duodenum by the ferments of the pancreas. Its action on the human system is, therefore, like that of salicylic acid and phenol combined, with this remarkable difference, that the latter may be taken in the form of salol without ill effects in larger doses than would be possible if taken alone. Salol is also said to be very effective in neuralgic and other similar complaints. After taking salol, the urine has a similar dark or even black colour to that of carbol urine, but it is singular that this dark colour is not present in all cases, even though comparatively large doses of salol are taken. Sahli attributes the valuable antipyretic properties of salol to some extent to the phenol which it contains, and thinks that this fact also accounts for its action as an antirheumatic, being more powerful than that of salicylic acid. Salol is further recommended as an immediate and very efficient antiseptic, and for surgical operations it may be found of the highest value, as it is neither caustic nor irritating, like phenol and salicylic acid. Dr. Sahli also employs salol as a dentifrice, and considers it to be, perhaps, the only one that will effectually prevent the spread of caries in the teeth. He dissolves salol in alcohol, and adding a small quantity of this solution to water, uses the milky emulsion for rinsing the mouth. His theory is that small particles of the insoluble salol in this finely divided state become lodged in the small crevices of the teeth, and thus act for a certain length of time as an antiseptic. Chemically as well as physically, salol behaves in a similar manner to fats; it is soluble in ether, alcohol and petroleum spirit; crystallises in large and well-developed crystals, and possesses a not disagreeable aromatic smell. Its melting-point is 43°C . The fact of its possessing similar properties to fats, and its solubility in petroleum and other solvents, renders it very suitable for impregnating bandages or preparing salol-wool, as it adheres far more readily than salicylic acid.

I think enough has been said to show that this interesting substance may be destined to play an important part in medicine, in hygiene, and probably in the arts and manufactures. I have to thank Messrs. Durand and Huguenin for the specimen of salol which you have seen this evening, and which represents their commercial and absolutely chemically pure product.

We will now turn our attention to the next chemical substance which will occupy a portion of these fragmentary notes—viz., lanolin.

CHOLESTERIN OR LANOLIN.

Cholesterin, $\text{C}_{26}\text{H}_{44}\text{O} + \text{H}_2\text{O}$, although in a strict sense chemically differing from fats, possesses very similar physical properties. It is present not only in the animal organism but also in the vegetable kingdom. Liebreich has recently demonstrated its presence in the human epidermis, in hair, whalebone, tortoiseshell, hornshavings, feathers of geese, fowls, turkeys and pigeons, bristles of the hedgehog, hoofs and warty excrescences on the leg of the horse, horny substance of the sheep's foot, etc. Until a short time ago, however, the usual material for obtaining cholesterin for scientific purposes was furnished by gall-stones, which consist principally of cholesterin, although many years ago F. Hartmann

and E. Schulze had already found that the fat of greasy wool (wool-grease) contained cholesterol. Indeed, as far back as 1872, Schulze described a method of obtaining cholesterol from wool-grease. He heated the latter for about twenty hours in a closed vessel with alcoholic potash lye at 100°C ., and on drawing off and evaporating the clear hot solution, mixing the residue with water and treating it with ether, he obtained two separate layers,—the watery layer, containing the fatty acids of the wool-grease as potash soaps, and the ethereal layer, holding in solution cholesterol—which, after evaporation was obtained pure by repeated crystallisation of an ether-alcohol solution.

Cholesterol crystallises in thin monoclinic tablets; it has a neutral reaction, being neither alkaline nor acid; it is free from smell and tasteless, insoluble in water, sparingly soluble in cold, but easily soluble in hot alcohol, ether, and chloroform; dissolves also readily in fatty acids; its melting-point is 145°C ., and its specific gravity 1.067.

Professor Liebreich observed that cholesterol fat possesses the peculiar property of being able to absorb more than one hundred per cent. of water, and this singular property was denominated by the great pharmacologist Lanosation, while the cholesterol mixed with water was termed by him lanolin. He also first called attention to the great therapeutic value of lanolin, and shortly afterwards the industrial production of pure lanolin was commenced by a Berlin firm,* and its manufacture has been of late steadily increasing, which is not surprising when we consider the valuable properties possessed by this substance. Indeed, it is impossible to foresee the manifold applications which it may yet find in medicine, arts and manufactures. Lanolin is already taking the place of vaselin, paraffin and lard, and there is every probability that before long it will exclusively replace these substances for medical purposes. Its efficiency in the composition of plasters, salves and ointments has already been established beyond doubt, and its superiority is due to the extraordinary readiness with which it is absorbed by the skin. While vaselin, for instance, directly hinders the passage of medicaments into the skin,—so that even some poisonous substances mixed with vaselin and rubbed into the skin produce neither local nor general symptoms of poisoning,—on the other hand, lanolin is absorbed by the skin with the greatest ease, and this ready absorption is not known to belong in a similar degree to any other fatty substance. So marked is the power of penetrating the epidermis possessed by lanolin that, according to Dr. W. G. Smith, when mixed with poisonous drugs, such as the toxic alkaloids, only about half the usual proportions should be prescribed in ointments. In attempting to account for the ready passage of the lanolin into the skin, Liebreich thought this property might probably be due to the fact of its originating from keratinous tissue. Lanolin may also be advantageously used in place of vaselin in *massage*. It is not so smooth as vaselin, but it possesses this advantage, that the skin, after being rubbed dry with a cloth, still remains soft and pliant; it is further recommended in cases where the epidermis is broken, as, for instance, in chapped hands, and is said to be very serviceable in the treatment of dandruff or scurf. Liebreich, however, warns us against many substances sold under the name of pure wool-oil or wool-grease, which have found their way into trade both before and since the introduction of lanolin.

He considers these injurious, as they contain free acids and various other irritating substances.

Besides the medical uses which have been found for lanolin during the short period of its existence, it has also been already introduced into various branches of industry, such as perfumery, soaps, creams, and pomades, also for greasing leather-belt and for improving the pliability of leather, while quite recently a German officer—Von Kleist—was induced by Liebreich's discovery, that cholesterol is present in the hoof of the horse, as well as in the skin of various animals, to employ it with very successful results as a lubricant for horses' hoofs.

The process employed in the industrial manufacture of lanolin is based on Schulze's method. The crude wool-grease or wool-oil (of which I have here a sample in the bottle marked "II."), is obtained in the usual way by treating the natural greasy wool—specimen I.—with soap liquors, and then decomposing these by mineral acids. According to Jaffé and Darmstädter, the crude wool-oil contains about 70 per cent. (principally cholesterol), and 30 per cent. of fatty acids. The main object of the industrial chemist is to obtain from this mixture the lanolin in a pure state, and this difficulty has been successfully overcome by the two Berlin chemists just referred to, who (according to Liebreich) have succeeded in producing a lanolin of great purity, and to their kindness I am indebted for this collection of samples, showing the different stages of manufacture.

The first operation consists in saponifying the fatty acids of the crude wool-grease by means of caustic soda. An emulsion is thus obtained, which, on dilution with water, gives the so-called wool-milk (specimen III.). When this milk is subjected to centrifugal action, it separates, like cows' milk, into so-called cream and skim-milk. The cream (specimen IV.) contains the lanolin, and on precipitation by a lime-salt, we obtain the crude lanolin (specimen V.). This is heated, when water separates from it, and the lanolin is then further purified from its waxy impurities—higher-melting cholesterol—which are always present in the crude form, by a process which has been patented quite recently. The lanolin is much improved by the removal of these waxy substances, and the product thus obtained is the *Lanolinum anhydricum* (specimen VI.), and this pure anhydrous lanolin is finally converted by being kneaded, with 30 per cent. of water, into *Lanolinum purissimum* (specimen VII.).

In conclusion, I may add that Liebreich, in his investigations, in order to ascertain the presence of lanolin or cholesterol in other fats, made use of the method first described by Liebermann for proving the presence of cholestol, a substance closely allied to cholesterol, which test consists (*Berichte*, 1885, p. 1803) in dissolving the substance to be tested for cholestol or cholesterol in as much acetic acid anhydride as will allow it to remain in solution on cooling, and then adding, drop by drop (cooling at the same time), concentrated sulphuric acid. If cholesterol is present, the solution first turns pink, but soon changes to a fairly permanent blue colour.

The following tests are recommended for ascertaining the purity of commercial lanolin:—

1. If 2–3 grms. of lanolin be put into a small flask with 10cc. of a 30 per cent. solution of caustic soda, and the mixture be heated, red litmus paper placed at the top of the flask must not turn blue—disengagement of ammonia.

2. If 10 parts of lanolin be heated with 50 parts of distilled water in a water-bath, the lanolin must separate as a clear oil. Impure lanolin becomes frothy and turbid.

* Messrs. Jaffé & Darmstädter.

3. If oily, lanolin thus separated must be free from glycerin.

4. If mixed or well rubbed with water on a ground-glass plate with an iron spatula, the result must be a product containing over 100 per cent. of water; and if the lanolin employed is pure, the kneaded mass will be sticky and paste-like; but if impure, the mass will possess a soap-like smoothness, and will not adhere to the spatula.

The last chemical substance, formerly, and till quite recently, a preparation or specimen only figuring in the museum or laboratory of the organic chemist, now an article of chemical industry, is one called "Antifebrin."

Antifebrin or Acetanilide, C_8H_9NO .—It may interest some of our members to inspect the specimen which I have here of the above-named very latest febrifuge. It has been known to chemists for a considerable number of years. Acetanilide is said to be far more effective than quinine in the reduction of fever, and even four times more powerful in its action than antipyrin. As its method of preparation is extremely simple, and the raw materials from which it is made not costly, its price is, of course, very much lower than that of antipyrin. I need scarcely add that antifebrin is made by simply heating for some time aniline and glacial acetic acid, and afterwards distilling the acetanilide.

$NH_2C_6H_5 + HO.CO.CH_3 = N(CO.CH_3)C_6H_5.H + H_2O$.

—This specimen has been made by Messrs. A. Leonhardt & Co.

DISCUSSION.

Mr. WM. THOMSON said that reference was made to the antiseptic and antipyretic properties of salol and antifebrin. There was a general impression that substances which reduced the temperature of the body during fever, such as salicylic acid, were necessarily antiseptics, and that it was due to their antiseptic properties that the temperature of the body during fever was reduced; that is to say, that the antiseptic prevented the rapid development in the blood of the microbes which caused the disease, and consequently the temperature fell. Some time ago he obtained a sample of "antipyrin" which Dr. Leech, of Owens College, informed him had a greater influence in reducing the temperature in fevers than salicylic acid. He tested this substance to ascertain whether it was a powerful antiseptic, and was surprised to find that it possessed little or no action in preventing the growth either of mould or of bacteria. He mentioned this fact to Dr. Leech, who said that he believed the drug acted on the nerve centres in such a way as to more fully open the pores of the skin, the temperature becoming reduced by the more rapid evaporation of the moisture from the surface of the body. Antipyretics were therefore not necessarily antiseptics.

SOME NEW REACTIONS FOR RESORCINOL AND THE RECENTLY DISCOVERED COAL-TAR FEBRIFUGES AND ANTIPYRETICS.

BY WATSON SMITH, F.C.S., F.I.C.,

Lecturer in Chemical Technology in the Victoria University, etc.

DR. EDLEFSEN, in a note in a recent issue of the *Chemiker Zeitung*, describes certain reactions for resorcinol and thalline sulphate or tartrate, and I have tried to discover if any colour reactions are given also with phenol, antipyrine, kairine, "anti-febrine" (acetanilide), α - and β -naphthol,

quinine, and a variety of other bodies, and I find that no reactions are thus given. Hence I concluded that the tests in question would be of very considerable value, and particularly useful in therapeutics, as well as to those of our Society interested in fine chemicals. I have also made one of the tests applicable to cases in which medical men or others may have specimens of "salol," and may desire to know positively if they consist of the phenol- or resorcinol-salicylic ether. My note thus follows not unsuitably the paper of Mr. Levinstein.

Test for Resorcinol.—To a dilute freshly-prepared aqueous solution of the so-called β -naphthaquinone

$C_{10}H_6 < \begin{smallmatrix} CO.CO \\ CH:CH \end{smallmatrix} >$ a few drops of a 1 per cent.

resorcinol solution are added, and then two or three drops of ammonia. The sample at once assumes a beautiful dark bluish-green colour. If a portion of this solution be shaken with ether, little or none of the colour is taken up by the ether. If to the bulk of the green fluid nitric acid be added to acid reaction, the green colour gives place to a fine red, and ether shaken with this solution takes up the red and becomes finely tinted, the lower layer proportionately losing colour, and at length becoming pale yellow or colourless. Chloroform answers as well as ether; the layer, in this case, sinking to the bottom of the vessel. The reaction is specially beautiful if the ethereal solution of β -naphthaquinone be used; α -naphthaquinone does not give the reaction.

Test for Thalline Sulphate or Tartrate.—If to the dilute solution of the β -naphthaquinone, a small quantity of a solution of thalline sulphate or tartrate be added, and then a drop or two of caustic soda solution, a fine red or cherry-red colour is produced, the beauty of which is heightened by acidifying with nitric acid. By shaking the sample with chloroform or ether, they take up the colour and become themselves finely tinted.

To distinguish a Resorcinol "Salol" from a Phenol "Salol".—Fuse some of the sample with a little pure potash or sodium hydrate in a small silver dish, or boil for some time with a little concentrated alcoholic potash, when the ether is decomposed, and the resorcinol or phenol remains combined with potash. Dissolve in water and pass carbonic acid in excess to decompose the phenol or resorcinol alkaline compounds, and shake with ether. The ethereal solution will contain the phenol or resorcinol, and now the foregoing test may be usefully applied, when, as you have seen, phenol, if present, will give no reaction, only resorcinol giving the beautiful reaction characteristic of it.

Precaution.—Only a dilute solution of β -naphthaquinone must be used, for with a strong one, ammonia will cause a colouration deepening to a tint somewhat similar to that produced by resorcinol. In such case phenol or any other substance would seem to react like resorcinol.

I mentioned that if a too strong solution of β -naphthaquinone is taken, alkali alone would give an immediate greenish colour reaction; I also said that α -naphthaquinone gives no colour reaction under the circumstances referred to. There is no need of surprise at this, for whereas α -naphthaquinone is a true quinone, β -naphthaquinone is a diketone, and years ago Bamberger, Hinsberg and Körner showed that the orthodiketones give colour reactions with alkalis.

Thus—e.g., β -naphthaquinone, $C_{10}H_6 < \begin{smallmatrix} CO.CO \\ CH:CH \end{smallmatrix} >$ and phenanthrenequinone— $\begin{smallmatrix} C_6H_4-CO \\ | \\ C_6H_4-CO \end{smallmatrix}$ are very similar,

whereas α -naphthaquinone is a true quinone, and is constructed on the same pattern as benzoquinone—

and these are both para-compounds, whereas the diketones referred to are ortho-compounds. The antipyratics, kairine and antipyrin, which gave no reaction under the treatment described, can, however, be readily distinguished from the foregoing and from each other by the following reactions, which have been sent me by my friend, Dr. C. A. Kohn, who has been engaged sometime with a study of kairine and its derivatives:—

Commercial Kairine, or the Hydrochloride of Hydroxyhydro-ethylquinoline.—(1) One drop of ferric chloride produces in a dilute aqueous solution a violet colouration, which almost at once changes to brown. Excess of ferric chloride gives a dark brown colouration, and in concentrated solutions a brown-black precipitate. (2) Potassium bichromate when added to a neutral aqueous solution forms a dark colouration at first; after a few seconds or minutes, according to circumstances, a violet colouring matter separates, dissolving in alcohol to a mauve-coloured solution.

Antipyrin (Methyl-pyrazol) $C_{10}H_{10}N_2O$, behaves quite differently from the foregoing. It is distinguished:—(1) By the red colouration produced on addition of ferric chloride. One part in 100,000 can be detected by this reaction. (2) By the pure blue-green colouration produced by nitrous acid in dilute solutions. The colour develops fully after a few seconds. In concentrated solutions green crystals separate. One part in 10,000 can be detected by this test.

"Antifebrin" or *Acetanilide* $C_6H_5.NH(CO.CH_3)$ gives no colour reactions with the foregoing reagents. A small quantity of the substance should be boiled with alcoholic potash, when the following decomposition will take place:— $C_6H_5.NH(CO.CH_3) + KOH = C_6H_5.NH_2 + CH_3.COOK$. The aniline is easily tested in the usual way, and after distilling it off the residue contains potassium acetate, also readily identified.

ON A NEW APPARATUS FOR READILY DETERMINING THE CALORIFIC VALUE OF FUEL OR OTHER ORGANIC SUBSTANCES BY DIRECT COMBUSTION IN OXYGEN.

BY WILLIAM THOMSON, F.R.S. ED.

I HAVE been for some time engaged in the attempt to determine accurately the quantity of heat produced by the combustion of coal, by a simple and convenient process. There are two or three processes which purport to give the heat produced by the combustion of the fuel. The first is that of Berthier, which consists in heating to fusion 1grm. of the coal, with 70grms. of litharge, and 10grms. of oxy-chloride of lead. The weight of the button of lead obtained is certainly a measure, under the conditions of the experiment, of the reducing or deoxidising power of the fuel, and as such, it is no doubt in some cases of much value—such, for instance, as in determining the quality of coal to be employed for reducing the sulphate of soda in the production of black ash; but it is useless as a calorimeter, because an equivalent of hydrogen would be

less efficient as a reducing agent under those conditions than an equivalent of carbon, although when burned in the air the hydrogen would produce more heat than the carbon.

The next simple process is the one devised by Mr. Lewis Thompson, M.R.C.S., which consists in intimately mixing 1grm. of the coal with 22grms. of a mixture of chlorate and nitrate of potash (in the proportion of 3 of the former to one of the latter).

This mixture is placed in a copper tube called a furnace, and fired by a fuse made by soaking a few strands of ordinary lamp wick in a solution of nitrate of potash or lead, and drying. About three-quarters of an inch of fuse is placed upright in the mixture, the tube or furnace containing it being placed in a stand surrounded by four upright brass springs (strips of brass fitted to the stand, and curved upwards and inwards). When the fuse is ignited, a copper cylinder closed at the top, and to which is attached a long narrow tube furnished at the end with a stop-cock, is pushed over the springs; the whole apparatus is then lifted by the narrow copper tube, and immersed in water (about 2000 cubic centimetres), contained in a thick glass cylinder of 13½ in. long by 4½ in. diameter, the temperature of the water being accurately taken before and after the experiments: the difference indicates the heat given to the water and apparatus by the combustion.

The mixture burns away like a squib, often projecting a considerable quantity of the fused mass from the furnace, the hot gases bubbling through the water to which they part with their heat. When the combustion is complete, the stop-cock at the end of the narrow tube is opened to allow the residual gas in the apparatus to escape, and to allow the water to take up the heat still retained by the copper tube, and by the salts left from the combustion.

It is admitted that this process is not an accurate one; still, although the results are rough, it has proved of considerable service in the hands of several eminent chemists.

The method of calculating the quantity of heat produced, as stated by Lewis Thompson, is to add 10 per cent. to the result obtained, for loss of heat by different ways, such as by absorption of the apparatus itself, etc. The amount of heat absorbed by the apparatus may easily be measured, but there is a number of other both losses and increments of heat produced in the apparatus which it would be difficult, if not impossible, to measure, as they would probably vary more or less in each experiment.

When chlorate of potash is heated it dissociates, and in doing so liberates a considerable quantity of heat, so that with the same weight of coal the heat obtained increases in proportion to the increase in the quantity of oxygen or chlorate mixture employed. The nitrate of potash absorbs heat on being dissociated. The oxygen, on being liberated from the solid condition, expands to the ordinary pressure of the air, and absorbs heat, whilst the copper tube or furnace itself liberates heat as it becomes burned, a cake of the oxide of copper being afterwards found both on the outside and on the inside of the tube, whilst the potassium chloride, which is left when the potassium chlorate is decomposed, absorbs a considerable quantity of heat when it comes in contact with, and dissolves in, the water of the calorimeter. The gases also come off so rapidly as to escape being cooled by the water, and carrying much water vapour with them. Lastly, the outside of the glass cylinder is generally uncovered, and so is unprotected from the warmer or colder air around it, and from radiant heat, so that in standing before one of these vessels, in which is placed a delicate thermometer, it may be observed, if the temperature of the water be below that of the

atmosphere, that the mercury goes on rising comparatively rapidly in the thermometer. Lastly, the glass of the cylinder is so thick that it only slowly, if it ever does, come throughout to the temperature of the water inside.

In a communication which I made to the Physical and Mathematical Section of the Philosophical Society relative to the difficulties which I had experienced in working with the Lewis Thompson apparatus, our excellent vice-president, Dr. J. Prescott Joule, suggested the idea to me of burning the fuel in pure oxygen. This was done in the classical researches of Andrews and of Favre and Silbermann, and more lately Gottlieb has made many determinations by an apparatus very similar to that used by Favre and Silbermann; but all these appliances are either costly or complicated, or they are capable of yielding good results only in the hands of the expert manipulator. My first attempts to devise a simple and efficient calorimeter were made by burning the coal in a glass jar

FIG. 1.

previously filled with oxygen in the manner employed by Dr. Andrews. This proved useless in my hands, the combustion, at first rapid, soon became very slow, and ultimately left a considerable residue of unconsumed carbon. In burning pure and simple substances such as hydrogen or carbon, and determining the quantity of material consumed by weighing the products of combustion, which was the method usually adopted by Dr. Andrews, good results could no doubt be obtained, but with such a complicated substance as coal, it is evident that this method would not prove satisfactory. My subsequent attempts were made by placing the fuel in a small glass diving bell,

which was sunk to the bottom of water contained in a thin glass cylinder, the oxygen being conducted by a tube continuously on to the burning fuel. I found it difficult to obtain a steady flow of oxygen, and to obviate this I devised the gas-holder, which I shall describe further on. Various shaped platinum vessels were employed on which to place the coal, the more open vessels or shallow trays exposed the coal too much to the comparatively limited supply of oxygen, so that it gave off its volatile matters so rapidly as to cover the sides of the glass diving bell with a more or less thick deposit of soot. At last I found the combustion could be perfectly performed in a small deep platinum crucible, supported on a non-conducting stand. Fig. 1 shows the apparatus placed in position for making a determination of the heating power of a fuel. A shows the small platinum crucible, $\frac{1}{2}$ inch diameter and $1\frac{1}{2}$ inch deep, resting on the clay support B. I used at first the bowl of a clay tobacco pipe for this purpose. 1 grm. of the fuel is weighed into the crucible, which is then placed on the clay support on the stand H. The inverted test tube C, which is 6 in. long by $1\frac{1}{2}$ in. diameter, has fused to it the small tube J, 1 in. long by $\frac{1}{2}$ in. diameter. Over this is fitted the small piece of black indiarubber tube L, through which passes the long thin copper tube E, about $\frac{1}{2}$ in. internal diameter. This is arranged so that it can be pushed through the indiarubber tube without difficulty, and this is the more easily done by rolling or folding backwards the upper part of the rubber tube on itself. The long thin copper tube terminates in a tap and piece of bent tube, which is placed in communication with the oxygen gas-holder by a piece of indiarubber tubing. The tube C has also attached to it four circles of copper or brass wire gauze K, which fit as accurately as possible into the large thin glass beaker D. The part of the long tube at F is covered with felt or other non-conducting material, so that when the tube is held by it the heat of the hand will not be communicated to the gas passing through it.

The large thin glass beaker is filled with 2000 cc. of water from a supply which has previously been kept in the room in which the experiment is to be made, so that it has come to about the same temperature as the atmosphere. The temperature of the water is accurately noted after being stirred well with a wire or glass plunger, which may be made by bending the wire or glass at right angles to itself, and coiling it round itself so as to form a disc. The thermometer should be fixed in the arm of a retort stand so that both may be removed at once, and so adjusted that the bulb and about two inches of the stem would be immersed in the water of the calorimeter.

When the temperature of the water has been noted, the diving bell C should be arranged with the tube E drawn up to near the top and attached to the supply of oxygen, which should be under slight pressure, with the tap M closed: a fuse of lamp wick similar to that used in the Lewis Thompson apparatus, is placed upright in the coal in the crucible and ignited. The bell glass is now pushed over it, and fixed in position by the springs G, and the whole lifted into the beaker of water and sunk to the bottom; simultaneously with doing so, the tap M is opened gradually and a stream of oxygen passed through the apparatus. The coal burns quietly at first. The thin copper tube should not be pushed far down till all or nearly all the volatile hydrocarbons have been consumed, as for this purpose it is well to have plenty of oxygen in the upper part of the bell glass. When the coke is left in a glowing condition, it is more difficult to burn, and it is advisable then to push the thin copper tube down till the end

is immediately over the platinum crucible. A slight rotating movement can now be given to the tube, so that the gentle stream of oxygen falls on any particles of unburned coke in the bottom of the crucible. So intense is the heat which may be thus produced, that a piece of rather strong perforated platinum foil which I used in one experiment was melted by it. The ash of the coal is left in the form of a number of fused pellets, some very minute, some of considerable size. The bubbles of gas as they pass from the bottom of the bell glass, rise, and are repeatedly broken by the layers of wire gauze *k*, so that they leave the water at the same temperature as the water. When the experiment is completed the taps are closed, and the rubber tube conveying the oxygen detached. The tap on the thin copper tube is now gently opened to allow the water to enter the bell, which is then drawn to the surface and again pushed to the bottom two or three times to thoroughly mix the water in the beaker and to ensure that all

the metallic cylinder, or it may be rested on three sections of a phial cork placed at the bottom of the metallic cylinder.

The oxygen is delivered from the gasholder (Fig. 2), which is filled with that gas by opening the stop-cocks *A* and *B*; after it has been filled with water, the rubber tube *C* is connected with the oxygen generator, and the tube *d* is raised to about the height of the cylinder before the taps are opened. The oxygen enters at *A* and expels the water at *B* by the tube *d*, or by both tubes *e* and *d*. The tube *f* is of glass, and serves to tell the height of the water in the cylinder. The glass tube *g* is attached to the tube *h*, and is open at the top. This serves to indicate the pressure, whilst the rubber tube *e* is used for running out water after the experiment, so as to bring the gas inside to the atmospheric pressure if desired, and thus to enable the operator to measure the amount of gas used for the experiment. In using the calorimeter, the rubber tube *d* is attached to an ordinary tap from the town water supply, so that when the combustion is started the tap *A* is opened full, and the quantity of gas passing through the apparatus accurately adjusted from the town supply tap. The stream of oxygen is thus kept very regular, as the rising of the water in the cylinder makes little difference in the pressure of the water entering.

All the glass, copper, mercury, iron, brass, etc., connected with the calorimeter, are weighed; and from their specific heats their equivalent in water is calculated.

The oxygen employed may be measured, and from its specific heat the quantity of heat carried off may be calculated. The specific heat of oxygen being 0.2160, and of carbonic acid 0.2163, and the weight of oxygen used in each experiment being about 8 or 10 grammes, the correction for the heat thus carried off, especially as the total rise of temperature in each experiment does not exceed from 6 to 8 degrees, is very small. The mean temperature of the gases passing away from the water for each experiment would not exceed three or four degrees of a rise. The water converted into vapour may also be calculated from a table, which gives the quantity of water vapour contained in saturated air at different temperatures. Such a table has been calculated from the observations of Magnus and Regnault, and may be found, p. 316, in Kohlrausch's "Physical Measurements," but, taking the latent heat of water vapour at 965 F. units, the total heat lost, either from evaporation of the water or from that carried off by the air itself, is so small that both together lie within the range of experimental error, half the total rise of temperature being taken for reference to the table.

Lastly, the loss of heat through the apparatus should be taken into account, and as this will vary with the temperature of the surroundings, it is well to take the temperature of the water in the calorimeter immediately after the experiment, and having noted the time which the experiment took to make, notice the loss of heat which takes place during a similar period, and add this on to the temperature of the water. It would, of course, be still more accurate to allow the temperature to fall to somewhere about the mean between the temperature at the beginning and at the end of the experiment, and then notice how much it loses during three or five minutes which were taken to perform the experiment; but I have found the loss at the higher temperature not to exceed an average of about one hundredth of a degree per minute.

It is necessary to find what weight of glass in the thin beaker is in actual contact with the water, and this is done by first weighing the beaker, then

FIG. 2.

the heat has been given up to the water. As the water can only rise in the bell glass to the bottom end of the copper tube through which the residual gas makes its exit, it is well to push it under the water so that it may give up its heat. The whole apparatus is now withdrawn, and the temperature again taken. For the sake of correction the time during which the experiment lasts (generally from 3 to 5 minutes) is noted. When a determination is being made the long beaker containing the water is set in a thin, bright-tinned, silvered, or nickel plated iron or copper vessel, with an opening of about half an inch wide and 9 or 10 inches long, cut down the side, fitted with a glass window, through which the experiment can be observed; the metallic vessel protects the calorimeter from radiated heat and from contact with the colder atmosphere. The calorimeter is suspended in this case by the neck, so that no portion of it, in contact with the water, touches

finding the quantity of water it displaces. This may be easily done by filling a beaker (the size larger than the one intended for use) with water; the one intended for use is now filled with the water from the larger beaker. Some of the water from the larger beaker is also poured into another empty vessel, and the smaller beaker inserted into the larger one. Water is now poured from the vessel above mentioned into the larger beaker till the smaller one is completely covered, and till the water reaches the mark at which it originally stood. The remainder of the water in the vessel into which it was poured shows the total volume of the glass of the beaker.

The smaller beaker is now removed and emptied, and the larger one is again filled with water. The smaller one is now filled to the mark on the glass (2000cc.) with water from the larger. Some more water is again poured into an empty vessel from the larger beaker, which is filled to the mark at which it originally stood, after the smaller one has been sunk into it so that the level of the water inside the smaller beaker is the same as the original mark on the larger one, the excess of water left shows the bulk of glass which would be heated by the water in the calorimeter, and from the total bulk and weight of the smaller beaker, and the water displaced in the second experiment, the actual weight of glass in the calorimeter in actual contact with the 2000cc. of water may be calculated. To obtain the quantity of mercury used in the thermometer the bulb is introduced into a narrow measuring tube and the amount of water which it displaces observed. From this the weight of mercury may be roughly calculated, the weight of mercury being 13.596 times the weight of water displaced. The weight of the two inches of the stem can be calculated by weighing the thermometer and deducting from it the weight of the mercury; the difference will give about the weight of the stem, the length of which is then measured, and the weight of the two inches calculated therefrom. The stirring rod or wire and the long copper tube are weighed and their lengths measured to find the weights actually in contact with the water; the other parts of the apparatus are weighed directly.

The following gives the figures obtained for the apparatus I used:—

MATERIAL USED.	Weight in Grammes.	Specific Heat of Material.	Equivalent to Grammes of Water.
Glass of beaker = 7.812oz.	221.472	.1977	13.784
Glass bell	18.015	.1977	9.192
Brass	106.017	.09391	9.956
Iron	12.993	.11379	1.478
Platinum	7.3496	.03211	.238
Clay support	16.875	.1977	3.336
Indiarubber	1.181	.2	.237
Mercury	27.192	.0333	.905
Thermometer-glass..	1.161	.1977	.822
Copper gauze.....	27.122	.09515	2.531
Water employed	—	—	2000.000
Total material heated in the calorimeter equivalent to water	—	—	2072.829

Calometric valuations by this apparatus can be rapidly performed, and the results obtained agree

very well with each other. The thermometer employed is graduated about half-an-inch to the degree.

DISCUSSION.

Dr. BAILEY: I might suggest to Mr. Thomson that he would still further increase the accuracy of his apparatus by using a larger quantity of water, and if he considers the loss by radiation serious, I cannot see any objection to using a larger quantity of water. I should like to ask whether any allowance is made for the amount of hydrogen in the coal? I would also suggest that the water at the beginning of the experiment should be a little below the temperature of the room, so that it would be a little above that temperature at the close of the experiment.

Mr. GEORGE E. DAVIS: I have used Mr. Lewis Thompson's apparatus very largely for determining roughly the calorific power of many varieties of fuel, from the rich silikstone to ordinary anthracite, and even coke, and have not found so much difficulty in using it as the reader of the paper has made out. I think, however, that Mr. Thomson's apparatus is certainly an improvement, as it enables the operator to regulate the speed of combustion, which is impossible in the case of Mr. Lewis Thompson's apparatus. After all, the employment of either of these forms will only give a comparative idea of the calorific utility—so to speak—of various fuels, and gives no idea whatever of what can be obtained on the large scale, as it does not take into account the physical condition of the fuel, as everyone is well aware that in ordinary furnaces good round coal will always produce better results than small coal or smudge, even if both kinds are identical in chemical composition and give the same results in the laboratory with one of these fuel-testing pieces of apparatus.

Meeting held in the College of Science, Wednesday, November 3.

PROF. P. P. BEDSON, D.S.C., IN THE CHAIR.

CHAIRMAN'S ADDRESS.

AFTER some introductory remarks the speaker then drew attention to certain recent additions to the knowledge of the elementary bodies, making special mention of germanium, and of the recent isolation of fluorine, also of some of the results of Von Welsbach's investigations of certain rare earths; the Welsbach light being cited as a practical outcome of these latter investigations.

An account was next given of the history and mode of manufacture of the febrifuges, kairin, thallin, and antipyrine, obtained from hydrocarbons contained in coal-tar; also of "iodol" or tetra-iodopyrrol, which is manufactured from pyrrol by the process patented by Professor Ciamician and Silber. This compound is of interest as possessing antiseptic properties, and is recommended as a substitute for iodoform. In reviewing matters relating to the alkali industry, mention was made of the recent improvements made

in the plant for the decomposition of ammonium chloride by magnesia, of Dr. Witt's proposal for obtaining hydrochloric acid from ammonium chloride by decomposing it with phosphoric acid; also of the two methods of Messrs. Simpson and Parnell for manufacturing soda. Attention was directed to the important part the dissociation of ammonium compounds plays in these two processes, and after reviewing the history of the investigations of the phenomena of dissociation, and pointing out their importance to the progress of chemical theory, the speaker concluded his address with the following remarks:—But it is not the advantages which the science of chemistry has already gained from the investigations of the phenomena of dissociation that I would speak of, but what is of greater interest is the evidence before us in the proposals of Messrs. Simpson and Parnell, as also in the Claus's process for the purification of coal-gas, described in the August number of the Journal, for the practical application of facts, a knowledge of which has been brought to light by investigations pursued with an object of a purely theoretical interest, and one apparently so remote from the aims of industrial chemistry. Surely facts such as these should serve as a warning to us, and prevent us from assuming toward the theoretical side of the science of chemistry, either the useless attitude of indifference or the impractical attitude of the practical man, or again the attitude of cynicism, finding expression for itself in words akin to those of Mephistopheles to the student: "Grau, theurer Freund ist alle Theorie und grün des Lebens Goldner Baum." For whether we turn to the investigations of rare earths, or to the study of organic chemistry, or the examination of laws relating to the constitution of compounds, we find each contributing its share of facts, which, sooner or later, find an application in some industrial pursuit. Again, in considering what should form the best training for those upon whom will devolve the duty of carrying on the manufactures of this country, we should not only remember the advantages that have accrued to practical pursuits from purely theoretical investigations, and formulate a system accordingly, but remember also these advantages have resulted not from inquiries undertaken with a view to their practical application. Then I think we shall give the theoretical training its true position in our system of education, nor begrudge the time and expenditure that such an education requires. And taking a lesson from Germany, we shall bestir ourselves to promote the extension of Universities similar to those existing in that country, which the various States have spared no effort to equip fully and completely for their work in all branches of knowledge. To the laboratories of these institutions the chemical manufacturers look for chemists to carry on the various industries, and we have it on the authority of Dr. Perkin, that the students from these laboratories find greater favour with the manufacturer than those from the avowedly more practical institution, the Polytechnicum. The universities have also promoted the intellectual activity of the German people, and have, as Professor Beyer has pointed out—in a speech quoted by Mr. Levinstein at a recent meeting of the Manchester Section—in this manner contributed to place Germany in an industrial position superior to that occupied by France and our own country, whose natural resources are superior to hers.

Remembering these facts, also, we shall be the more ready to assign a more honoured position to the theoretical side of the science of chemistry in relation to manufactures. Not looking to its growth and development merely for the provision of methods and

instruments for testing the efficiency of well-established processes and the like, but rather, by making provision for the prosecution of scientific investigations in connection with these manufactures, contribute to the advancement of knowledge, and give to these industries that elasticity and versatility, and resourcefulness in meeting demands for variety in products and commodities, which has been the main characteristic in the growth and development of the coal-tar industry in Germany.

In conclusion, the Chairman said that he should like to say a word with respect to the position of this Section in relation to the other Sections of the Society of Chemical Industry. It was a matter which had already been mentioned in the Committee's Report, and which is of such importance that he could but refer to it once more. He need scarcely say that he referred to the most striking feature in that report—viz., the great falling off in the number of communications brought before the Section during its last session. The majority have been in the form of short notes merely, and one-third of the communications come from a foreign source. He would not emphasise this latter fact, for science recognised no nationality, but this, together with the small number of communications, would appear to denote a want of activity, if not of interest, in the objects for which this Society was formed. He trusted that the proceedings of the coming session would prove that this lack to which reference had been made, represented but a temporary lull, and that the Section would take a position which, for activity and spirit, would worthily sustain its reputation amongst the different sections of the Society of Chemical Industry.

DISCUSSION ON MR. SISSON'S PAPER ON "MAGNESIUM SULPHYDRATE."*

THE CHAIRMAN stated that he had used the sulphhydrate as a source of hydrogen sulphide; he had found the gas quite pure, and thought the method of obtaining it had great advantages over the ordinary method with ferrous sulphide. He thought the cost of the solution rather prohibitory. He would like to know whether the decomposition was complete, and also whether any experiments had been tried as to the solubility of hydrogen sulphide in the solution, at the ordinary pressure and under compression.

MR. B. S. PROCTOR inquired as to the keeping properties of the solution.

MR. CLAGUE thought that the solution would probably commend itself for use in the preparation of sulphur baths. It would seem much more convenient than the ordinary method, and would probably produce a much better imitation of natural sulphur springs.

MR. SISSON stated that the solution gave up a great part of its gas on merely heating to boiling, but to expel the gas completely required a good deal of boiling. The solution would keep for any length of time in closed bottles. He did not know whether it would absorb hydrogen sulphide or not.

A NEW FORM OF APPARATUS FOR COLOUR TESTS, AND NOTES ON STEAD'S ALKALI METHOD FOR ESTIMATING LOW PERCENTAGES OF CARBON.

BY C. H. RIDSDALE, F.C.S.

At the spring meeting of the Iron and Steel Institute in 1883, Mr. Stead read a paper on "The Estimation

* See April number of this Journal, p. 210.

of Minute Quantities of Carbon in Iron and Steel, and a new form of a Chromometer." He described a method for dissolving the combined carbon in an alkali, and estimating the percentage of it from the relative height of two columns of liquid required to give the same depth of tint, one being a solution of a steel containing a known amount.

At the North-Eastern Steel Works we have very often occasion to test rapidly steels containing under '09 carbon, and sometimes as low as '02 per cent.

It was out of the question to use the combustion process, being much too slow for practical working, and on the other hand the ordinary Eggertz colour test was unavailable, as it was incapable of showing any difference when the carbon content was below '07

of CO_2 obtained, causes a large difference in the percentage.

On a 10grm. portion by combustion, 1milligram. of CO_2 represents a difference of '0027 per cent.

On a 1grm. portion by the alkali method, one division on the scale (which makes a marked difference in the depth of tint) represents with a '05 C. standard, '0025 per cent, or barely as much as 1milligram. on a 10grm. portion by combustion, and it is considerably easier to work to one division by the colour method, than to 1milligram. by combustion.

Mr. Stead's method, as published, is as follows:— Dissolve 1grm. of the sample in 12cc. nitric acid, of sp. gr. 1'20; heat to 90° or 100°C . till the sample is dissolved, which will take about 10 minutes. Then

RIDSDALE'S ROTARY CHROMOMETER.

per cent. We, therefore, at once adopted Mr. Stead's method, and found it to answer very well indeed, the results being both rapid and accurate.

As regards *rapidity*, we regularly test one blow before the next but one is brought in, the average time for the analysis being 35 to 40 minutes, and the time from the taking of the sample of molten steel to the sending out of the result, being under the hour, which is obviously very desirable when making from 25 to 27 blows per 12 hours.

As regards *accuracy*, with a suitable standard the results may be taken as fully equal to those obtained by a carefully conducted combustion process, for there are more possible sources of error in the latter, besides which, a very slight discrepancy in the weight

add 30cc. boiling water, and 12cc. sodium hydrate solution of sp. gr. 1'27; shake and make up to 60cc. for the test.

We adhere to this method, except that we add 18cc. caustic soda solution, let rest 10 minutes after shaking, and then take up to 70cc.

The chromometer itself, however, we do not use, as by its form of construction it is very liable to breakage in changing the standard; and to meet the requirements of rapid work, together with several other desiderata, I devised the form of apparatus which I now describe:—

DESCRIPTION OF APPARATUS.

The apparatus consists of the following parts (see illustration):—

Three glass tubes of equal bore throughout. The centre one is sealed at the bottom. Each of the outside ones is drawn out fine, and prolonged about three inches, passing through an indiarubber cork to within half-an-inch of the bottom of a bottle of ruby glass. On each of the tubes is loosely fitted a small cylinder, about one inch long, of glazed china clay or porcelain, or a sealed glass tube containing some heavy white powder, such as barium sulphate. Two syringes, one for each bottle, are connected therewith, either directly or with indiarubber tubing, to a small piece of glass tube, which just passes through the cork. There is also a third tube with a tap on it, which passes from the lowest point of the bottle, through the cork, and bends over for about two inches towards the back of the apparatus. Above the three comparison tubes is a mirror, which can be turned to any angle so as to enable the operator to see down them. On one side is a scale for measuring the height of the column of liquid in the tube, on the other a pointer which slides on a brass rod. A framework of mahogany for the above, the whole of which *revolves* on a circular bottom weighted with lead. The apparatus can thus be instantaneously turned round for better comparison of colour, without sacrificing its stability.

DIRECTIONS FOR USE.—Fill the centre tube up to 20 divisions with the liquid to be tested. The tubes on each side are for the standards, which may be of different depths of tint, thus enabling better comparison to be made than if only one standard is used.

To fill with standard.—Open the cock on the bent tube, stop the top of the comparison tube either with a cork or the finger, then hold a little beaker, containing the standard, so that the bent tube dips into it, and draw up the syringe, when the liquid will at once rush into the bottle.

To make the comparison.—Turn off the tap of the bent tube, remove the cork or finger from the comparison tube, and force the liquid up till the depth of tint, as shown by the mirror at the top, is equal to that of the 20 divisions of liquid being tested. Read off the height of the column on the scale, calculate, $\text{Number of divisions of standard} \times \text{percentage of standard} \div \text{number of divisions of liquid being tested} = \text{the percentage.}$

To empty out old standard.—Stop the top of the comparison tube, open the tap of the blow-out tube, and force the liquid out of the bottle by pressing down the syringe.

To clean the bottles out.—When a new standard is to be used, it is better after emptying the bottle, to suck a little of the new standard in, and force it out again. If necessary, from time to time, the bottles can be cleaned out in the same way with dilute hydrochloric acid and then water.

The ultimate selection of the form of each part has been made with reference to some special advantage, or the avoidance of some weak point.

Glass syringes have been selected as most suitable for adjusting the height of the column of liquid, as by their use it can be kept stationary at any height as long as wanted, say whilst the apparatus is revolved to compare the colour. This turning round is as necessary as the changing from side to side of the comparison tubes in the ordinary colour method, being necessitated by the light striking unequally on both tubes, thus making the depth of tint apparently vary.

I found that the standard, though not as sensitive to the action of light as in the ordinary colour method, was still somewhat subject to change in the course of the day, and as each fresh portion required 1 grm. of the standard steel, it was desirable not to have to renew it more frequently than necessary.

The bottle for holding it has, therefore, been made

of ruby glass, and by thus excluding actinic rays, one standard may safely be used for 12 hours at least.

To avoid risk of breaking the fine part of the comparison tube in the uncorking and corking the bottle for introduction of the standard, this has been dispensed with, as owing to caustic soda getting on the cork, it was difficult to keep it tight, and in trying to screw the cork more firmly in, the fine tube almost always got broken. I have, therefore, adopted the arrangement for pumping the standard in and out, so that the cork never need be removed.

Again, when testing carbons varying from '03—'08 per cent. with a '05 standard, those with '08 showed *proportionately* too dark a tint, and required to be done with a higher standard. There are, therefore, three comparison tubes, the centre one being for the sample to be tested, and the outside ones for two standards of different percentages.

If the *same* standard be used on both tubes the apparatus will not need to be turned round, the relative position of the left hand to the centre tube being the same as that of the right-hand tube to the centre one when turned round.

We have now used this apparatus constantly for over two years, and though several thousand determinations have been made with it, we have never broken any part of it, although with the old form we were constantly breaking it just at the most inconvenient time, or finding the cork leak, through its having to be removed every time a fresh standard was inserted.

ON THE RATE AT WHICH BLEACHING POWDER LOSES ITS AVAILABLE CHLORINE.

BY JOHN PATTINSON, F.I.C., F.C.S.

IN 1874 I read a paper with the above title to the Newcastle Chemical Society. The experiments then made, which extended over about a year, were made upon samples kept in small bottles in the laboratory, and the question naturally arose: Do experiments made upon such samples indicate also if available chlorine is lost at the same rate when the bleaching powder is kept in casks of the size used in commerce? In order to ascertain this, I have made monthly tests of three casks of bleaching powder of the usual size, containing about 6 cwt. each, over a period of about twelve months, and also, for comparison, monthly tests of samples of the same kinds of bleaching powder kept in bottles holding about 4 oz each.

Two of the casks, marked A and B respectively, were filled with bleaching powder made from Irish limestone from Larne by different manufacturers. The third cask, marked C, contained bleaching powder made from "French Cliff." Twelve bottles of each kind of bleaching powder were filled at the same time and the corks sealed, and both casks and bottles were stored in a cellar. A maximum and minimum thermometer was kept near them, and a careful record of the temperature was made each working day during the year. It will be seen from Table I. (page 588), that the bleaching powder had been kept at a comparatively low and uniform temperature during the whole year, the lowest temperature noted being 38° F., and the highest 62° F.

In taking the samples from the casks, each cask was bored in a different part at the end of each month, and a sample withdrawn and tested. One of each of the bottles, marked respectively A, B, and C, was also tested each month at the same time.

Table II. shows the percentage amounts of available chlorine found in each of the various samples in each month.

TABLE I.

	Lowest.	Highest.	Average.
February	40	49	44.7
March	42	46	43.5
April	42	51	45.7
May	45	52	47.5

September	50	60	54.9
October	46	52	49.2
November	42	50	46.6
December	38	48	43.7

The casks and bottles were filled on the 26th and 27th of January, 1885, and the first samples were tested on the 29th January.

of calcinm. To determine chlorine existing as chlorate, a portion of the bleaching powder was boiled with a solution of sulphurous acid, to reduce both chlorates and hypochlorites to chlorides. After excess of sulphurous acid was expelled by boiling, and by the addition of a few drops of nitric acid, the solution was neutralised by carbonate of lime, and the total chlorine then ascertained by titration with standard nitrate of silver solution. The difference between the total chlorine and that existing as hypochlorite and chloride, gave the chlorine existing as chlorate. The other constituents were determined by the usual methods of analysis.

On examining the tables, it will be seen that, on the whole, there has been a gradual and regular loss of available chlorine during the eleven months over which the tests were made. The total loss of available chlorine in each sample was as follows :—

	Casks.	Bottles.
A	3.20%	2.30%
B	3.20	1.80
C	3.10	1.80

It must be remembered, however, that in the case of the casks, the loss of chlorine is reduced by this consideration : On referring to the complete analyses it will be seen that the cask samples have absorbed

1886.						
January 5	33.80	35.10	32.90	34.90	36.20	34.30

A complete analysis of each of the cask samples was made at the beginning and also at the end of the experiments. These analyses are given in Table III. (page 589).

The bottle samples were also examined at the beginning and end of the period for chlorine existing as available chlorine (hypochlorite), chlorate and chloride, with the results given in Table IV. (page 589).

The methods of analysis employed were the following :—The available chlorine was determined by Penot's method—that is, with a standard solution of arsenious acid. To determine the chlorine existing as chloride, the portion in which available chlorine had been determined was acidulated with nitric acid, the excess neutralised with carbonate of lime, and then titrated with standard solution of nitrate of silver. The difference between the amount of chlorine thus indicated and the amount indicated by Penot's test, gives the chlorine existing as chloride

carbonic acid and water from the atmosphere during the year, and thereby increased in weight. The amount of this absorption is no doubt greater in these experimental casks than it would be in casks under ordinary circumstances, for the gradually-increasing number of holes bored in these casks and into the middle of the bleaching powder necessarily allowed greater access of air to the bleaching powder than would be the case with casks that are not so treated. The additional amounts of carbonic acid and water absorbed by the cask samples were as follows :—

A cask	2.32%
B "	2.05
C "	2.95

On making allowance for this increase in weight, the amount of loss of available chlorine in the cask samples is reduced to the following percentages :—

A cask	2.40%
B "	2.46
C "	2.10

Thus showing that the loss of available chlorine in the cask samples does not differ much from the loss in the bottle samples—the average loss in the cask samples being 2·32 per cent., and in the bottle samples 1·97 per cent., or a difference of 0·35 per cent.

And so with regard to the total chlorine; the loss of total chlorine in the casks and bottles, as sampled, was as follows:—

	Casks.	Bottles.
A	1·36	0·86
B	1·45	0·43
C	1·71	0·63

When, however, the same correction as above is made for gain of weight in carbonic acid and water in the cask samples, the loss of total chlorine in these is as follows:—

A cask	0·50
B "	0·67
C "	0·65

Or just about the same amount of loss as in the bottle samples, the average loss of the cask samples being 0·61 per cent., whilst the average loss of the bottle samples is 0·66 per cent.

increased by the following percentage amounts during the year:—

	Casks.	Bottles.
A	2·69	1·62
B	1·83	1·54
C	1·65	1·38

From a consideration of the above results, it will be seen that when bleaching powder is kept either in casks or in bottles for about twelve months under the conditions above specified—that is, at a temperature not exceeding about 60° F., it loses not more than from two to three per cent. of its available chlorine, and under one per cent. of its total chlorine.

It is not often, however, that bleaching powder can be stored in places where so low a temperature as 60° F. can be maintained for any length of time, at any rate, in the summer months, and in many cases it will be stored in places where a temperature of 70°, or even 80° F. will prevail. It seems desirable, therefore, to determine at what rate available chlorine is lost at these higher temperatures, more especially as my experiments made in 1874 indicated that a much greater loss of available chlorine took place

The small quantity of chlorine found as chlorate in each sample at the beginning of the experiments, ceased to exist in this combination at the end, and from tests made it was found that all chlorate had disappeared in May, or about four months after the casks and bottles were filled.

The amounts of chlorine existing as chloride had

during the summer months than during the colder winter months. It is my intention to keep samples of bleaching powder at fixed higher temperatures for a lengthened period, and to note the changes which take place from time to time. The results obtained will be laid before the members of this Society at a future time.

Glasgow and Scottish Section.

Chairman: J. Neilson Cuthbertson.

Vice-chairman: Prof. Mills.

Hon. Vice-chairman: E. C. C. Stanford.

Local Secretary:

G. G. Henderson, Chemical Laboratory,
University of Glasgow.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

The First Meeting of the Session was held in the Rooms, 207, Bath Street, Glasgow, on Tuesday, November 2, 1886.

MR. J. NEILSON CUTHBERTSON IN THE CHAIR.

CHAIRMAN'S ADDRESS.

THE CHAIRMAN, in his introductory address, gave a brief account of the proceedings of the parent society during the past year. The roll of membership, he mentioned, stood now at 2271, of whom 251 belonged to the Glasgow Section, only two of the sections being larger, London and Manchester, with 442 and 312 members respectively. During the past session 82 original papers were read, of which 17 were contributed by their own Section. One important matter in which the Section took part was that in promoting the success of the Edinburgh Exhibition. A small sub-committee was appointed and drew up a circular, which was sent to the chemical manufacturers of Scotland. The committee also attended the meetings of the local executive, and the result was that there was at Edinburgh a very respectable, if not complete, exhibition of the chemicals manufactured in Scotland. It had been announced that Exhibitions were to be held in Manchester and Newcastle next year, and the citizens of Glasgow had agreed that there should be one here in 1888. He thought the Section would form a very good organisation for interesting the chemical manufacturers of Scotland in securing a good chemical collection for the Glasgow Exhibition. He was old enough to remember a small chemical exhibition got up in Glasgow many years ago, and he believed the proceeds of that exhibition, small as it was, formed the nucleus of the Philosophical Societies' fund that had been invested in the building in which they were now met. He hoped that there would be a surplus as the result of the forthcoming great Exhibition, and that it might be devoted to some great local undertaking or institution. It would be observed from the programme that the title of the Section had been changed, and that it was now called the Glasgow and Scottish Section. The object of this was to provide for occasional meetings in Edinburgh, and probably in Dundee. The meeting in February was to be held in Edinburgh, and he looked forward to its being eminently successful. He saw no reason why they should not spread their wings all over Scotland, and excite much larger interest than they had yet attempted. Another most important matter was that they had invited the parent society to hold its annual meeting in Glasgow in July next,

and that the invitation had been accepted. That the sixth meeting of the Society should be held in Scotland was only due to the importance and extent of the chemical industries and manufactures of this neighbourhood. Before the Exhibition of 1888 was opened he hoped we should have a revival of trade. He was sure the members of the Society must be wearying for the return of prosperity. He believed he was correct in saying that the chemical industries, as well as others, had for a long time been labouring under a state of dulness and absence of remuneration which was not formerly experienced. In looking over a price list that morning, he found that all chemical articles were lower in price, or not higher, than they were a year ago, with one exception—namely, bleaching powder—and he did not know that they could attribute that to a revival of trade. He had no doubt that the depression which we had been experiencing for some time past would have good effects. It would lower costs all round, and be the means of enabling them to compete with other countries, and lead to what always helped in that and all other industries, the survival of the fittest.

A METHOD OF USING ANTIMONIOUS CHLORIDE FOR FIXING COAL-TAR COLOURS ON COTTON FIBRES.

BY GEORGE WATSON, F.C.S.

IN dyeing and calico printing processes, the only use made of compounds of the metal antimony is as an auxiliary in the fixation of coal-tar colours on cotton. Their application for this purpose depends upon the fact, that on mixing their aqueous solutions with aqueous decoctions of certain tannin substances, precipitates are produced capable of being dyed with various coal-tar colours, thus forming lakes. In practice it is usual to produce these lakes directly on the fibre by a proper combination of the three operations of tanning, antimoniating, and dyeing.

For various reasons, tartar-emetic was the salt of antimony adopted when this method of fixing was introduced, and, technically speaking, it served the purpose admirably. One drawback, however, it possessed—viz., its comparatively high price, due to the large percentage of potassium tartrate contained in it, and all the preparations proposed as substitutes are merely intended to give a salt as suitable, at a less cost.

Now, antimonious chloride is a salt possessing the necessary qualification of cheapness, being the least expensive salt producible, but unfortunately it, like most other antimony salts, is basified by water, and is thus rendered useless for the purpose of the dyer. It is the object of the method which I am going to describe, to show how this basification by water may be cheaply and efficiently prevented, thus enabling baths of any desired strength to be prepared.

It is known that antimonious chloride is capable of forming double salts with certain other metallic chlorides, such as the alkaline chlorides, and as it is obviously necessary for the production of these compounds that both salts should be simultaneously co-existent in solution, I concluded that antimonious chloride ought to be miscible in any degree with strong or saturated aqueous solutions of these chlorides. On making preliminary experiments, I found that to appearance, perfect miscibility was produced on admixture with saturated solutions of sodium, ammonium, magnesium and calcium chlorides; while potassium and barium chlorides yielded liquids more or less turbid. I thought it would therefore be

of interest, and possibly of value, to examine, under similar experimental conditions, the effect of varied quantities of the three first-named chlorides in preventing the decomposition of antimonious chloride by water. To these I have added potassium chloride for the sake of comparison.

For this purpose, I have carried out a number of experiments, the description of one of which will suffice to show the method of procedure of the whole.

Into a glass beaker of 300cc. capacity, 210cc. of water were placed. A definite weight of the metallic chloride under examination was then added and stirred till dissolved. The whole was next allowed to stand several hours, generally over-night, in order that the cooling effect due to solution might become dissipated. The temperature was then noted to make sure that each experiment was approximately similar in this condition. Exactly 1grm. of aqueous solution of antimonious chloride (of a known percentage of antimony), weighed in a watch-glass, was then added and well mixed by stirring. The whole was next allowed to stand eighteen hours. The treatment at the end of this time varied. In some experiments the watch-glass was withdrawn, freed from adherent precipitate by friction with a glass rod, tipped with indiarubber, the precipitate separated by filtration, washed with 210cc. of water, containing in solution an amount of metallic chloride identical with that used in the experiment, and the antimony in the precipitate determined by titration with standard solution of potassium permanganate. In other experiments, the antimony remaining in solution was estimated by titration of an aliquot portion of the clear supernatant liquid. The results of these experiments are embodied in the annexed table and diagram.

On examining these figures, several remarkable

case of sodium and ammonium, appears to be manifested in a regular manner, until saturation is nearly reached, when a great increase in efficiency takes place. The action of magnesium chloride occurs in a more uniform manner throughout, while potassium chloride exhibits a remarkable increase in effect at 53grms., decreasing again on further additions of the salt, and finally increasing on the saturation point being reached.

Diagram illustrating the effects of Sodium, Potassium, Ammonium, and Magnesium Chlorides.

Represented graphically, the action of sodium and ammonium chlorides consists each of three straight lines, forming different angles with the abscissa, while that of magnesium chloride consists of one straight line only. Representing by E the chemical effect or antimony retained in solution, and by y a weight of sodium chloride, the equation for the first part of the action may be put in the form $E = my + c$, m being the tangent of an infinitely large angle, is equal to 0. Hence $E = c$ for all values of y . From the point represented by 49.966grms. the effect is proportional to the sodium chloride, and may be expressed by the equation $E = (y - d)b$, where d and b are constants. The values of d and b , calculated from the experiments with an asterisk, are 49.784 and

facts are revealed. For instance, in the case of sodium, potassium, and probably of ammonium chlorides, the effect of the metallic chloride, although appreciable, is constant until about 40grms. have been added. From about this point the effect, in the

case of sodium and ammonium, appears to be manifested in a regular manner, until saturation is nearly reached, when a great increase in efficiency takes place. The action of magnesium chloride occurs in a more uniform manner throughout, while potassium chloride exhibits a remarkable increase in effect at 53grms., decreasing again on further additions of the salt, and finally increasing on the saturation point being reached.

then $E = b$. Hence b is the effect produced by 1 grm. of sodium chloride.

The equations for ammonium chloride (for the analogous part of the effect) and magnesium chloride are of the same form; the values of the constants d and b being 31.774 and 0.00511 for ammonium, and 39.063 and 0.0194 for magnesium. The calculated results are given in the table.

If γ and γ_1 represent equal weights of sodium and ammonium chlorides respectively, then the quotient of the expression—

$$\frac{(\gamma_1 - d_1)b_1}{(\gamma - d)b}$$

is the efficiency of ammonium chloride when that of sodium chloride is unity. On calculating this for different but equal values of γ and γ_1 , it is found that the efficiency of ammonium chloride as compared with that of sodic chloride is variable, and decreases as the values of γ and γ_1 augment. Under-noted are the ratios for certain values of γ :—

$\gamma = \gamma_1$	$\frac{E_1}{E}$
= 33.003	2.1781
" = 35.967	1.7526
" = 40.000	1.6035
" = 42.000	1.4360
" = 44.000	1.3136
" = 46.000	1.2250
" = 48.000	1.1511

For an equal weight, then ammonium chloride is twice as efficient as sodium chloride at the point 33.003 grms., and decreases gradually until at the point 68 grms. it is only about equally so. Making

$$\frac{E_1}{E} = 1,$$

then the corresponding values of γ and γ_1 are the mutual equivalents of the two chlorides. These are inversely proportional to their efficiencies, so that if the equivalent of sodium chloride is unity, that of ammonium chloride will be the reciprocal of its efficiency.

Calculating in the same way the efficiency of magnesium chloride as compared with ammonium chloride, I find that the ratio increases as the amounts of chloride augment. At the point, 50 grms., it is twice as efficient, at 54 grms. $2\frac{1}{2}$ times, and at 58 grms. $2\frac{3}{4}$ times. With saturated solutions of the three alkaline chlorides, taking potassium chloride as unity, the efficiencies of sodium and ammonium are 2 and 3 respectively.

In adapting these results to practice, potassium chloride, from its low efficiency, and ammonium chloride from its high price, will not be available. We are therefore reduced to the use of sodium or magnesium chlorides, or a mixture of both. As sodium chloride, even in saturated solutions, does not retain all the antimony in solution, means had to be devised to overcome this objection.

When a large proportion of water is added to antimonious chloride, the precipitate formed is said to have a composition represented by the formula $Sb_4O_3Cl_2$. Assuming that the antimony precipitated has carried down chlorine according to this expression, then the ratio of the antimony to chlorine remaining in solution is found on calculation to agree with the expression $Sb : 4\frac{1}{2}Cl$. Hence if this ratio exist before adding the antimony to solution, no precipitation should occur. This is verified on trial. In order to prepare a bath, then, we simply take a cold saturated solution of sodium chloride and add the antimonious chloride previously acidified in the above proportion.

By a suitable admixture of magnesium chloride with the sodium chloride, the amount of free hydro-

chloric acid present may be greatly reduced, or indeed dispensed with altogether. In manufacturing antimonious chloride on the large scale, a small proportion of free hydric chloride is always necessarily present, as it is impossible to fully saturate hydrochloric acid of 1.160 sp. gr. with antimonious oxide by boiling. The resulting liquor contains about 23 per cent. of antimony calculated as metal, the ratio of antimony to chlorine being about $4Sb : 15Cl$. Using the antimonious chloride in this condition, perfect solution is obtained on adding to a bath prepared according to the following formula :—

10 gallons water.
30lb. sodium chloride.
20lb. magnesium—in crystals.

If it is desired to use magnesium chloride alone, then we simply take a solution of this salt of a strength in accordance with the experimental results—viz., about 60 grms. of the anhydrous salt in 210 grms. of water. By taking the antimonious chloride in the condition above described, however, this proportion of magnesium chloride may be greatly diminished, the following being the formula for the preparation of a bath :—

10 gallons water.
62lb. magnesium chloride in crystals.

The method of applying the trichloride consists then simply in this, that a bath is prepared according to one of the formulae given, and to it is added the antimonious chloride. I now proceed to consider the advantages offered by this salt used in this way over tartar emetic and the double oxalate with potassium. These may be divided into two groups, those of a financial and those of a technical or chemical value.

Tartar emetic of ordinary quality costs about 1s. 1d. per lb., and contains 35 per cent. of antimony calculated as metal. Antimony potassium oxalate contains 22 per cent. of antimony as metal, and costs 8½d. per lb., while the chloride solution contains, as already mentioned, 23 to 24 per cent. of antimony, and is sold at 7d. per lb. Calculating these to the basis of tartar emetic, the following relative costs are obtained :—

Tartar emetic (35 per cent. antimony)	13d. per lb.
Oxalate	13½d. "
Chloride	10½d. "

So that regarding only the contents of antimony, the double oxalate is not any cheaper than tartar emetic, while the chloride is only 4.5ths of the cost of either. To the price of the latter, however, must be added that of the sodium or other chloride used in conjunction. Supposing sodium chloride alone to be used (and this salt, from its low price, will probably be mostly used in practice), the addition to the cost will be very small, and should not exceed one penny per lb. If a mixed solution of sodium and magnesium chlorides be used, the cost will of course be more, but will in any case be dependent on the amount of antimony (per gallon of the bath) consumed before the bath is discarded.

Considered technically, it is also probable that the chloride will possess certain advantages over tartar emetic.

One might conjecture, from the facility with which antimonious chloride is basified by water, that its solution in conjunction with any of the before-named chlorides would be in a state of very unstable equilibrium, ready to deposit its antimony on the least inducement. That this is so, a very simple experiment shows. If the sides of a glass vessel, containing some antimonious chloride dissolved in saturated solution of sodium chloride, be scratched with a glass rod, the fine lines thus formed become traced out, in

a short time, by the deposition of basic antimonious chloride. Now, when an abrasion is produced on any surface, a certain amount of energy is expended in overcoming the cohesion of the material composing the surface. This energy assumes the potential state, and resides in the path of the abrasion. When, therefore, such abrasions are placed in suitable conditions, their potential transforms itself—that is, does work which, in the experiment described, consists of the separation of a small quantity of antimonious oxide from its combination with chlorine. A similar solution of tartar emetic in water treated in the same way does not give any deposit. In this case the potential of abrasion is not powerful enough to overcome the mutual attraction of antimony and tartaric acid. The double oxalate behaves similarly to the chloride.

Now cotton fibres exert an attraction for reagents, by virtue of which they decompose weak solutions of certain metallic salts in such a way that the metallic oxide becomes fixed in the pores of the fibre. If we have to choose, then, between two salts of a given metal, we select that which gives least work for the fibre to do, as this means economy in time and possibly in material. Proceeding on this basis, antimonious chloride would be a better salt to use than tartar emetic. This conclusion, in the case of the double oxalate, is said to be verified by practical experience on the large scale, and indeed constitutes its sole advantage over tartar emetic.

In order to test this deduction in the case of the chloride, I have performed several dyeing experiments with the two salts used under like conditions.

Similarly tanned hanks of bleached cotton yarn, of equal size, were immersed for 30 seconds in solutions of tartar emetic and of the chloride respectively. The strengths of the solutions were 0.5, 1 and 1.5 grms. in 200cc. of water and mixed solution of sodium and magnesium chlorides, the temperature during the immersion being 15° C. The percentage of antimony in the tartar emetic was 38.0, and in the chloride 24. The hanks were then dyed up with Victoria green and safranin. From these it is seen that in each case the chloride, although only two-thirds of the strength of the tartar emetic, has given quite as full a colour as the latter, showing that equal amounts of antimonious oxide have been absorbed in each case.

Minor advantages which suggest themselves are contained in the fact that the tannate of antimony is more insoluble in solution of sodium chloride than in water, and will be more completely fixed, in consequence of which the bath will not be so quickly fouled. It is also evident that as the stability of the bath increases during absorption of its antimony, and consequent liberation of acid, by the simple addition of water in regulated quantities, the influence of the acid may be eliminated, and any desired degree of instability again produced. In this way it may be possible to absorb all the antimony from a bath, the acid may then be neutralised by the addition of alkali, and the bath will again be ready for a new addition of antimonious chloride.

I shall now exhibit some samples of cotton yarn, dyed by myself, by means of the process, also for comparison some similar hanks fixed with tartar emetic. All these hanks were tanned in the same way, one half of them being fixed in a solution of tartar emetic, containing 1 grm. in 200cc. of water, the remaining half being fixed in a solution of 1 grm. of the chloride in 200cc. of mixed solution of sodium and magnesium chlorides. They were then all dyed up in the same way. I have also here some strips of calico fixed with the chloride, and kindly prepared for me by the Fereneze Printing Co., Barrhead. These will serve to

give at least an idea of the results obtainable by the process.

It may be of interest to say here a few words regarding the action of hydrochloric acid solution on antimonious sulphide. This reaction, as well as all others in which solids are concerned, is largely influenced by a factor to which not much thought has been given—viz., cohesion. It is obvious that the finer grained the antimonious sulphide is, the shorter will be the time required to convert it into chloride. The production of a state of comminution is accompanied by the transformation of some of the force of cohesion into some other form of energy. This can only be the storage of its equivalent of potential in the solid substance so divided. Hence, when such a divided solid is undergoing chemical change, its potential of comminution reappears in the form of heat, and accelerates the reaction. The element of time—an important factor in all changes—is shortened. The reaction of hydrochloric acid solution and antimonious sulphide, which is usually expressed by the so-called equation $\text{Sb}_2\text{S}_3 + 6\text{HCl} = 2\text{SbCl}_3 + 3\text{H}_2\text{S}$, could only possibly occur if the time allowed were enormous; that is, if the antimony sulphide be in compact masses. If it were possible to reduce a solid to a state of infinite tenuity—that is to say, to a state in which, although possessing many of the properties of a solid, cohesion is non-existent—all reactions, in which it then took part, would at once proceed to a termination, expressible by the usual chemical symbols, using as coefficients the smallest possible integers. This is a condition impossible to realise, and, therefore, all such reactions must stop as soon as the forces concerned are equilibrated.

In manufacturing operations in which antimonious sulphide in a state of moderate fineness, such as is produced by grinding in a pan mill, is heated with hydric chloride solution of sp. gr. 1.160, the point of equilibrium is reached when about one-half of the antimony, indicated in the above expression, has been dissolved. Bearing in mind the alleged existence of an acid chloride having the formula $\text{SbCl}_3 \cdot 3\text{HCl}$, this fact may be possessed of some importance.

In conclusion, it gives me much pleasure to record my indebtedness to the Fereneze Printing Co., Barrhead, for their kindness in preparing the pieces of calico exhibited. I may also be allowed to state that this process, in all its modifications, has been patented.

DISCUSSION.

Prof. MILLS considered the paper as a model of scientific as well as technical investigation. There was plenty of room for a new and cheaper antimony mordant; and Mr. Watson's had obvious advantages over those in common use. He considered the precipitation of oxychloride in a rough glass surface to be probably due to the same cause as the mordanting of cotton goods, and suggested trying the experiment in a beaker wholly roughened inside.

Mr. PATTISON asked how much tannic acid was used with the dyed samples? Because, if tannic acid was present in large quantity, being itself a mordant for aniline colours, the dyed samples would look equally well, independent of the antimony salts, and the relative merits of tartar emetic and antimony chloride would not be so well brought out.

Mr. WATSON, in reply, said he intended to try the experiment as suggested by Professor Mills, later on. Replying to Mr. Pattison, he stated that the amount of sumac used was 8 grms. to 50 grms. cotton yarn. The sumac was boiled with water, and the solution filtered off from the residue. The yarn was treated with filtrates in the usual way.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in the Manufacture of Cement, and in Machinery or Apparatus in connection therewith. R. Stone, London. Eng. Pat. 10,934, Sept. 15, 1885. 8d.

THE improvements specified consist of (1) an improved wash-mill, wherein the chalk or lime and river mud are broken up and incorporated by agitator arms provided with toothed harrows attached thereto by chains, ropes, or rods; (2) a blending-mill, consisting of an upright cylindrical vessel, provided with an agitating shaft fitted with arms; (3) improved forms of crushing-rods, the peripheries of which are serrated and fit into each other.

—C. C. H.

Improvements in Furnaces for Distilling and Refining Mineral Oils. A. Morton and J. Fyfe. Eng. Pat. 13,096, Oct. 30, 1885. 8d.

THIS is an application of the principle of the Siemens regenerative furnace to the furnaces of oil-stills, etc. In addition to the ordinary flue leading to the chimney, other flues and passages are so arranged, by dampers or valves, that any proportion of heated air after passing through the hotter furnaces may be transferred or conducted to the colder furnaces, thus economising fuel and consuming smoke. Drawings are given.—W. L. C.

Improvements in Machinery or Apparatus for Separating Dust from Air. H. H. Lake. From the Knickerbocker Company, Michigan. Eng. Pat. 9423, July 20, 1886. 8d.

THE inventor claims to clear air from dust or small particles with which it may be laden in mills and factories, by leading it with a rotary motion into a vessel of special shape whereby the dust is deposited on the inner walls of such vessel, and the air escapes in a pure state. The proposed vessel is made in shape a plain inverted cone, the apex at the lower end being provided with a small opening. The broad upper end of the cone is closed, excepting a large central opening from which depends a short open cylinder reaching some distance down into the interior. The dust-laden air arrives at the periphery at the upper part of the cone in a tangential direction, and entering at considerable speed is forced to rotate in

close proximity to the sides of the cone, on which the dust and small particles are deposited. These slowly find their way to the discharge opening below, whilst the purified air, after losing its rotary motion, escapes under the edge of the depending central cylinder. In practice, the inventor finds that the fine dust follows the tapering sides of the cone towards the apex, whilst the larger and heavier particles move towards the large end, which peculiarity may be taken advantage of for separating the materials according to size. Scrapers may be fitted inside the cone to facilitate the movement of the dust.

Improvements in Apparatus for obtaining Fresh Water from Salt Water, and for Working, in connection with Motive Power, Heating and Cooking Apparatus on Board Ship. J. Weir. Eng. Pat. 9567, July 24, 1886. 6d.

ALTHOUGH not strictly within the limits of subjects for this Journal, the idea underlying this invention may be considered worth noting for possible application in chemical operations. It relates to improvements on a previous patent No. 11,865 of 1884, by the same patentee, in which he proposes the use of very high-pressure steam for heating and evaporating the water in a separate vessel with the view to the production of fresh steam at lower pressure and for independent application. The invention is intended to be applied primarily to modern steamships where steam at very high pressure is used for driving the main engines, whilst steam of lower pressure is required for the auxiliary engines, for the fresh water and cooking apparatus and for other purposes. In such cases the inventor simply proposes the use of what amounts to a secondary boiler, which, instead of being heated by fire in the ordinary way, is traversed by tubes through which the high-pressure steam circulates, transmitting heat to and raising steam from the water by which they are surrounded.—B.

II.—FUEL, GAS, AND LIGHT.

On Combustion, with Special Reference to Practical Requirements. F. Siemens. Iron and Steel Institute, Oct. 1886.

IN order to ensure perfect combustion: (1.) The gases must be supplied in the exact chemical proportion in which they are required for this purpose; an argument in favour of using gaseous fuel, which admits of perfect control over combustible as well as supporter of combustion. (2.) The gases must be brought together in such a manner that the different molecules which have to enter into combination may readily do so. This end may be attained by mixing the gases before combustion as in a Bunsen's burner, but this is only applicable where small surfaces are to be heated by direct contact with flame (a method highly destructive to the material heated),* large flames of high radiative power being more economical for most purposes. In reverberatory or boiler furnaces fired with solid fuel, no difficulty is experienced in obeying this rule, and the heating will be satisfactory in proportion as the coal used evolves gases yielding a flame of higher radiating power. In regenerative gas furnaces, however, the mixture involves a greater difficulty; if it be too intimate, a short hot flame of low radiative value is produced, whereas if the gases do not properly combine, perfect combustion cannot take place. The usual method of introducing the gases into the regenerative furnace, with the ports for the heavier air placed above those for the lighter producer-gas is satisfactory unless the specific gravities of the two gases approach by reason of the regenerators being applied to the heating of the air alone, a system attended therefore by great disadvantages. (3.) Everything must be avoided which interferes with the motion of the gases while combustion is proceeding. The reason previously assigned† for this interference of solid bodies, which prevent the free development of the flame, must now be supplemented by

" 2s. 4d., ..	2s. 4d.

considerations connected with the dissociation of gases at high temperatures,* as fully explained by the author in a recent lecture at the Royal Institution. Heated surfaces favour the dissociation of gases coming into contact with them; thus the earlier experimenters in this subject who passed the gases through heated tubes filled with roughly broken porous particles, have given too low a temperature for the dissociation limit of each gas examined. When the path of the gases is unobstructed, dissociation commences only at a much higher temperature, and the flame becomes shorter and more brilliant with each rise of temperature, instead of increasing in length, as the older theory of alternate combustions and dissociations would involve: this point may be proved by a study of the regenerative gas burner, where the flame, long at first, becomes, as the regenerators are heated, shorter and whiter, the passage of the gases during combustion being entirely free throughout. Thus, to obtain the maximum value from a fuel, the full radiative action of an unobstructed flame should be first secured, and then the residual heat in the products of combustion should be utilised by contact as thoroughly as possible.—W. G. M.

Improvements in Bunsen and other Atmospheric Gas Burners. T. Fletcher, Warrington. Eng. Pat. 13,433, August 4, 1886. 8d.

A GAUZE CAP with turned-down edges is fitted to the inside of the Bunsen burner. To prevent the cap entering further than is required, there is formed within the burner a shoulder or annular recess, against or within which the turned-down edge may rest.—A. R. D.

Improvements in Regenerative Gas Lamps. T. A. Green and C. M. Walker, London. Eng. Pat. 13,330, August 5, 1886. 8d.

JUST above the flame is situated a "generator" of spheroidal shape communicating with the atmosphere by lateral radial tubes, and opening underneath into another vessel which envelops both burner and generator. In the lower part of this enveloping vessel is placed a reflector of suitable material. Air enters the generator by the radial tubes, and being thus heated passes downwards to the burner. The products of combustion pass upwards on the outside of the generator between the radial tubes, and away by the chimney with which the enveloping vessel is surmounted.—A. R. D.

Improvements in the Manufacture of Compound Fuel. J. G. Penn, Cardiff. Eng. Pat. 13,990, August 16, 1886. 6d.

THE patentee mixes paraffin pitch with small coal and compresses the mixture into blocks. The paraffin pitch is the residue obtained in the distillation of rock oil, crude petroleum, or other such-like material. Fuel so made may be enriched for gas-making or other purposes by the addition of an illuminating oil. The proportions used vary, of course, with the kind of coal; but, generally, they are 7 to 10 per cent. of paraffin pitch, 4 to 8 of oil, and 82 to 89 per cent. of coal. This fuel is inodorous and smokeless, neither does it fall to pieces when stirred upon the bars.—A. R. D.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Occurrence of Acridine. J. Walter. J. Prakt. Chem. 1886, 34, 134.

THE author has isolated acridine from the last portions of the distillate obtained by subjecting crude diphenylamine to distillation. The production of this base is attributed to the synthetical formation of acridine from

orthotolylphenylamine, discovered by Graebe (this Journal, 1884, 474). The purest aniline of commerce contains minute quantities of toluidines, which, during the process of preparing diphenylamine, are resolved into ditolylamines and phenyl-tolylamines, and of which orthophenyltolylamine yields acridine by the elimination of two atoms of hydrogen.—D. B.

Occurrence of Cymene and an Aromatic Hydrocarbon C_9H_{12} in Rosin Spirit. W. Kelbe. Ber. 19, 1969—1970.

IN isolating metaisocymene from rosin spirit by means of the sparingly-soluble barium alpha-meta-isocymenesulphonate, the mother-liquor deposits on standing a crystalline compound from which, after several recrystallisations, barium paracymenesulphonate, $(C_{10}H_{12}SO_3)_2Ba + 2H_2O$, was obtained. The sulphonamide crystallises in large lustrous scales melting at 115.5°. As Jacobsen found the melting-point of paracymenesulphonamide to be 111—112° (Ber. 11, 2049), the author prepared this compound from paracymene and obtained a substance melting at 115.5°. He is therefore of opinion that both sulphonamides are identical, and claims to have established the existence of paracymene in rosin spirit.

On sulphonating the portion of the aromatic hydrocarbons of rosin spirit boiling under 160°, a barium salt was obtained having the composition, $(C_{10}H_{11}SO_3)_2Ba + H_2O$. The sulphonamide crystallises from water in small scales melting at 130°. Owing to the want of material the investigation of this hydrocarbon could not be pursued.—D. B.

On Pyrene. E. Bamberger and M. Philip. Ber. 19, 1995—1999.

IN a previous communication (this Journal, 1886, 449) it was shown that pyrenic acid, $C_{15}H_8O_3$, obtained by the oxidation of pyrene or pyrenequinone with chromic acid mixture, is a dibasic acid the carboxyl groups of which are attached to two carbon atoms directly united to one another, whilst the fifth oxygen atom belongs to the carbonyl group, hence the authors ascribed to pyrenic acid the constitution—

It is now shown that pyrenic acid possesses the character of a ketonic acid, the authors having obtained pyrene ketone, $C_{14}H_6(CO)_2$, by distilling pyrenic acid with lime. This body crystallises from alcohol in satin-like gold-coloured plates, melting at 141°, and is probably formed by depriving pyrenic acid of two molecules of carbonic anhydride. It combines with phenylhydrazine, and dissolves in sodium bisulphite, forming a well-crystallised double salt from which the ketone may be recovered by the addition of an acid. The properties which characterise this body seem to prove that (1) pyrenic acid belongs to the class of ketonic acids, and that (2) its ketone group does not occupy the α -position to the carboxyl group, otherwise the body obtained by the removal of the carbonic anhydride elements should have exhibited the properties of an aldehyde.

By the action of potassium permanganate on pyrenic acid in the cold, a colourless acid is obtained, having the composition, $C_{14}H_6O_5$. The acid is tetrabasic, as proved by the constitution of its silver and barium salts, hence the formula, $C_{14}H_6O_5 = C_{10}H_4(COOH)_4$. The acid is resolved into naphthalene and carbonic anhydride when distilled with lime; it is therefore naphthalene-tetracarboxylic acid.—D. B.

IV.—COLOURING MATTERS AND DYES.

Process for the Production of Mixed Azo-colours. Peter Jensen, London. From the "Actiengesellschaft für Anilinfabrikation," Berlin. Eng. Pat. 15,296, Dec. 12, 1885. 6d.

IN the specification claiming the production of "Congored" and analogous colouring matters (Eng. Pat. 4415,

* Referred to by Siemens: Discussion. Jour. Soc. Chem. Ind., 1885, 621.

1881; this Journal, vol. iv. 278), it is stated that the salt of tetrazodiphenyl must stand for twelve hours before complete combination with the naphthionic acid takes place. This is due to the fact that an intermediate compound of the formula—

is first produced, and this only combines slowly with the second molecule of naphthionic acid. The object of the present patent is to claim mixed azo-colours of the "Congo-red" type formed by the action of these intermediate compounds upon other amines, phenols, or sulphonic acids. All these colours dye cotton in an alkaline bath without the use of a mordant. As examples the patentees describe the preparation of the colours from (1) benzidine, naphthionic acid, and β -naphthylaminesulphonic acid, (2) benzidine, naphthionic acid, and metanaphthylsulphonic acid, (3) benzidine, naphthionic acid, and α -naphthylmonosulphonic acid, and (4) tolidine, naphthionic acid, and β -naphthylaminesulphonic acid. In these examples the order of combination may be reversed—i.e., the tetrazo-salt combined first with the second amine or phenol, etc., and afterwards with the naphthionic acid.—R. M.

Mulhouse Industrial Society. Meeting 14th July, 1886.

(1.) *Schweinfurt Green.* S. Camille Koechlin.—It was observed fifty years ago by Ehrmann, that Schweinfurt green may be prepared by treating Scheele's green (copper arsenite) with acetic acid, copper acetate with arsenious acid, or any copper salt with an alkaline arsenite, and then with acetic acid. The author finds that an equally brilliant green may be prepared by substituting formic for acetic acid. A solution of 100grms. of copper sulphate in 500cc. of water is treated with 187.5cc. of sodium arsenite (500grms. per litre), and the precipitate is digested for an hour, at 40–50°, with 62cc. of acetic acid, of 7–8° B., or with 3lcc. of pure formic acid. In both cases a beautiful brilliant green is obtained. With half the quantity of formic acid a pale blue product is formed; but it is not produced under any circumstances by acetic acid. The author remarks that since the danger attending the employment of arsenic is now almost entirely removed, legislators are no longer justified in altogether prohibiting its use.

(2.) *Removal of Gum from Chocolate Mordants.* Oscar Scheurer.—The author states that he has succeeded in employing phosphorous or hypo-phosphorous acid in combination with a copper salt, in place of an alkaline arsenite, in the removal of gum from chocolate mordants. A number of specimens were printed with a chocolate containing 3 per cent. of metallic iron, fixed by contact with steam at 36–40°, for 12 hours, in the psychrometer, freed from gum with cow's dung and chalk, and dyed with alizarin. The specimens were as follows:—(1) chocolate; (2) the same with addition of 3grms. arsenious acid per kilo.; (3) the same as (1), with the addition of 20grms. phosphorous acid, of 16° B. per kilo.; (4) chocolate, with addition of 4grms. cuprous chloride per kilo.; (5) chocolate, with 3grms. arsenious acid, and 4grms. cuprous chloride per kilo.; (6) chocolate, with 20grms. phosphorous acid and 4grms. cuprous chloride per kilo. The best results were obtained with arsenic and copper combined, and then follow in order of efficiency—phosphorous acid and copper, arsenic alone, phosphorous acid alone, copper alone, and lastly, chocolate alone.

(3.) *Estimation of Antimony-potassium Oxalate.* —Setlicks. Communicated by Nölting.—This reagent has recently been employed for the fixation of tannin. A solution of the salt is treated with standard soda solution, until a slight turbidity is observed; the amount of free oxalic acid is thus indicated. Phenol-phthalein is added, and the soda solution run in until the solution becomes alkaline. The second quantity of soda is equivalent to the antimony oxide. The potassium is estimated by precipitating the antimony in a fresh solution with ammonia, filtering, evaporating to dryness, igniting, and titrating the alkaline carbonate with standard acid. The method is accurate.

(4.) *Derivatives of β -Amido-alizarin.* Prudhomme.—A new dye, which gives a brown-red colour with aluminium mordants, is obtained by the condensation of β -amido-alizarin with phthalic anhydride. The two bodies are simply heated together to 200°, without dehydrating agents; the product is taken up with soda, precipitated by hydrochloric acid, and washed. The colouring matter is yellow, but its alkaline solutions possess a very blue-violet colour, and do not deposit a coloured resin, like those of β -amido-alizarin. By the action of concentrated sulphuric acid, β -amido-alizarin is again formed. The reaction is probably analogous to the condensation of phthalic anhydride with ortho-amidophenols, the substance formed being phthalidyl amido-alizarin—

A similar colouring matter is obtained with acetic anhydride, but in this case the alkaline solutions are red. This body, ethenylamido-

alizarin, $\text{C}_{14}\text{H}_5\text{O}_2(\text{OH})\text{NH} \begin{array}{c} \diagup \text{CH} \diagdown \\ \text{NH} \end{array} \text{CH}_3$, has already been prepared by Römer, but its tinctorial properties have not been described by him.—S. Y.

Azo-Compounds. W. Staedel and H. Bauer. Ber. 19, 1952–1956.

For the easy and rapid production of *diazamidobenzene*, the author recommends the following process:—50 parts of aniline are dissolved in about 1500 parts of water and 15 parts strong sulphuric acid, the whole is cooled with ice to 27° C., and whilst at this temperature 18 parts of commercial sodium nitrite in solution are well mixed with it. In 30 minutes the yellow crystalline precipitate is filtered off, washed and dried at the ordinary temperature. The yield averages 97–98 per cent. of the theoretical quantity. The temperature of the mixture must not fall below 25° nor rise above 35°, otherwise the product will be impure.

To obtain *amido-azobenzene*, the moist precipitate of diazo-amidobenzene is dissolved in two or three times its weight of aniline, with one-tenth of its weight of aniline hydrochloride, and the mixture heated for an hour to below 40°, and left to stand for 24 hours. Sufficient strong hydrochloric acid is then added, and on cooling, almost the theoretical quantity of amido-azobenzene crystallises out. Instead of first preparing the solid diazo-amidobenzene, the following process is recommended:—1mol. aniline hydrochloride is dissolved in 5–6mols. aniline, rather less than 1mol. of sodium nitrite is added, and well mixed at about 30–40° C. In about 12 hours the reaction is complete, and the amido-azobenzene can be obtained as above shown.

m-Nitrophenyl-azo-dimethylamidobenzene—

—10grms. dimethylaniline, 11.3grms. *m*-nitraniline, 4.5grms. sulphuric acid and 600–700cc. water are well shaken together, and being cooled to 27° C., are treated with 7grms. sodium nitrite in solution. In 30 minutes the reaction is ended, and the above compound is filtered off, washed, and dried. It crystallises from alcohol in small beautiful red brilliant plates, melting at 159–160°; it is sparingly soluble in all solvents. Strong reducing agents, such as zinc and acid, convert it into a mixture of *m*-phenylenediamine and *p*-amidodimethylaniline, which, on oxidation, yields a fine blue colouring matter, dyeing cotton and silk almost as well as methylene blue. When, however, the above compound is treated with the proper quantity of ammonium sulphide necessary to reduce the nitro group alone, this group is then not attacked, but the compound itself is split up into *m*-nitraniline and paramidodimethylaniline.

m-Chlorophenyl-azo-dimethylamidobenzene—

was obtained in a similar manner from *m*-chloraniline and

dimethylaniline. It is fairly soluble in alcohol, forming fine yellow leaflets melting at 98° C.

m-Nitrophenyl-azo-*m*-chlorodimethylanilindibenzene—

from *m*-nitraniline and *m*-chlorodimethylaniline. It crystallises from alcohol in small reddish-yellow plates, melting at 155–156° C.—T. L. B.

On the Influence on the Shade of Colouring Matters, caused by the Substitution of Elements and Radicals in their Molecules. Part I. K. Heumann and Th. Heidelberg. Ber. 19, 1989–1993.

IN many classes of colouring matters certain regularities are noticeable between their composition or constitution and the colour they dye. The authors consider the number of observations in this direction insufficient to formulate a general law, and in order to forego this, have studied the changes caused by the substitution of various elements and radicals in some of the more important coal-tar colours.

I.—The introduction of chlorine into the molecule of pararosaniline.—This can be done either by direct chlorination of the rosaniline, or by using chlorinated materials for the production of the rosaniline. The latter method was chosen, as it allowed the production of bodies of predetermined constitution. Thus a mixture of paratoluidine and chlorinated aniline would yield on oxidation a dichloropararosaniline, whilst chlorinated paratoluidine and aniline would form a monochloropararosaniline. Since, in order to form a rosaniline, the para position to the amido group must be readily available for the introduction of the methane carbon, those amines in which the para position is taken up by chlorine, should form no rosaniline at all, or only with difficulty. With this in view, mixtures of paratoluidine and ortho-, meta-, and para-chloraniline were oxidised by arsenic acid.

Dichloropararosaniline—

—20.9 grms. paratoluidine, 50 grms. orthochloraniline and 106 grms. 75 per cent. arsenic acid solution, were heated to about 190° C. until a sample showed no further change in shade. The melt was extracted with boiling water, the colouring matter thrown down with salt, filtered off, and redissolved in water, and from this solution the base precipitated with ammonia. After extraction with ether, the base was transformed into the hydrochloride, and this crystallised from alcohol. Dichloropararosaniline forms red flakes, soluble in alcohol, insoluble in water. With acids it forms beautiful bluish-red monacid salts; the acid salts are brown-yellow. The solution of the hydrochloride is decomposed on boiling, the base being partially precipitated. It dyes silk a blue-red shade, ordinary pararosaniline dyeing a yellowish shade. Its absorption spectrum, like that of rosaniline, shows a dark line between D and E, but rather nearer to D. Reducing agents form a leuco-base, forming a red, crystalline mass from alcohol. On heating with arsenic acid at 190°, 1 mol. paratoluidine and 2 mols. meta-chloraniline, or 1 mol. paratoluidine and 2 mols. parachloraniline, in either case no rosaniline was formed, the bulk of the meta- or otherwise parachloraniline remaining unaltered.

II.—The introduction of chlorine into the molecule of rosaniline-blue. *Trichlorotriphenylrosaniline*—

—Obtained by heating 10 grms. rosaniline, 100 grms. orthochloraniline, and 1.2 grms. benzoic acid together. It forms a red base, insoluble in water, which dissolves with a red colour in alcohol, the ether and benzene solutions being yellowish-brown. The hydrochloride is precipitated from alcohol as a dark blue powder, and dyes silk a blue violet, corresponding to methyl-violet 3B. With meta-chloraniline, a body was obtained similar to the above, but which dyes silk a much bluer shade, about 6B violet, whilst that obtained from para-chloraniline dyes a shade intermediate between these two.—T. L. B.

Action of Concentrated Hydrochloric Acid on Nitrosodimethylaniline. R. Möhlau. Ber. 19, 2010.

IF one part nitrosodimethylaniline hydrochloride be heated with 5 parts of conc. HCl gradually to 100–105°, the dark yellow solution changes to reddish-yellow, and after about a quarter of an hour the reaction is complete. On standing, colourless crystals separate out. This compound, when purified, has the composition and properties of dichloroparaphenylenediamine—(m.p. 164°). Bleaching-powder solution converts it into dichloroquinonedichlorodiamide. On adding conc. NaOH to the filtrate from the first reaction, a dark, heavy oil separates out, which can be fractionated without decomposition in *vacuo*, and has the composition and properties of dimethylphenylenediamine. This body, on oxidation, gives a corresponding quinone, and may be converted by the usual method into iodide of methylene-blue. That portion of the oil boiling above 258° gives, on oxidation, dichloroquinone. Treated with H₂S and then oxidised with Fe₂Cl₆, it yields the iodide of dichloromethylene-blue. It is therefore dimethyldiparachloroparaphenylenediamine. The action of hydrochloric acid upon nitrosodimethylaniline is one both of reduction and chlorination, according to the following equation:—
 $(\text{CH}_3)_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{NO} + 4\text{HCl} = (\text{CH}_3)_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{NH}_2 + \text{H}_2\text{O} + 4\text{Cl} = (\text{CH}_3)_2\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{Cl}_2\cdot\text{NH}_2 + \text{H}_2\text{O} + 2\text{HCl}.$

—J. B. C.

The Dyeing Properties of the Benzidine Azo-Colours. Richard Möhlau. Ber. 19, 2014–2015.

UNTIL about two years ago, the only two known colouring matters which dyed cotton direct fast shades without mordants were turmeric and safflower. Since then, however, several red, yellow, and blue dyes have been introduced into the market under the names of Congo-red, benzopurpurin, chrysamin and benzo-azurine, all of which dye cotton without mordants. These colours are produced by the action of diazotised benzidine or toluidine, on naphthionic acid, α -naphtholsulphonic acid, β -naphthylamine sulphonic acid and salicylic acid; also on amido- and hydroxyl-derivatives of naphthalene sulphonic acid, and of *o*-oxybenzoic acid.

As bleached or oxidised cotton absorbs the dyes much better than the unbleached fibre, a certain amount of probability was given to the idea that oxycellulose was the cause of this behaviour, by forming insoluble, salt-like combinations with the amido and hydroxyl groups of these bodies. But, were this the case, it should hold good in the case of other colours of like constitution; but it does not do so.

The author is of opinion that the real cause of the affinity of the benzidine colours for cotton is the presence, in their molecule, of the paradiamidodiphenyl group, as bleached cotton can easily be mordanted with benzidine itself. If bleached cotton be boiled in an unsaturated aqueous solution of benzidine hydrochloride, then left to soak twenty-four hours, wrung out, dried at the ordinary temperature, and washed with hot and cold water, it will have become mordanted with benzidine. On cotton prepared in this way, the various benzidine colours may be developed by diazotising in an acidified solution of sodium nitrite, and subsequent warming or boiling in an alkaline solution of naphthionic or salicylic acid, etc.

—T. L. B.

Dinitronaphthylamine. O. N. Witt. Ber. 19, 2032.

IN order to prepare dinitronaphthylamine, the author acts upon dinitronaphthol, obtained from Martins yellow, with alcoholic ammonia in sealed tubes. The action begins at about 170°, and is complete after six to seven hours at 190–200°. The yellow crystalline contents are filtered and washed free from dinitronaphthol salts with boiling water. The substance has a melting-point of 239°. On nitrating acetnaphthalide, an acetyl compound (m.p. 247°) is obtained, from which the free base is separated by heating with alcoholic ammonia to 160°. After recrystallising from glacial acetic acid, it has a melting-point of 238–239°. This naphthylamine derivative appears, therefore, to be identical with that

obtained from dinitronaphthol. With aqueous potash the acetaido-group is replaced by hydroxyl and dinitronaphthol reproduced. On heating dinitronaphthylamine with alcoholic ammonia above 200°, it is converted into a yellow substance, which is soluble in aqueous ammonia, and behaves like a nitro-anidonnaphthol.—J. B. C.

Further Communications on Colouring Matters from Furfuraldehyde. Hugo Schiell. Ber. 19, 2153–2155.

In a previous paper (this Journal, 1886, 377), the author has shown that in the reaction between furfuraldehyde and aniline bases the aldehyde group only is attacked,

whilst the "Furan group" $\begin{pmatrix} \text{C}-\text{C} \\ | \quad | \\ \text{C}-\text{C} \quad \text{O} \end{pmatrix}$ remains intact.

The marked basic character of the compounds produced in the reaction, and the fact that in the numerous ways in which they can be decomposed no aniline base or furfuraldehyde is reformed, all point to the view that these colouring matters have a similar constitution to rosaniline, and are therefore derived from a *Furandiamidodiphenylmethane*, $\text{C}_6\text{H}_5\text{O}.\text{CH}(\text{C}_6\text{H}_4.\text{NH}_2)_2$.

Furfuralcohol, $\text{C}_4\text{H}_5\text{O}.\text{CH}_2\text{OH}$, is best prepared by the action of aqueous potash on furfuraldehyde—10cc. of the aldehyde to 5grms. KOH and 10cc. water. The crystals of potassium pyromucate are dissolved in the smallest quantity of water, the solution saturated with CO_2 and the furfuralcohol extracted with ether. This alcohol gives no colour reaction with amido-benzoic acid, β -naphthylamine, or sulphite of leucaniline. With a tolerably dilute solution of furfuralcohol, aniline gives rise to a yellow flocculent compound according to the equation $\text{C}_{11}\text{H}_{11}\text{NO} = \text{C}_6\text{H}_5\text{O}_2 + \text{C}_6\text{H}_7\text{N} - \text{H}_2\text{O}$. With such a solution, however, aniline hydrochloride forms a deep red solution, from which red-green crystals are deposited. These crystals have the composition $\text{C}_{11}\text{H}_{11}\text{NO}.\text{C}_6\text{H}_7\text{N}.\text{HCl}$, and contain one molecule of water less than the normal furfuraniline hydrochloride.

When phosphorus pentachloride (10grms.) is gradually added to ice-cold furfuraldehyde (3.9grms.) no violent reaction takes place. A dark-green solution is obtained, from which, however, it is impossible to separate the furfuraldichloride, $\text{C}_4\text{H}_3\text{O}.\text{CHCl}_2$.—T. L. B.

Bromo- and Nitro-derivatives of Azo Bodies obtained by Direct Substitution. J. V. Jamovsky and L. Erb. Ber. 19, 2155–2158.

By the action of bromine (1mol.) upon a warm acetic acid solution of azo-benzene (1mol.) a mixture of *o*-, *m*-, and *p*-monobromazo-benzenes, $\text{C}_6\text{H}_5\text{N}_2.\text{C}_6\text{H}_4\text{Br}$, is obtained, which are separated by their different solubilities in alcohol. By complete reduction they give aniline and *o*-, *m*-, or *p*-bromaniline.

o-Bromazobenzene crystallises from alcohol in glistening golden plates of melting-point 187° corr.; sparingly soluble in cold alcohol.

m-Bromazobenzene forms large orange-yellow plates; easily soluble in alcohol, and melts at 53–55°.

p-Bromazobenzene crystallises from alcohol, acetone, or ether in flat, brilliant, golden-yellow needles, melting at 85°. The corresponding hydrazo-compound forms glistening white needles.

By nitration of azobenzene in acetic acid solution, *o*-nitrozobenzene, $\text{C}_6\text{H}_5\text{N}_2.\text{C}_6\text{H}_4(\text{NO}_2)[1:2]$, is obtained. This compound is more soluble in alcohol, ether, and acetone than the para-compound, and melts at 130° corr. In common with other nitro-azo bodies, it gives a colour reaction (due to the formation of a nitrole) when partially reduced with ammonium sulphide in alkaline alcoholic solution. When its alcoholic solution, after addition of aqueous NaOH is treated hot with ammonium-sulphide, a green colouration is produced, whereas the para-compound under the same circumstances yields a blue. Another reaction for nitro-azo bodies consists in the formation of a violet or reddish-brown colouration when their solution in acetone is treated with a few drops of alcoholic KOH.—A. G. C.

On Safranin and Methylene Blue. M. Andresen. Ber. 19, 2212–2217.

WHEN paradiamines are oxidised in the presence of aromatic monamines, blue oxidation products are formed, having, according to Nietzki (Ber. 16, 464), the following composition: $\text{ClR}_2\text{N}(\text{C}_6\text{H}_4)_2\text{N}.\text{C}_6\text{H}_4\text{NR}_2$,

where R equals hydrogen or an alkyl group. These compounds, when further oxidised in the presence of primary aromatic amines, yield members of the safranin class, very probably according to the equation: $\text{ClR}_2\text{N}(\text{C}_6\text{H}_4)_2\text{N}.\text{C}_6\text{H}_4\text{NR}_2 + \text{C}_6\text{H}_5\text{NH}_2 + \text{O}_2 = \text{C}_{18}\text{H}_{15}\text{N}_4\text{Cl} + 2\text{H}_2\text{O}$. In what way the second monamine combines with the intermediate blue product has not since then been elucidated. As a result of comparative studies of safranin and methylene blue, the author considers these two bodies to be intimately connected, and that since on oxidation in the presence of sulphuretted hydrogen Bindschedler's green is converted into methylene blue:

—so the same green on oxidation with a primary amine yields a tetramethylsafranin:

Safranin and methylene blue are alike in the following characteristics:—1. Both dissolve with a green colour in concentrated sulphuric acid, and the original colour returns on diluting the solution with water. 2. Both behave in the same way with alkalis, showing the equally stable combination of the chlorine molecule in each. 3. Both dye colours on wool which do not stand light, but are fast on cotton. 4. Both present great difficulty to the introduction of a sulphonic group. 5. Both require two molecules of hydrogen to reduce them to their leuco-compounds, which then most easily oxidise to the original body.

From the following facts the author considers this (*phenosafranin*) formula to be the correct one:

1. Given the right conditions of oxidation, almost theoretical yields are obtained from one molecule of paraphenylenediamine, one molecule of orthotoluidine, and one molecule of paratoluidine, which is added after the oxidation of the first two. The yield of colour is less, if aniline replaces the two monamines. 2. Besides the diamine two monamines are necessary. 3. The second monamine must be a primary one. 4. The combination with the second monamine takes place with the removal of four atoms of hydrogen. 5. Aniline, ortho- and paratoluidine and the xylylides, can be used as second amines, but para-toluidine gives the highest yield. As substitution in the nucleus of the second monamine does not interfere with the reaction, it shows the nucleus is not attacked. 6. The paradiamine may contain one dialkylised amido group, and the first monamine can also be dialkylised. 7. Tetramethylsafranin cannot be diazotised. 8. The two dimethylsafranins contain each one diazotisable amido group. 9. Phenosafranin only combines with one molecule naphthol after diazotation. 10. Diethylsafranin only forms a monacetyl compound, phenosafranin forming, however, a diacetylsafranin, from

which caustic alkali removes now the atom of chlorine with ease, setting free the base:

11. The second monamine in the safranines seems to enter into the ortho-position relatively to the nitrogen uniting the nuclei. The blue colours—toluylene blue—obtained by O. N. Witt, by oxidation of paradiamines with metadiamines, give rise on oxidation to a safranine. But as these blue compounds are only readily formed when the metadiamine has a para-position to one of the amido-groups free, one may assume the constitution of, for example, the leuco-compound of the blue obtained from dimethylparaphenylenediamine and metaphenylenediamine, to be: $(\text{CH}_3)_2\text{NC}_6\text{H}_4(\text{NH})\text{C}_6\text{H}_3(\text{NH}_2)_2$, $[\text{N}(\text{CH}_3)_2 : \text{NH} : \text{NH} : \text{NH}_2 : \text{NH}_2 = 5:2 \text{ and } 6:5:3]$; that is, that one amido group of the metadiamine occupies the ortho-position to the nitrogen uniting the nuclei, and that on oxidation to the safranine corresponding to it, this amine group enters into the corresponding ortho-position in the other nucleus. So that the constitution of the leuco-compound of Witt's toluylene-red would be expressed thus: $(\text{CH}_3)_2\text{NC}_6\text{H}_4 : (\text{NH})_2 : \text{C}_6\text{H}_3(\text{CH}_3)\text{NH}_2$, $[\text{N}(\text{CH}_3)_2 : \text{NH} : \text{NH} : \text{NH} : \text{NH}_2 : \text{CH}_3 = 5:2:3 \text{ and } 6:5:3:2]$. —T. L. B.

Synthesis of β -oreinol (p-Xyloreinol). H. v. Kostanecki. Ber. 19, 2318—2324.

THE " β -orein," isolated by Stenhouse and Groves from a few species of lichen, has never been obtained synthetically, nor its constitution determined. The author, in preparing the *m*-dioxy-*p*-xylene (*p*-xyloreinol), $\text{C}_6\text{H}_2(\text{CH}_3)_2(\text{OH})_2[1:4:3:5]$, finds that it is identical with β -orein. The method employed consisted in preparing the *m*-dinitro-*p*-xylene $\text{C}_6\text{H}_2(\text{CH}_3)_2(\text{NO}_2)_2[1:4:3:5]$ by nitration of *p*-xylene, reduction of this with alcoholic ammonium sulphide to *m*-nitro-*p*-xylylidine $\text{C}_6\text{H}_2(\text{CH}_3)_2(\text{NO}_2)\text{NH}_2[1:4:3:5]$, conversion into *m*-nitro-*p*-xylenol $\text{C}_6\text{H}_2(\text{CH}_3)_2(\text{NO}_2)(\text{OH})[1:4:3:5]$ by boiling the diazo-compound with water, reducing this with tin and HCl, and finally diazotising the *m*-amido-*p*-xylenol $\text{C}_6\text{H}_2(\text{CH}_3)_2(\text{NH}_2)(\text{OH})[1:4:3:5]$, and boiling the diazo-compound with water. The *m*-dinitro-*p*-xylene (m.p. 124°), *m*-nitro-*p*-xylylidine (m.p. 96°), and *m*-nitro-*p*-xylenol (m.p. 91°) have been previously described. *p*-Xyloreinol (β -orein) $\text{C}_6\text{H}_2(\text{CH}_3)_2(\text{OH})_2[1:4:3:5]$ has all the properties given by Stenhouse and Groves, with the one exception that it gives a green fluorescence when heated with chloroform and dilute NaOH, which, according to these authors, β -orein does not. It crystallises from water in well-formed prisms melting at 163°, and reddens in air containing NH_3 much more quickly than oreinol. By treatment with bromine in CS_2 solution it yields a *tetra*-bromo-*p*-xyloreinol $\text{C}_6\text{H}_2\text{Br}_4\text{O}_2$, and crystallises from petroleum ether in large tables of melting-point 101°. An aqueous solution of nitrosyl sulphate converts it into *nitroso-p*-xylorein $\text{C}_6\text{H}_2(\text{CH}_3)_2(\text{NO})(\text{OH})_2$, the properties of which are identical with the nitroso- β -orein. —A. G. G.

Creosol-carboxylic Acid. H. Wende. Ber. 19, 2324—2327.

CREOSOL cannot be converted into its carboxylic acid by boiling with aqueous NaHCO_3 , but the author has prepared this acid by the action of CO_2 on the sodium compound. Four grams of sodium were gradually added to 50 grms. of crude creosols (fraction of beechwood creosote 219—224°), whilst a dry stream of CO_2 was passed in and the fluid gently heated. A vigorous reaction set in and the mixture became thick; the cooled product was acidified with dilute HCl and the oily layer treated with aqueous Na_2CO_3 to separate the carboxylic acid from unconverted creosol. The acid was precipitated from the soda solution by adding HCl. *Creosol-carboxylic acid* $\text{C}_6\text{H}_2\text{CH}_3(\text{OCH}_3)(\text{OH})\text{CO}_2\text{H}[1:3:4:5]$ crystallises in concentric needles melting at 180—182°; it is readily soluble in alcohol and ether,

sparingly in water, nearly insoluble in benzene. It sublimes undecomposed. With Fe_2Cl_6 it gives a deep blue colouration. The potassium salt forms readily soluble needles; the barium, lead, and copper salts are sparingly soluble. The *methyl ether* $\text{C}_6\text{H}_2\text{CH}_3(\text{OCH}_3)(\text{OH})\text{CO}_2\text{CH}_3$ forms small colourless trimetric crystals melting at 92°; it gives a bluish-green colouration with Fe_2Cl_6 . The *ethyl ether* $\text{C}_6\text{H}_2\text{CH}_3(\text{OCH}_3)(\text{OH})\text{CO}_2\text{C}_2\text{H}_5$ forms small needles or prisms melting at 77°. —A. G. G.

On the Methylanthragallols. Ernst L. Cahn. Ber. 19, 2333—2336.

THERE are theoretically four methylanthragallols which can be formed by condensation of the three toluic acids with gallic acid. All four bodies resemble each other, and also anthragallol, very much; they are all readily soluble in alcohol, dissolve in hot ammonia with a blue, in strong alkalis with a green, and in dilute with a violet colour. Concentrated sulphuric acid dissolves them, forming a red solution, to which a drop of nitric acid gives a green colouration. This acid solution shows almost the same absorption bands as does that of anthragallol. They also give the same shades of colour with mordants as are obtained with anthragallol.

1-Methylanthragallol—

is obtained by heating for 12—15 hours 3 parts of ortho-toluic acid and 2 parts of gallic acid at a temperature of 130—135°. The best yield obtained was about 30 per cent. of the theoretical amount. It sublimes in orange-red needles melting at 297—298° with decomposition, and is soluble in hot water and acetic acid, insoluble in baryta-water.

Triacetyl-1-methylanthragallol—

crystallises from acetic acid in sulphur-yellow tablets, melting at 208—210°. On distilling with zinc dust a hydrocarbon is obtained, melting at 197°, which on oxidation yields a quinone, melting at 278—279°.

3-Methylanthragallol [$\text{CH}_3 = 3'$] was obtained in a similar manner from para-toluic acid and gallic acid. It sublimes in small orange-red needles, melting at 275°. Its triacetyl compound forms nice yellow prisms from glacial acetic acid solution; it melts at 203—208°.

2- and 4-Methylanthragallols [$\text{CH}_3 = 2'$, and $\text{CH}_3 = 4'$]. — These two compounds are formed when meta-toluic acid is condensed with gallic acid. They are very difficult to separate from each other, the best way being repeated fractional crystallisation from alcohol of their acetyl compound. The one of these two bodies melts at 312—313°, and its acetyl derivative crystallises in needles melting at 188—190°. The other melts at 235—240°, and its acetyl compound forms small well-shaped prisms melting at 217—218°. —T. L. B.

The Action of Aniline on Oreinol. Zega and Buch. Journ. Prakt. Chem. 33, 1886, 547—548.

By the action of aniline and calcium chloride upon oreinol at 260—270°, phenyl-*m*-oxytolylamine is formed; with a mixture of zinc chloride and calcium chloride, the chief product is diphenyl-*m*-toluylenediamine, together with a small quantity of oxyamine; above 220° a quantity of a dark resinous product is formed. These compounds may be expressed by the following formulae:—

The yield of pure phenyl-*m*-oxytolylamine is about 50 per cent. of the theory; that of diphenyl-*m*-toluylenediamine, 30 per cent.

*Phenyl-*m*-oxytolylamine* crystallises from a mixture of benzene and petroleum ether in needles. Melting-point 79°. It dissolves in a small quantity of boiling water, readily in alcohol, ether, glacial acetic acid and benzene;

also in dilute potash and soda solution. The hydrochloride forms a white crystalline, easily decomposable powder. On heating with zinc dust the oxyamine is reduced to phenyl-*m*-tolylamine.

Diphenyl-m-tolylendiamine crystallises in indistinct needles, melting at 165° . It is soluble with difficulty in alcohol, ether, benzene, etc., in the cold; easily soluble on heating. The following compounds have been prepared:—Diacetyl compound— $C_{13}H_{16}(C_2H_3O)_2N_2$, m.p. = 160° ; dibenzoyl compound— $C_{13}H_{16}(C_7H_5O)_2N_2$, m.p. = 190° ; dinitroso compound— $C_{13}H_{16}(NO)_2N_2$, m.p. 170° ; dimethyl compound— $C_{13}H_{18}(CH_3)_2N_2$, m.p. = 124° . On adding a nitrite to a solution of the diamine in concentrated sulphuric acid the latter is coloured violet, and afterwards violet blue; with nitric acid or a nitrate it turns directly violet blue. The lemon-yellow nitroso compound gives a dark violet in contact with concentrated H_2SO_4 .—J. B. C.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

Absorption of Dye-stuffs by Living Cells. W. Pfeffer. Chem. Zeit. 10, 1259.

It has previously been supposed that dye-stuffs do not penetrate into living cells; the author, however, shows that aniline dyes, such as methyl violet, methylene blue, rosaniline, etc., can be fixed upon living cells, while others, such as aniline blue or nigrosin, are not effective. The dye-stuff must be used in very dilute solution, 1 in 1000, for example. In many plants, tannic acid, and in others, substances of unknown composition, serve to retain the dye. Thus, either a precipitate is produced, or the dye remains dissolved in the cell contents. Methylene blue passes by exosmosis through the protoplasm of the cells without colouring it, while methyl violet, cyanine, etc., impart a more or less decided tinge. The dye-stuff can be removed by very dilute citric acid, which decomposes the tannate, and then the citrate formed is removed by exosmosis.

—V. H. V.

Improvements in the Production of Azo Colours on Cotton or other Vegetable Fibre. T. Holliday, London. Eng. Pat. 13,790, Nov. 12, 1885. 6d.

THE inventor has found that oxide of lead or the compounds formed by oxide of lead and oily bodies, which compounds he calls "lead soaps," when fixed on cotton or other vegetable fibre will take up alpha- or beta-naphthols from mixtures of those naphthols with, or their solutions in, water, and his method has for its object the utilisation of this action for the purpose of fixing azo colours on cotton or other vegetable fibres, either in a raw state, spun, woven, or otherwise manufactured. For this purpose he employs a weak solution of oxide of lead in caustic alkali, and "lead soap" is formed by passing the cotton through a weak solution of soluble soap or oily emulsion, either before or after passing it through the solution of oxide of lead. The cotton is then ready for the formation of such azo colours as are formed by any suitable process. Other methods of fixing oxide of lead may be used, such as passing the fibre through a solution of a lead salt, then through caustic soda solution, which fixes the lead oxide, and then through a solution of soap, when lead soap will be fixed.

—J. H.

Improvements in the Construction of Apparatus for Scouring, Washing, and other Analogous Purposes. R. H. Ainsworth and S. B. Manby, London. Eng. Pat. 14,031, Nov. 17, 1885. 8d.

THIS relates to a method for scouring, washing, dunging, dyeing and similarly treating cloth or woven fabrics by the combined agency of liquor and steam, water and steam, or dye liquor and steam.

The apparatus consists of two tanks, one inside the other, the inner one being inverted and fixed to the outer casing in such a way as to leave cavities at each end for the passage of cloth into and from the same. Internally the tank is fitted with top and bottom friction rollers, the bottom ones being immersed in liquor or water, the upper ones being in the space allotted to steam.

When steam is admitted into the apparatus, the liquor or water from the bottom end rises in separate columns up the cavities at each end, sufficiently to balance the pressure of steam employed, which causes the liquid in the internal part of the tank to fall to a lower level than when admitted, and ensures scouring, washing, or otherwise by the combined action of liquor, or water and steam alternately. The novelty of this invention is that cloth is passed through liquor, water, or dye liquor into steam, in which it is operated upon by the squeezer rollers. Thus the cloth is subjected to the action of steam whilst scouring, washing, dyeing, dunging and during the other operations. After this it is redipped or drawn through the liquor or water, and the steaming and squeezing operation repeated alternately or otherwise until the end of the tank is reached, when the cloth is passed through the liquid in the outer cavity, from whence it is passed through another pair of squeezer rollers to remove the surplus liquid, and return it to the tank by the outlet cavity.—J. H.

Improvements in or applicable to Machinery for Scouring and Washing Wool and other Fibrous Materials. J. McNaught and W. McNaught. Eng. Pat. 14,168, Nov. 19, 1885. 8d.

THIS invention relates to the mechanism for squeezing the moisture from wool or fibrous material, fed to the machine from a washing trough.

In the ordinary machine great expense is caused by the repeated renewal of the fibrous material with which the upper roller is covered, the wear and tear arising to a great extent from the frictional action of the lower or driving roller upon it, the bearings of the covered roller having in the ordinary arrangement to be of large diameter to resist the heavy strain put upon the journals by the weighting arrangement. The improvement consists of a combination of anti-friction bowls with weighted levers in such a way that the levers do not act directly upon the axle bearings of the upper roller, but upon the axles of the anti-friction bowls, which bowls press upon and revolve with the axle of the upper roller and rise and fall with it. The anti-friction bowls are carried by a shaft or axle, having bearings upon which the weighted levers press. The weighted levers have their fulcrums in the framing, as in the ordinary arrangement of levers and rods hitherto used for weighting fibrous-covered rollers directly. The axle of the upper roller is or may be guided and held laterally in place by vertical guides in the framing, or anti-friction bowls may be arranged at the sides of the axle to take the lateral pressure and hold it in position.

With this arrangement the friction is considerably reduced, and there is less slipping tendency between the squeezing rollers, and consequently less wear and tear upon the fibrous-covered roller.

A further improvement consists of an arrangement for heating the scouring or washing liquor, and applies to a machine where the water squeezed from the wool is collected and returned by a pipe to a trough from which it is elevated by buckets of a revolving wheel back to the washing trough. Steam is admitted into the pipe or cavity connected with the pipe bringing the liquor from the squeezing rollers to the trough for the elevator, by which arrangement the liquor is heated as it passes along the pipe.—J. H.

Improvements in Detergents and Dyes. C. P. Andersen, Denmark. Eng. Pat. 8528, June 29, 1886. 4d.

HEMATEIN is prepared by mixing hematoxylin, derived from logwood, with ammonia, and oxygenating the

mixture in air. This is used as a detergent and dye, with or without soap, and with or without a decoction of "quialaire" bark.—W. L. C.

VII.—ACIDS, ALKALIS, AND SALTS.

A New Process for the Production of the Alkali Metals.
H. Y. Castner, New York. Abstract from a Paper read before the Chemical Section of the Franklin Institute, October 12, 1886.

THE process consists in reducing either the hydrate or the carbonate of an alkali, when in a fused state, by the "carbide" of a metal. By the latter is meant an intimate mixture of carbon and iron, produced by coking a mixture of tar and iron in a fine state of division. Such proportions of tar and iron are used as will produce, when the mass is coked, a metallic coke, containing 70 per cent. of iron and 30 per cent. of carbon— FeC_2 . This compound, after being ground, is ready for use in the process, based upon the reaction which is expressed by the following formula:— $3\text{NaOH} + \text{FeC}_2 = 3\text{Na} + \text{Fe} + \text{CO} + \text{CO}_2 + 3\text{H}$. The reduction of the mixture of "carbide" and alkaline hydrate is carried on in large cast-iron crucibles, in a furnace, the heating space of which is divided into separate chambers. An aperture is provided at the bottom of each chamber, through which the crucible may be raised by mechanical means into its position in the furnace. The necessary cover for the crucible is fixed stationary in each chamber, and from this cover projects a tube to the outside of the furnace, into the receptacle for the condensation of the metallic vapours. The edges of the covers are made convex, while the edges of the crucibles are concave, so that the edges form a tight joint when the crucibles are pressed upwards. The furnace is heated by gas, and the reduction and distillation of the sodium commences at 1000°C . As soon as the operation is finished, the crucible is lowered, and a new one containing a fresh charge raised in its place, thus making the process practically continuous. The crucibles after treatment contain a small amount of sodium carbonate, and all the iron of the "carbide" in a fine state of division. The residue is, therefore, treated with warm water, to recover the sodium carbonate, while the iron is dried, mixed with tar, and coked to produce more of the "carbide".—S. H.

Specific Gravities of Different Salts and Solutions. G. Gerlach. Chem. Ind. 9, 241—245.

THE specific gravities of the salts were determined by comparing their weight in the air with that of an equal volume of petroleum, the sp. gr. of the latter being 0.8024 at 19.5°C , water of 19.5°C . being 1; and 0.8015 at 19.5°C , water of 4°C . being 1.

Conditions necessary for the Complete Elimination of Arsenic from Hydrochloric Acid by means of Sulphuretted Hydrogen. R. Otto. Ber. 19, 1903—1910.

FROM a series of experiments on the presence of minute quantities of arsenic in hydrochloric acid, the author infers that even the pure acid of commerce, denoted as free from arsenic, contains traces of this element, and should therefore not be employed in forensic examina-

tions for metallic poisons. It was found that on treating "pure" hydrochloric acid with sulphuretted hydrogen it was not possible to remove the last traces of arsenic; if, however, the acid is first mixed with a small quantity of ferric chloride, potassium dichromate, mercuric chloride, cadmium sulphate, copper sulphate, sulphurous acid, or even arsenious acid, the whole of the arsenic can be removed by means of sulphuretted hydrogen. The author has found that commercial hydrochloric acid (crude) can be readily freed from arsenic by the following method: After diluting the acid with water to a specific gravity of 1.12, the solution is saturated with sulphuretted hydrogen. It is then allowed to remain quiescent in a closed vessel for 24 hours at 39–40°, after which it is again treated with sulphuretted hydrogen, and the operation repeated until the acid assumes a permanent odour of sulphuretted hydrogen. The solution is allowed to settle, decanted, filtered, and distilled until one-tenth remains in the retort. It is best to reject the first portions of the distillate containing the sulphuretted hydrogen.—D. B.

Improvements in the Manufacture of Sulphide of Zinc. J. B. Spence, London. Eng. Pat. 13,462, Nov. 6, 1885. 4d.

AN iron vessel is filled with a strong solution of a caustic alkali, and metallic zinc, in the form of plates, suspended in this solution. The zinc is then brought into metallic contact with the iron of the vessel in any convenient manner; this produces galvanic action, and causes the rapid dissolution of the zinc. Sodium or potassium sulphide is added to the solution, and the precipitate of zinc sulphide thus obtained allowed to settle. The supernatant liquor, consisting of either sodium or potassium hydrate, is decanted and used over again for dissolving another lot of zinc.—S. H.

Improved Apparatus for the Manufacture of Chlorine Gas. H. H. Lake, London. From Count R. de Montgas, Philadelphia, U.S.A. Eng. Pat. 10,009. August 4, 1886. 6d.

THE patent relates to an apparatus for making chlorine on a small scale. It consists of an earthenware pot, the cover of which may be clamped down, and which is provided with a perforated tray. The pipe for the acid supply passes to the space below the tray, while another pipe issuing from the top carries away the gas generated. There is also an arrangement for running off the liquid contents of the vessel.—S. H.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

The Hydraulic Properties of Cements. E. Michel. Jour. Prakt. Chem. 1886, 33, 548–558.

THE author has made a series of tests with a view of determining the proportions of silica to lime and of silica to alumina required to produce the most effective hardening properties in hydraulic cements. He found that when gelatinous silica, previously dried at 110°, was mixed with very finely-powdered calcium hydrate, moistened with the smallest quantity of water, the proportions being 1mol. silica to 1½mols. calcium hydrate, a cement was produced which in a fortnight could not be scratched with the finger-nail. A mixture of gelatinous silica, pure sand, and lime also gave satisfactory results. The author confirms Fuch's theory—viz., that the silicic acid is essential to the hardening process. The latter is also dependent upon the addition of lime, on the density and thorough mixing of the materials, and upon the amount of water in the mixture.

Alumina forms a cement with lime only when dried at 110° before mixing, negative results being obtained with strongly-heated or gelatinous alumina. The method of Frühling was found to give good results. This consists in well incorporating the respective substances in a mortar, enclosing them in a wrapper of filter-paper, and then allowing the whole to become moist under water. Alumina, under these conditions,

combines with lime to form a cement. Contrary to the opinion of Winkler, Heldt, and Fremy, alumina is not the only essential binding ingredient in cements. The author finds that gelatinous and strongly-heated silica, as well as the dried substance, mixed with lime, and placed in filter-paper under water, forms a hard, solid mass after some time. Silica and alumina have no action upon each other. From these experiments it follows that both silica and alumina have cementing properties; but, whilst the alumina hardens quickly and produces the first adhesion of the mixture, the silica acts more slowly, and produces subsequent hardening. The lime has a double part to play: in the first place, it combines with silica and alumina; in the second place, it has a protective action on these bodies by forming on the surface a layer of calcium carbonate. It has been found, practically, that the necessary amount of lime is much smaller than the calculated quantity; for, with 1 mol. of silica, a sixteenth mol. calcium hydrate was sufficient to produce hardening. The author, in order to determine the actual chemical change in cement, has made a series of analyses showing the composition of cements after hardening. He finds that the amount of calcium carbonate varied from 14 to 33 per. cent., and of silicates from 4 to 10 per cent. These results agree with experiments which show that a much smaller proportion of calcium is necessary than is requisite to combine with the whole of the silica and alumina present. The author explains this by the supposition that the particles on hardening become covered with a coating of silicates of lime and alumina which bind them together, and this view explains also the fact that Portland cement after hardening, when re-burnt and re-pulverised, may be used again, fresh surfaces being exposed. The results of these experiments may be summed up shortly as follows:—The hardening depends on: The amount of water, which must be as small as possible, and regularly distributed. The density and thorough mixing of the materials. The formation of calcium carbonate. Further, the necessary amount of lime is comparatively small. The three principal constituents, SiO_2 , Al_2O_3 , and CaO , are chemically active. The alumina produces rapid, silica slow hardening. The chemical action is mainly a surface one. The alkalis are not essential constituents.—J. B. C.

Improvements in the Manufacture of Cement. W. T. Timewell, Devon. Eng. Pat. 11,806, Oct. 3, 1885. 6d.

THE object of the inventor is to make cement from hard limestones which contain over 60 per cent. of carbonate of lime. The limestone is first reduced to an impalpable powder. Any silicious aluminous material—e.g., fine clay, porcelain clay, or river mud—is mixed with silica and alumina so that the percentage of the former in the mixture shall be from 58 to 68 per cent., and that of the latter from 18 to 24 per cent.; it is then reduced to an impalpable powder. A slurry of the two, powdered limestone and the silicious matter, is made, dried, and furnace in the usual way. The proportions used should be from three to five parts of carbonate of lime to one part of silica and alumina. The patentee also finds in the preparation of the finely-ground materials it is more convenient to use a blast of air in conjunction with subsiding chambers to eliminate the coarse particles than it is to use sieves.—C. C. H.

Improvements in the Manufacture of Lime Cement applicable to the Production of Cements, Mortars, and Hydraulic Concretes, and Artificial Stone replacing Natural Stone. S. Pitt, Sutton, Surrey. From A. Speyser and L. Pillivayt, Paris. Eng. Pat. 12,908, Oct. 27, 1885. 6d.

SLAKED and crushed "fat lime" is mixed with crushed dried clay, 2 to 4 volumes of the former to 7 to 9 volumes of the latter; the whole is thoroughly incorporated with water into a paste and moulded into bricks, which are subsequently dried and crushed into grains about the size of a pea. The grains are furnace in rotating cylinders from 10 to 18 hours, and when cool reduced to an impalpable powder. From 1 to 3 volumes of powdered fat lime are finally mixed with the powder above

described, the product forming a good hydraulic cement. The latter addition may be made at any time, the two materials being kept separate until the cement is required for use.—C. C. H.

Improvements in the Manufacture of Composition adapted for Use in Mural and other Decorations, and in the Method of Producing the said Decorations. R. Bennett, Manchester; and H. Peet, Nottingham. Eng. Pat. 13,132, Oct. 31, 1885. 6d.

THIS invention relates to an improved composition suitable for application to walls, ceilings, etc., and particularly adapted to receive decorative impressions immediately after its application and whilst in a soft condition. The following materials, in the proportions indicated, are used in the manufacture of the composition in question:—Common whiting, 40 parts; plaster of Paris, 6 parts; glue, 3 parts; and molasses, 3 parts. Dry or moist colour or oil paint may be added. When the composition has been laid on, and is still soft, it is treated with suitably-formed combs, stamps, rollers, or blocks, by the application of which sunk or relieved decorations may be produced upon the soft surface.—E. G. C.

Improvements in Manufacturing Artificial Stones or Marbles. A. G. Brookes, London. From R. A. Meyn and J. F. O. Arnack, Hamburg. Eng. Pat. 13,595, Nov. 9, 1885. 6d.

VERY FINE CEMENT is mixed with barytes, the paste being tinted by any suitable mineral colour. For the production of imitation marble or granite, a convenient number of pastes of different colours are made by mixing the prepared and coloured cement with water, then dividing such pastes in pieces of small size when granite is to be imitated, and in pieces of large size for imitating marble. Dry cement of different colour is spread over these moist lumps, and the whole mass is then well kneaded, care being taken that the coherent nature of the lumps is maintained. After a few days, when the stones are somewhat hardened, they are shaped by means of suitable shaping tools.—E. G. C.

Improvements in the Manufacture of Cement. H. Mathey, New York. Eng. Pat. 7674, June 8, 1886. 4d.

ARGILLACEOUS LIME-STONE, commonly called "natural cement rock," used in the production of cement, by simply burning the natural mineral, does not contain sufficient alumina to form the double silicates of lime and alumina for the requirements of a high-class cement. The patentee effects the introduction of this alumina into the cement as follows:—The "cement rock" is reduced to a fine state of division, so as to pass through a four to eight mesh screen; dried crushed clay is added, the mixture agitated, furnace, and crushed to an impalpable powder, all in the manner usual in the production of Portland cement.—C. C. H.

Notes on Cement. Diagl. Polyt. J. 261, 529–541.

C. SCHUMANN (*Deutsche Bauzeitung*, 1886, 14) compared cement made from basic blast-furnace slag, erroneously termed "Puzzolan cement," with Portland cement, and finds the latter preferable for all the usual purposes. Puzzolan cement hardens very slowly, and its final hardness is inferior to that of Portland cement, which latter also offers greater resistance to the passage of water through it. Cement made from slag may be used as an addition to lime-mortar, the quality of which is thereby improved, but its admixture to Portland cement deteriorates the quality of the latter.

Tetmaier (*Schweizer Bauzeitung*, 1886, Nos. 14–17) examined slag cement, as regards its formation and applicability. He finds that to increase its cohesive power it is very important to granulate the slag before mixing it with lime. This is probably owing to the change of position the molecules undergo, when the hot slag is suddenly cooled by being thrown into water. The slag also loses thereby a small portion of its sulphur, and part of the silica is rendered soluble.

must, therefore, not be used if the temperature is below freezing point. Its principal applicability is for building under water or in a moist atmosphere, the lime then being gradually dissolved, in which state it acts on the slag, combining with silica. Its property of setting slowly is, therefore, due to the gradual action of the lime as it dissolves. For surface building the mortar must be kept moist for the first fortnight at least. Unfortunately the mortar from slag-cement is liable to shrink. F. M. Meyer (*Thonindustrie Zeitung*, 1885, 515, and 1886, 101) compared the working of an annular kiln with that of a Dietzsch cement-furnace. The fire-gases of the former contain on an average 6.2 per cent. carbon dioxide. 1734kilos. of cement are obtained per hour with a consumption of 238kilos. of coke and 109kilos. of coal. 41 per cent. of the total heat generated escapes with the fire-gases, the temperature of which is 232° C. Each kilo. of cement requires 835 calories. In a cement furnace 2070kilos. of coal are consumed for the production of 16,000kilos. of cement. The combustion is more perfect, the temperature of the fire-gases is 102° C., and each kilo. of cement only requires 710 calories. The cement-furnace is, therefore, more economical for burning cement than the annular kiln.

Another mortar, prepared with one equivalent of alumina and two equivalents of lime, tested five months after preparation:—

Dissolved in the Ammonium Chloride Solution.	(Combined Water	13.53

	No. 1. Annealed.	No. 2. Annealed.	No. 3. Tempered in oil and annealed dark red.
Elastic limit per sq. mm.	10.2 kilos.	10.3 kilos.	110 kilos.
Ultimate tensile strength per sq. mm.	73.0 "	70.8 "	150 "
Elongation, per cent.	17.9	21.2	6.2
Relation of ruptured to original section ..	0.308	0.333	0.708

—W. G. M.

A Portland-cement mortar, several years old, tested:—

Dissolved in the Ammonium Chloride Solution.	(Combined Water	9.29
	Soluble Silica	1.90
	Alumina and Iron Peroxide ..	5.47
	Lime	30.51
	Calcium Carbonate	23.07
	Insoluble Residue	9.14
	Aluminium Silica	2.09
Residue.	Calcium .. Aluminium and Iron Peroxide ..	3.43
	Silicate .. Lime	1.80
	Alkalis and Loss	4.27

It therefore appears that from a chemical point of view only a small quantity of the materials used in the preparation of cement-mortar is instrumental in the setting, which does not appear to be due to any chemical process. The amount of new compounds formed is very small indeed, and this also accounts for the fact that old cement-mortar, burned and powdered afresh, recovers the property of setting and hardening.—S. H.

X.—METALLURGY, Etc.

On Chrome Pig-iron and Steel. M. Brastlein. Iron and Steel Inst. Oct. 1886.

CHROMIUM—like manganese, but in a much higher degree—favours the combination of carbon with the metal; but the ferro-chromes, unlike ferro-manganese, never crystallise in large plates, but rather as needles, or with small facets, and a much larger quantity of chromium (sixty-five per cent.) is necessary to destroy the magnetic properties of the iron. In ferro-chromes the chromium is readily oxidised on heating, and since it remains infusible *per se*, and its silicate is also refractory, it follows that chromium-pig cannot be puddled,

nor can it be used as a substitute for ferro-manganese in the Bessemer or open-hearth processes; and, similarly, chrome-steel cannot be welded, whilst the metal, when melted, retains the earthy oxide produced on exposure to air, forming veins which no amount of forging can remove. Nevertheless, a good chrome-steel may with care be produced, the percentage of chromium employed being capable of considerable variation; a metal with two per cent. carbon and twelve per cent. chromium may be forged well. In steel, chromium increases the tenacity without affecting the percentage elongation under strain, but chrome-steel is always harder under the tool, though less so than one with an equivalent proportion of manganese. Chromium-steel tempers equally well with ordinary steel, but the temper penetrates deeper, owing probably to the tendency of chromium to combine with carbon; before tempering, the fractures are almost alike, the former being slightly more fibrous, but after tempering it becomes much finer, those richer in chromium resembling tungsten steel. If overheated, the chrome alloy becomes brilliantly crystalline and brittle, but it is less easily burnt than manganese-steel. Under the hammer it behaves like a carbon-steel of similar quality, though somewhat harder when cold drawn; worked hot, it is inferior to a manganese-steel. The hardening power of the metal suggests its use in the form of chromium-pig for rolling-mills and the like; but, if so employed, the carbon percentage should be small, in order to prevent the brittleness induced by much of that element. Bars turned to 9mm. diameter, with a length of 75mm. between the shoulders, gave the following tests by tensile strain:—

Some Preliminary Experiments on the Removal of Metalloids in the Basic Siemens Furnace. F. W. Harbord. Iron and Steel Inst. Oct. 1886.

THREE experiments with metals of known composition were made in a five-ton circular Batho furnace with a basic lining and suspended roof, samples of metal and of slag being taken for analysis immediately on complete melting, and at half-hour intervals subsequently until the end of the operation. In each case the charge consisted of sixty per cent. pig, thirty per cent. steel scrap, and three per cent. spiegel. The pig used in the first two trials had the following composition:—

	C	Si	P	Mn	S
White pig	2.61	1.27	3.50	0.31	0.31
Mottled	3.20	1.50	3.80	0.50	0.23

The scrap being chiefly lalle and hammer scrap. In the course of melting, which occupies four hours, slags very rich in protoxide of iron are formed; and by contact with these the metal is deprived, by the time it has completely run down, of over ninety-eight per cent. of the silicon, ninety-three per cent. of the manganese, and forty per cent. of the phosphorus, it originally contained, together with eighty-one per cent. of the carbon, and a very small percentage of the sulphur. In the third experiment, which was made with a low grade pig, containing 0.488 per cent. of sulphur, the slag formed during melting contained from 52 to 63 per cent. of ferrous oxide, and the metal was found to be almost completely freed from carbon, silicon, phosphorus, and manganese, though the sulphur, which was finally reduced to 0.20 per cent., had been scarcely affected. On comparison with the curves representing the removal of the metalloids in the other decarburising processes commonly employed, the curve obtained from these experiments approaches most nearly

A Method of Lining Furnaces. F. Siemens, London. Eng. Pat. 14,142, Nov. 18, 1885. 6d.

THE interior of the furnace is heated to the softening point of the bricks, and the lining material, in a pulverulent condition, is introduced into an air or steam injector, and thus directed through suitable doors or holes against such portions of the walls or roof as require to be lined; the dust adheres at this point, and by alternate heating and injection the lining may be thickened as required.

—W. G. M.

Regenerative Gas-furnace for Continuous Reduction of Iron Ore. F. Siemens, London. Eng. Pat. 14,143, Nov. 18, 1885. 8d.

THE furnace is of rectangular form, with all the gas and air ports at one end, one set being above or at the side of the other, so that the flame and heated gases sweep completely round the chamber. The opposite end of the furnace is inclined upward to the roof, through an opening in which the ore, mixed with reducing material and flux, is continuously fed on to the slope; here reduction is effected, and the metal is melted by the radiant heat of the flame, the molten iron collecting in a deep well situated at the regenerator end. The slag is drawn off continuously, and the metal at intervals, through tap-holes, of which several are provided at different levels in the sides of the furnace.—W. G. M.

Improvements in the Production of Aluminium and Aluminium-bronze. R. Grätzel, Bremen. Eng. Pat. 14,325, Nov. 23, 1885. 6d.

ALUMINIUM may be obtained from the double fluoride of aluminium and sodium or potassium by fusion with metallic magnesium, or by conducting magnesium vapour into the liquid compound; or it may be reduced electrolytically by a current of comparatively low tension if magnesium chloride be present. If a suitable proportion of copper be added in any of the above processes, aluminium-bronze will be produced. Barium, strontium, or calcium, if their cost were not prohibitory, could be substituted for magnesium; a salt of either of these metals may be employed in place of one of magnesium for the electrolytic method.—W. G. M.

Improvements in the Manufacture of Chloride of Aluminium and Double Chloride of Aluminium and Sodium. H. H. Lake, London. From Count R. de Montgela, Philadelphia, U.S.A. Eng. Pat. 10,011, August 4, 1886. 4d.

ALUMINIUM OXIDE, in the form of powder, is mixed with an equal weight of sodium chloride and of powdered charcoal, worked into lumps with molasses, dried, and ignited at a white heat in closed crucibles. These lumps are heated in dry chlorine for 16–18 hours, when aluminium chloride distils over, aluminium-sodium chloride being left in the retorts. The sodium chloride may be omitted or replaced by sodium carbonate.—W. G. M.

Improvements in Apparatus for the Manufacture of Chloride of Aluminium and Double Chloride of Aluminium and Sodium. H. H. Lake, London. From Count R. de Montgela, Philadelphia, U.S.A. Eng. Pat. 10,013, August 4, 1886. 6d.

SER in a brick chamber, fired by an oil spray, are horizontal retorts, each surrounded by an iron jacket and communicating behind with a condensing chamber for collecting the volatile chlorides; a perforated tube is passed into the retorts for chlorine delivery. Above, and set in the brickwork, are retorts for drying the charge before chlorinating.—W. G. M.

An Improved Process of Extracting Aluminium from Chlorides of the same, and of Aluminium and Sodium. W. R. Lake, London. From Count R. de Montgela, Philadelphia, U.S.A. Eng. Pat. 10,605, August 18, 1886. 4d.

TO a melted mixture of aluminium chloride and aluminium-sodium chloride granulated zinc is added, and the

whole well fused; an alloy containing 50 per cent. of aluminium may thus be made. This alloy is remelted with fresh double chloride and a small proportion of magnesium. The resulting alloy may, if wished, be still further enriched by a repetition of the process, or it may at once be fused with "muriate of potassium" and sodium chloride in equal quantities, by which the zinc will be removed from the alloy.—W. G. M.

An Improved Process of Extracting Aluminium from its Chlorides. W. R. Lake, London. From Count R. de Montgela, Philadelphia, U.S.A. Eng. Pat. 10,606, August 18, 1886. 4d.

THE chloride is mixed with lead oxide, charcoal, and sodium chloride, fused, crushed, and remelted with magnesium filings and "muriate of potassium." The mass, on cooling, is pulverised, re-fused with fresh "muriate" and nitrate of potash, poured into water, and the globules of aluminium separated.—W. G. M.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

An Improved Process for Improving or Increasing the Viscosity of Oils. Wm. and H. Marriott. Eng. Pat. 11,726, Oct. 2, 1885.

THE "brown grease" recovered from the wash-waters of woollen factories is distilled with superheated steam, and the best portion of the distillate is completely saponified by soda. The soap is then treated with alum, a mixture of aluminium stearate and oleate being thus formed, which is purified by washing and is finally dehydrated. This "viscom" is added to mineral lubricating oils to increase their viscosity.—W. L. C.

Improvements in the Manufacture of Candles, and Apparatus therefor. G. A. Sweetser, D. W. Bell, and W. Bolun. Eng. Pat. 13,417, Nov. 5, 1885. 8d.

THIS specification explains in detail, with the aid of drawings, apparatus by which candles may be moulded from plastic material in the solid condition, instead of the material being melted and poured into moulds as usual. The moulds, through which a continuous wick runs, are connected with a cylinder and piston which, in their turn, are in communication with a reservoir of the candle material. The latter is thus forced through the moulds, cut off to any desired length, and then trimmed and pointed by suitable machinery.—W. L. C.

Improvements in the Manufacture of Soap for Toilet and Cleansing Purposes. R. Ross. Eng. Pat. 14,380, Nov. 24, 1885. 4d.

ORDINARY SOAP is dissolved in water, about 6 per cent. of carbonate of potash (salts of tartar) are added, and about four times that quantity of methylated spirits. The whole is boiled for five minutes, and formed into bars or tablets as desired.—W. L. C.

Improvements in Apparatus for Extracting or Separating Oil or Grease from Cotton Waste and Similar Materials. J. Whittle. Eng. Pat. 8924, July 8, 1886. 8d.

THE apparatus is arranged in three tiers: (1) top tier, consisting of two vessels to hold the substance to be treated; (2) condensing coils leading into small reservoir; (3) large reservoir for hydrocarbon. In operating, hydrocarbon vapour, driven by steam out of the lowest reservoir, condenses like dew in the substance to be extracted, and the solution of grease produced therein drains back into the lowest reservoir. Both the recovered grease and the material whence it was extracted are freed from hydrocarbon by steaming in the usual way. A drawing of the arrangement is given.—W. L. C.

Improvement in Lubricating Compounds. J. L. Mott, jun. Eng. Pat. 8933, July 8, 1886. 4d.

SIXTY POUNDS paraffin wax and 100lb. tallow are melted together, 210lb. refined petroleum oil are added, and 1½lb. refined plumbago are then incorporated with the mixture, which is then cooled off for use.—W. L. C.

Improvements relating to the Bleaching of Fats and Oils. H. H. Lake. Eng. Pat. 9415, July 20, 1886. 4d.

FINELY-POWDERED FULLER'S EARTH is well mixed with the oil, which should not be heated (as it usually is); after some hours' subsidence, clear bleached oil is drawn off. A "Johnson" filter, and steam, are employed to remove the last traces of oil from the Fuller's earth. —W. L. C.

An Improved Antiseptic Soap. J. Thomson. Eng. Pat. 9591, July 24, 1886. 4d.

BINODIDE OF MERCURY (usually dissolved in iodide of potassium) is incorporated with soap, in the proportion from 0.01 per cent. to 1 per cent.—W. L. C.

Improvements in the Manufacture of Soap. H. H. Lake. From N. J. Clute, P. B. Rose, and J. M. Aubery, Chicago, U.S.A. Eng. Pat. 10,226, August 10, 1886. 4d.

THE tank water formed in the "rendering" of lard, tallow, or other fats, is evaporated to a syrupy consistence, then holding in solution 20 per cent. of solids, about one-fifth of which is nitrogenised substance furnishing ammonia. This is saponified in the usual way with tallow and rosin: "100lb. of tank water after being reduced 50 per cent. by evaporation, 90lb. tallow, 15lb. resin, with an amount of caustic soda sufficient to render saponification complete."—W. L. C.

XII.—PAINTS, VARNISHES, AND RESINS.

The Manufacture of a Composition suitable for making Wall Coverings, Boiler Coverings, and other Fabrics, Moulded Articles, and other uses. W. Clark. From E. D. Fagnet, France. Eng. Pat. 10,492, Sept. 4, 1885.

To a mixture of equal parts of linseed and some other oil, from 15 to 40 per cent. of calcium carbonate is added, and then from 10 to 30 per cent. of chloride of sulphur. The paste thus obtained is ground up with cork, sawdust, etc., and is then spread upon canvas or some other foundation.—W. L. C.

Improved Compound for the Manufacture of Pigments and as Material for the Manufacture of Articles usually made of Clay. A. J. Ward, Westminster. Eng. Pat. 10,838, Sept. 12, 1885. 6d.

THE inventor claims:—1. "The combination of mica, or clay, and oxide of lead, either with or without slate debris, as a compound or body for the manufacture of pigments, applicable also to the purposes for which white lead is ordinarily used." 2. "The combination of slate debris and mica, or clay; or slate debris, mica, and clay, as a material for the manufacture of articles usually made of clay."—E. G. C.

Improvements in the Manufacture of Waterproof Cloth, Felt, Board, Paper for Roofing, Packing, and Insulating Purposes. J. E. A. Pierret, Belgium. Eng. Pat. 13,140, Oct. 31, 1885. 6d.

THE petroleum residues are first neutralised with lime. The waterproofing compound is obtained by melting together a variable quantity of the residual matter obtained from the refining of petroleum with natural dry bitumen, resin colophony and Spanish white or lime stone. There are five claims to this patent.—E. G. C.

Improvements in the Preparation of Materials to be used in Making Paint. J. B. Spence, London. Eng. Pat. 14,128, Nov. 18, 1885. 6d.

THE inventor prepares sulphide of zinc and sulphate or carbonate of barium in the following manner:—Metallic zinc is dissolved in a solution of caustic alkali, and sulphide of barium is added to the product. Sulphuric or carbonic acid is now introduced, the result being a deposit or precipitate consisting of sulphide of zinc and sulphate or carbonate of barium. This precipitate is dried, and is then ready for use as a body or base for paint. —E. G. C.

A New Varnish and a Method of applying the same for Fixing Lithographic or other Transfers. C. F. Rousset, Paris. Eng. Pat. 606, Jan. 14, 1886. 6d.

THE new varnish is composed of:—Heavy benzene, 760—860grms.; Judaea bitumen (mineral pitch), 90—120grms.; and essence of copaiva, 7—20 drops. For the mode of application the specification must be consulted. —E. G. C.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

Improvements in the Process of and Apparatus for Tanning Leather. E. Edwards, London. From Charles Kollen-Corneille, Rheims. Eng. Pat. 14,414, Nov. 24, 1885. 8d.

THIS invention is for improvements in tanning-drums. By means of two wooden brackets on each side of the interior of the drum, a movable platform is fixed to facilitate the introduction and withdrawal of the leather from the drum. To facilitate the tanning of flanks or pieces of much greater length than breadth, the drum is divided in the centre by a transverse partition. The axes of the drum are hollow, so that by suitable appliances, fresh air, or the gases from the interior of another drum, can be aspirated through the drum while working. A tap is placed on the circumference of the drum by which samples of the liquor can be taken. After each tanning operation the liquor is filtered, and to prevent the injurious effect of the frothing of the liquor in the drum, "raw pulverised borax," in small quantity, is added. —B. H.

Improvements in and relating to Machines for Putting Out and otherwise Treating Hides and Skins. Joseph Warren Vaughn, Massachusetts, U.S. Eng. Pat. 5344, April 16, 1886. 11d.

THIS is a machine for "striking," setting or "putting out" hides or skins, and it can also be used for unhairing or fleshing. The hide or skin to be operated upon is put on a holder which, when raised, brings it into contact with two rolls. These rolls are each provided peripherally with a series of spirally arranged flanges made of iron, and revolve in opposite directions. The speed of the rolls and the pressure put on them, and also the speed of the holder, can be varied according to the class of work done. For details of the mechanism the bluebook must be consulted. There are seventeen claims to the patent.—B. H.

A New Product for Depilating and Preserving Hides. A. H. Mangin, Paris. Eng. Pat. 7145, May 27, 1886. 4d.

IN this invention a mixture of caustic soda and sulphhydrate or mono-sulphide of sodium is used. The proportions of the ingredients used and the strength of the liquor may vary within wide limits, according to the nature of the hides to be treated.—B. H.

An Improved Composition for Treating Leather and Leather Articles. T. N. Ashman, Bristol. Eng. Pat. 8413, June 26, 1886. 4d.

THIS composition consists of "asphalte" melted with cod or other fish, animal, or vegetable oil, beeswax, spermaceti,

or other wax, litharge, and linseed oil well boiled, terebene, or other dryers, Venice turpentine, ground mica or asbestos mixed with gum damar dissolved in alcohol, dry white lead, and gutta-percha or indiarubber dissolved in any of the usual solvents. For medium tanned leather about equal proportions of the ingredients are to be used. The leather is to be either immersed in the melted composition or the composition can be applied by means of a brush, or otherwise, to one side.—B. H.

XIV.—AGRICULTURE, MANURES, Etc.

Influence of the Protoxide of Iron in Basic Cinder on the Growth of Plants. Dr. J. M. H. Munro, College of Agriculture, Downton, Salisbury.

THIS report contains experiments supplementary to those which form the subject of the abstract following this. Seeds of various sorts—barley, white turnips, clover, white mustard, garden cress—were sown in mixtures of garden soil with basic cinder, in order to ascertain whether the large proportion of protoxide of iron in the basic cinder exercises any unfavourable influence on germination or growth. In order to put this question to the severest possible test, enormously exaggerated doses of basic cinder were employed—viz., 10 per cent. of the mixed soil, 25 per cent., 50 per cent., and pure basic cinder without any soil. Most of the seeds tried germinated even in the pure basic cinder, and some of the plants lived until starved for want of nitrogenous food. All the other mixtures produced plants which flowered and seeded in due course. The barley plants in the mixture of equal parts of basic cinder and garden soil were actually better than those grown in garden soil alone. These plants produced full ears of grain of unimpaired germinating power.

As basic cinder is an alkaline substance, containing free lime, it is only natural that in the three stronger mixtures fewer seeds germinated than in the weaker mixtures or garden soil alone. The conclusion arrived at by the author is that the ferrous oxide contained in basic cinder is absolutely without injurious influence on either germination or growth.—J. M. H. M.

Report of Experiments on the Manurial Value of Basic Cinder. J. Wrightson and Dr. J. M. H. Munro, College of Agriculture, Downton, Salisbury.

THE basic cinder employed in these experiments (1885) was produced by the Thomas process at the works of the North-Eastern Steel Company, Middlesborough. The sample employed, which was rather poorer in phosphate of lime than that now being produced, had the following composition:—CaO, 41.54; MgO, 6.13; Al_2O_3 , 2.60; FeO, 14.66; Fe_2O_3 , 8.64; MnO, 3.81; V_2O_5 , 0.29; SiO_2 , 7.40; P_2O_5 , 14.32; SO_3 , 0.31; S, 0.23—99.93.

Ohlendorf & Co. This precipitated phosphate contained 30.89 P_2O_5 , with 29.91 CaO , 3.62 Fe_2O_3 , 7.53 SiO_2 , 18.72 water and moisture, etc. The P_2O_5 in this product is practically all soluble in ammonium citrate.

Duplicate series of experiments were made on soils of totally different character—a thin light chalky soil on the Wiltshire Downs (College of Agriculture Farm), and a deep stiff clay soil at Ferryhill, Durham. The Downton soil had been somewhat heavily cropped during the last few years, and the Ferryhill soil had received no manure for many years.

Duplicate plots of each dressing were employed at both stations; the number and arrangement of the plots, and the kind and quantity of manure used on each, were exactly the same at Ferryhill as at Downton. At each station there were 35 plots, each 1 chain square, or $\frac{1}{16}$ th acre, and these were so arranged as to permit a comparison of every manured plot with one or more *adjacent* unmanured plots. The special comparisons between the different manures were also obtained from *adjacent* plots. There were six unmanured plots at each station. The crop grown at Downton was swedes, and at Ferryhill yellow Aberdeen turnips; the season, being very dry, was a disastrous one for root crops over the greater part of England, and the crops obtained on the experimental plots were very much below average in consequence. Notwithstanding this, the effect of the different manures is shown in a most striking manner, as will be seen from the few selected results which follow. Twenty-four out of the thirty-five plots at each station were devoted to a comparison of the raw ground basic cinder, with the manures already named, and with the six unmanured plots. These plots when weighed up gave the results as in Table I.

On the unmanured plots at Ferryhill, the young plant was unable to struggle through the early stages of its existence, and to withstand the attack of the "fly"—hence the very small number of roots that came to maturity. On the Downton unmanured plots there was no extensive failure of the plant, but the roots were extremely small. The manured plots gave the mean yields and increases over the mean of the six unmanured plots as shown in Table II.

These results place beyond all doubt the manurial value of the phosphoric acid contained in basic cinder. They also exhibit pretty clearly its relative efficacy as compared with the phosphoric acid in superphosphate, precipitated phosphate, and ground mineral phosphate; and they indicate the differences that may be expected from the use of basic cinder on soils of different qualities.

The general conclusion deducible from these experiments is that phosphoric acid exists in basic cinder in a condition to be easily assimilated by plants, and that in this respect it resembles soluble phosphoric acid and precipitated phosphoric acid much more than the insoluble phosphoric acid of ground mineral phosphates;

TABLE I.

	DOWNTON.		FERRYHILL.

Increase on $\frac{1}{16}$ acre over unmanured plots		5 0 3		11 0 21

This ground cinder was tried side by side with ground Cambridge coprolites containing 25.1 per cent. P_2O_5 , mineral superphosphate of ordinary quality containing 12.0 per cent. soluble P_2O_5 , rich (Curacao) superphosphate containing 20.1 per cent. soluble P_2O_5 , and also with precipitated phosphate of lime prepared from the basic cinder itself by Scheibler's process, and sold by

hence it is likely to occupy a very important position as a phosphatic manure. In the two years 1884 and 1885, there were no signs of injury to the crop, even from the heaviest dressings of basic cinder—viz., 1 and 2 tons per acre. On poor pasture land, also, dressings of basic cinder were found to produce large increases in the hay crop.

According to one of these patents (Munro and Wrightson, Eng. Pat. 250, 1885), ground basic cinder is used as a precipitating agent for the soluble phosphoric acid of rich superphosphate, and by mixing the two substances in suitable proportions, a manure of moderate richness is obtained, free from any excessive proportion of oxides of iron, and containing phosphoric acid in three highly-assimilable forms—viz., soluble, precipitated, and "cinder" phosphoric acid. The experimental plots on which this manure was tried show that the efficacy of the soluble phosphoric acid was not weakened by

on the dose, a small quantity being sometimes beneficial, and a large quantity invariably noxious. On the experimental plots to which the "dissolved cinder" was applied, the effect appeared to be uniformly disadvantageous. The dissolved cinder in all cases had *some* manurial value, giving increases over the unmanured plots; but these increases were *less* than were obtained with the same quantity of cinder not dissolved by acid, so that the sulphate of iron appears to have neutralised a part of the benefit derived from the phosphoric acid.

—J. M. H. M.

partial precipitation, and that the cinder phosphoric acid in the mixture exercised a manurial effect over and above that due to the phosphoric acid of the superphosphate. The manufacture of a soluble phosphate from basic cinder itself has also been tried and patented (Munro, Eng. Pat. 7740, 1885). When treated with the proper quantity of sulphuric acid, basic cinder is converted into a light green, dry, friable, and very porous substance, containing a large proportion of sulphate of lime, soluble phosphate of lime, and about 12 per cent. of crystallised green vitriol (a portion of the phosphoric acid exists as *soluble ferrous phosphate*). In view of the recent experiments of Griffiths, it was thought that the sulphate of iron contained in this manure might exert a beneficial effect on vegetation, instead of being, according to common belief, an absolute poison. The effect of ferrous sulphate on vegetation seems to depend entirely

On the Use of Gypsum and Related Substances in Preventing Loss of Ammonia from Liquid Manure. Adolf Mayer. *Journ. f. Landw.* **34**, 121.

THE author has arrived at the following conclusions:—The addition of a quantity of gypsum to liquid manure, equivalent to the ammonia present, is not sufficient. There must be so much that the liquid is always saturated with calcium sulphate. Nessler has shown (*Jahresber f. Agriculturchemie*, 1862, 157) that 5 equivalents of gypsum are required. The gypsum should be finely divided and well mixed with the manure. The best plan is to mix the gypsum intimately with the solid dung, and to bring the liquid repeatedly in contact with this by means of pumps. The availability of other sulphates depends on the formation of an insoluble carbonate or hydrate by the action of the ammonia. Ferrous

sulphate is considerably better than gypsum, but is more expensive. Potassium sulphate cannot be employed on account of the solubility of potassium carbonate. The whole of the ammonium carbonate is not converted into sulphate, and as the unaltered carbonate volatilises, the chemical equilibrium is constantly being restored by reconversion of ammonium sulphate into carbonate. Magnesium sulphate is not suitable owing to the formation of soluble double salts.—S. Y.

XV.—SUGAR, GUMS, STARCHES, Etc.

Manufacture of Sugar. Zeits. Deutschen Vereins für Rübenzuckerind., 1886, 489.

THE following were communicated to the annual meeting of the above Society:—

Hellriegel investigated the necessary amount of nitrogen necessary for the growth of the sugar-beet, and found that in the presence of sufficient phosphoric acid and potassium each kilo. of soluble nitrogen produced 220 kilos. of beet, yielding 32 kilos. of sugar. The strength of the beet was not appreciably influenced by the addition of a large amount of soluble nitrogen.

Schulz and *Schultze* contributed papers on buying beets on a basis of the amount of sugar they contain. They conclude that it is necessary to take 20 to 30 roots for the determination of sugar, in order to arrive at a correct result.

Landolt considers that Fahlberg's saccharine will have no influence on the sugar industry, and that starch-sugar sweetened with saccharine will never displace cane and beet-sugar.

Sichel modifies his former method for polarising cane-sugar, molasses, etc., with alcohol, by first adding acetic acid to decompose the alkaline sucrates present, and which would be precipitated by the alcohol.

Degener has investigated the different defecating agents used in determining the value of beet-juice, and finds that an examination of beet-juice and the impure products is not possible without the use of alcohol. Glutamine and glutamic acid become strongly levo-rotary by the inconsiderate addition of lead acetate. By the use of alcohol alone in examination of beets, too high a polarisation is generally obtained, which is lessened by the addition of a few drops of lead acetate, and the filtration of the separated precipitate. It is not quite determined in what way the precipitated compound acts, but a considerable error results if this slight addition of lead acetate is omitted. *Degener*, therefore, in examining beets and beet-juice, adds 5 drops of lead acetate solution to each 100cc. of the juice, after it has been treated with alcohol in the usual manner, quickly filters off the precipitate, and examines the solution with the polariscope. In examining impure products, and especially molasses, by this method, it is necessary to add a larger quantity of lead acetate. 20 drops are necessary for molasses, and it is preferable to use a 100mm. tube for polarisation than to add a larger quantity of lead acetate. The error is less in the former case than in the latter. Potassium acetate does not affect the rotation of sugar.

Herzfeld has studied the use of peat in place of animal charcoal. He finds that it decolourises better than the latter, and also reduces the amount of ash, but communicates colour to an alkaline solution, and is, therefore, not to be recommended.

Franken recommended the use of acid sulphite of aluminium for purifying beet-juice. The sugar obtained by means of this reagent should be free from invert sugar.

Sternberg brought forward the results of carrying out Steffen's method for separating sugar from molasses. By this method it was possible to obtain more than 88 per cent. of the sugar contained in the beet—a beet containing 11.985 per cent. sugar, yielding 11.115 per cent. of the finished sugar; and from molasses containing 50 per cent. sugar, 45.22 and 44.45 per cent. pure sugar were obtained.

Degener discussed the influence on the amount of invert sugar of the alkalinity of the beet-juice. He considered that it increased the keeping qualities, but caused an after colouration.

Degener also recommended Soldaini's reagent for detecting the presence of invert sugar. This is prepared by adding a solution of 40grms. of crystallised sodium carbonate to 40grms. of copper sulphate in solution. The precipitated basic copper carbonate is filtered off, and gradually added to a concentrated solution of 416grms. of bicarbonate of potassium. The solution is then made up to 1400cc., warmed for 2 hours on the water-bath, and filtered from the undissolved portion of carbonate of copper. The reagent so prepared is a deep blue liquid of 1.185 sp. gr. This solution should give no reduction on boiling, either alone or with cane sugar, for 5 minutes over a naked flame; and 0.0014gm. qualitatively, invert sugar can be determined by using 50cc. of the reagent, with certainty. In presence of cane sugar the delicacy is greater, it being then possible to detect 0.005 per cent. of invert sugar in cane sugar. Ammonia or ammonium salts diminish the reducing action of invert sugar.

Bodenbender contested the possibility of determining 0.05 per cent. invert sugar. All sugars reduce Fehling's solution slightly, and thus interfere with the estimation of small amounts of invert sugar.—G. H. M.

Treatment of the Waste Acid Liquor from Starch Factories. R. Schütze. Landw. Vers. St. 33, 197.

IN factories where starch is made by the acid process, it is proposed to render the residual liquors harmless from a sanitary point of view by heating them in a wooden tank to 60–70° C., by means of the waste steam from the engines, stirring in a slight excess of thick milk of lime, and then neutralising with more of the acid liquor. The precipitate settles quickly, and the clear liquor is then run off, and may be used for manuring purposes, whilst the sediment may be pressed in cloths or mixed at once with other food for pigs. The process is recommended for large factories, as the amount of lime, time and labour required is very small.—E. E. B.

XVI.—BREWING, WINES, SPIRITS, Etc.

Determination of the "Dry Extract" in Wines. E. Bouillon. Compt. Rend. 103, 498.

THE author has found from numerous experiments that when wine is evaporated in vacuo, any increase in the area of the surface of the liquid causes considerable diminution in the weight of the extract, owing to the volatilisation of some of the glycerine. Details of some of the experiments are given. When the bottom of the evaporating basin is covered with a layer of sand (5mm. deep), the loss is still more marked. To obtain comparative results, it is recommended to use basins with flat bottoms, of the same diameter, and to always take the same volume of wine for each experiment. (See Nessler u. Barth, *Zeit. f. Anal. Chem.* 23, 323–332.)

—E. E. B.

On the Employment of Fuel in Breweries. W. Goslich. Wochenschr. f. Brauerei, 1886, 3, 546.

As a result of the inquiry held by the Brewing Institute in Berlin, the author states that the quantity of coal employed in different breweries per ton of malt differs far more than is generally supposed. For the kiln-drying and boiling processes, $56.6 + 94.7 = 151.3$ kilos. of coal per 100 kilos. of malt are, on the average, employed. The extremes are $32.5 + 50 = 82.5$ and $90.5 + 162 = 252.5$ kilos. of coal per 100 kilos. of malt. To these numbers must be added the amount of coal required for other purposes—for instance, that employed in steam breweries for heating the ovens and engine boilers. For a copper heated by steam, about 50 kilos. of coal per 100 kilos. of malt are required. Of 100 parts of coal employed for brewing purposes (total amount without copper), 62.5 parts go to the brewing house and 37.5 to the kilns; including fuel for coppers, the proportions are, 47.0 parts to the brewing house, 28.1 to the kilns, and 24.9 to the coppers.—S. Y.

Improvements in the Preparation of Finings for Clarification of Beers and Wines. F. Keeling, London. Eng. Pat. 15,168, Dec. 10, 1885. 4d.

THE patentee claims the use of a 0.1 per cent. solution of sulphuric acid, or a 0.2 per cent. solution of hydrochloric acid, for dissolving the isinglass.—G. H. M.

Improvements in the Distillation and the Rectification of Alcoholic and other Liquids. L. Béchaux, Porrentruy, Switzerland. Eng. Pat. 9630, July 26, 1886. 8d.

THIS is an apparatus in which the liquid to be distilled or rectified is led through a vertical flat coil heated to the required temperature by means of a water-bath. The flat pipes of the coil work independently of each other, owing to hydraulic joints, and the vapours formed in each flat are successively passed through analysers and refrigerators, which are kept at the temperature required for rectification by means of vapour circulating through a coil. The original must be consulted for full description and drawings. The patentee claims that good alcohol, free from essential oils, etc., can be obtained by a single distillation.—G. H. M.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

Inorganic Foods. N. A. Randolph, M.D. Jour. Franklin Inst. 122 [729], 177.

THE author demonstrates the physiological value of water and certain inorganic salts—*e.g.*, those of sodium, potassium, and calcium—as food-stuffs. In the adult, from 59 to 65 per cent. of the weight of the body is water, and defective nutriment increases this amount. Farinaceous materials as food impart an appearance of plumpness by favouring the accumulation of water in the tissues. The chemical reactions which occur in the body require the presence of a certain quantity of water, and it is most essential to the healthy action of the nervous and muscular functions. Certain diseases—*e.g.*, cholera—diminish the percentage of water in the tissues. On the other hand, starvation does not decrease its quantity, because the destruction of the albumens sets free their water of combination; hence, combined hunger and thirst are better endured than either alone. Increased consumption of fluid only temporarily increases the quantity secreted by the tissues. In growing children, an increased consumption of water is necessary to wash away the products of tissue-change.

To the healthy physiological condition certain solid inorganic foods are essential, and their presence seems essential to the integrity of proteid matter, and inorganic salts appear to enter into combination with the albumenoids. Starvation results in the elimination of inorganic salts—those set free in the destruction of the albumens—and the administration of foods free from salts results in an almost complete absence of salts in excretions. Salt starvation, before referred to, finally results in death, and of this fact the author points to many striking experiments. The different tissues appear to exercise a distinctive action upon the various salts taken into the body; thus, the muscles contain an excess of potassium, and in fever urine the amount of this element is three or four times greater than in healthy urine. Herbaceous food decidedly increases the quantity of potassium in the urine. The carbonates of the alkalis perform an important part; hence the value of fresh vegetable foods. The presence of hydrochloric acid in the gastric juice appears to be due to the double decomposition of acid sodium carbonate and sodium chloride; hence the necessity for the presence of both these salts for normal digestive functions. Calcium salts play an important part in the formation of the bones of young animals. Iron is undoubtedly a valuable food, and, contrary to popular opinion, exists more largely in the muscular tissues than in the blood.—C. C. H.

Preservation of Milk, Meat, and Eggs. L. Liebermann. *Maly's Jahresh. f. Thierchemie*, 1885.

EXPERIMENTS are described on the use, as antiseptics, of various preparations of boric acid, such as boroglyceride, a mixture of borax and boric acid, and of the latter with salicylic acid. Milk was preserved for seven, and meat for five days, by boroglyceride. A mixture of borax and boric acid preserved meat for seven days, eggs for eighteen days, and milk (in closed vessels) for from ten to fourteen days. An injection of a mixture of salicylic and boric acid into the veins of a living animal served to prevent the carcase from decay, provided that it was cleaned immediately after death.—V. H. V.

On Normal and Pathological Cow's Milk, its Analysis: Dilution with Water, Albumen. H. Lajoux. *J. Pharm. Chim.* 14, 216.

IN the municipal laboratory of Paris it is assumed that the extractive matter in milk amounts to 130grms. per litre, but the author finds, from numerous analyses of the milk from Rheims, that the average is 126grms. He states that the amount depends on the food and the length of time the cows are kept in the stalls, and not on differences of breed. The author believes that an estimation of total albumenoids affords the best criterion of purity. The method of analysis adopted by him is as follows:—(1) determination of specific gravity; (2) estimation of total solids at 95°; (3) determination of salts; (4) estimation of milk-sugar by polarimeter after treatment with lead acetate; (5) determination of butter—10grms. of milk are evaporated in a small basin with 5grms. of fine sand; the residue is extracted with ether, and the fat dried at 95°; (6) determination of albumenoids. The author considers the ordinary methods unreliable, and takes the amount of albumen to be the difference between the total extractive matter and its components other than albumen. The mean of numerous analyses gives 33.02grms. per litre as the normal amount of total albumenoids; if the cow is healthy it is never less than 30grms. A milk with less than 30grms. should be rejected, while, if the amount is greater than 40grms., the health of the cow is doubtful.—S. Y.

Certain Improvements in the Production of Evaporated Milk. A. H. Reed, London. From R. Ellin, Yonkers, N.Y. Eng. Pat. 10,518, August 17, 1886. 8d.

THE milk is first mixed with about 10 per cent. by weight of cane sugar, and one or two drops of glycerine to each gallon. It is then evaporated to dryness in a pan, heated by a water or air-bath to a temperature of from 90–130° F., and under a vacuum of 26 to 29 inches of mercury. The interior of the pan is provided with cutting blades, and also a series of scrapers, set on a shaft and revolving in opposite directions; these thoroughly agitate the condensed milk, and keep the sides and surfaces of the pan free from solid accumulations. The product is a dry granular powder.—C. C. H.

Improvements in the Manufacture of Vinegar. G. G. Picking, W. H. Hopkins, John Dore, and James Dore, Bromley, London. Eng. Pat. 12,035, Oct. 9, 1885. 6d.

WHITE VINEGAR is obtained by subjecting malt or other vinegar to a process of distillation in vacuo, in an apparatus consisting of a still, a condenser, and a receiving vessel. The vacuum is maintained in every part of the apparatus by an ordinary vacuum pump, a water column, or a steam jet.—C. C. H.

Improvements in and Apparatus for the Treatment of Rancid Butter and other Materials for Purifying, Flavouring, and Mixing the same. J. Y. Johnson, London. From C. Marchand, New York. Eng. Pat. 4062, March 23, 1886. 8d.

Two vessels of any shape are arranged side by side, communicating with each other by small holes at the bottom ends. Each is fitted with a piston, to which motion is communicated by cranks, one of which is 180

degrees in advance of the other. The butter, together with the purifying liquid, is placed in one vessel, and by the rotation of the driving cranks transferred from one to the other through the small holes before mentioned. The butter is thus brought into intimate contact in fine threads with the purifying liquid, and in such a manner that "the grain" is not destroyed. It is then washed with water in the same apparatus, finally with butter-milk. The temperature must be kept normal at about 57–62° F.—C. C. H.

Improved Treatment of Alimentary Substances for their Preservation, and Apparatus for that purpose. H. Pischon, Berlin. Eng. Pat. 14,697, Nov. 30, 1885. 8d.

For the preservation of flour, or small grains of rye, wheat or peas, it must be rendered free from water, and compressed so as to exclude air. The apparatus shown is for effecting this object. The substance is passed from the hopper *a* in measured quantities by the valve *d*, on to steam-heated revolving trays *e*, enclosed in a cylinder *b*, from which the air is exhausted through a passage *c*. Agitators *f*, *f*¹ distribute the flour, etc., in

through the kitchen chimney. If this is not practicable, a special tube of galvanised iron is carried high up through the interior of the house and should be warmed by a gas flame or otherwise. It is a mistake to allow the closet to be exposed to the air of the house on the supposition that the drainage gases can be removed, as the pressure of the external atmosphere is for the most part of the year greater than that on the upper part of the soil-pipe. The drainage gases would be thus forced into the house.—V. H. V.

(C) DISINFECTANTS.

Process and Means for Disinfecting, Deodorising, and Purifying Sewage and other Foul Waters or Matters. J. Hanson, Wakefield. Eng. Pat. 12,261, Oct. 14, 1885. 4d.

BLACK-ASH or alkali waste, spent gas-lime, or any such substances as contain sulphites or hyposulphites, are added to the sewage in conjunction with sulphuric or hydrochloric acid, setting free sulphurous acid.

—C. C. H.

thin layers on the fixed and revolving trays *e*¹, *e*, and pass it from one to the other. Finally it is delivered into the small cylinder *o*, where it is pressed through a restricted orifice *n* by a reciprocating piston *q*, pure nitrogen or carbonic anhydride being simultaneously supplied through the pipe *s* to effectually displace any air.—C. C. H.

(D) SANITARY CHEMISTRY.

The Water-closet System in Dwellings. Recknagel. Chem. Zeit. 10, 1259.

IN water closets, the drainage gases can be removed by a stream of water flowing continuously through the soil-pipe with a certain velocity. In the dry systems, the flap must be closed air tight, and the soil-pipe connection must also be air-tight; a second pipe must be led from under the seat to the roof of the house, preferably

Improvements in the Preparation of Agents to be used in the Treatment of Sewage, etc., and Improvements in the Treatment of such Matters. J. W. Slater and The Native Guano Company, Limited, London. Eng. Pat. 13,750, Nov. 11, 1885. 6d.

THE sewage, if acid, must first be neutralised and then treated with clay, peat, or carbonaceous matter, sometimes previously mixed with sulphate or chloride of manganese, or copper. A mixture of solutions of copper and iron slag in hydrochloric acid, or a solution of chloride of aluminium, is then added.—C. C. H.

Improvements in the Treatment of Sewage and other Liquid or Semi-liquid Putrescent or Putrescible Matters. W. C. Sillar and The Native Guano Company, Limited, London. Eng. Pat. 13,749, Nov. 11, 1885. 6d.

SEWAGE, or similar matter, is treated with solutions of salts of the heavy metals—*e.g.*, aluminium, iron

or copper, or solutions of salts of "true earths" (excluding the so-called "alkaline earths"), heated to a temperature higher than the sewage itself. Clay, carbon, or carbonaceous materials suspended in water, heated to a temperature higher than the sewage, may also be used in conjunction with the solutions of the salts mentioned above.—C. C. H.

The Complete Purification of Sewage from Organic Matter. J. H. Kidd, Wrexham. Eng. Pat. 16,060, Dec. 31, 1885. 4d.

A SOLUTION of protosulphate of iron (20 parts) is treated with 4 parts of caustic lime, producing "a mixture of suboxide and hydrated sesquioxide of iron," and this, together with 1 part of refuse soap, is added to the sewage after the latter has been allowed to subside. Bog-iron ore, without the addition of lime, may also be employed. Where the effluent from the above treatment cannot be passed over land, it may further be purified by the addition of potassium permanganate, potassium or sodium bichromate, or chromic acid, with a small quantity of sulphuric acid.—C. C. H.

Improvements in the Preparation of Materials suitable for use in the Treatment of Sewage and for other Purposes. F. Caudz, London. Eng. Pat. 1792, Feb. 6, 1886. 4d.

CAUSTIC LIME, at a temperature of 150–200° F., is thoroughly incorporated with from 5 to 12 per cent. of tar. The mixture is carbonised out of contact with air in any ordinary suitable apparatus. The carbonaceous mixture so produced is added to the sewage in such cases where it may be requisite to render it alkaline, prior to the addition of other precipitants.—C. C. H.

XVIII.—ELECTRO-CHEMISTRY.

Improvements in the Manufacture of Carbon Filaments for Electric Lighting. T. V. Hughes, Wales; and C. R. Chambers, London. Eng. Pat. 11,876, Oct. 6, 1885. 8d.

INTO a crucible, kept at a bright red heat, a stream of gas containing certain proportions of marsh gas, hydrogen, and ethylene, is introduced by a perforated nozzle. After a while, fine hair-like filaments grow from the nozzle to the walls of the crucible. These filaments are not only very dense and homogeneous, but are very strong and flexible.—E. T.

Improvements in the Composition and Decomposition of Compound or Complex Bodies. J. G. Lorrain, London. Eng. Pat. 12,074, Oct. 10, 1885. 1s. 1d.

IN the vessels in which chemical action is being carried on, electrical gravity contacts are placed, automatically operated by the density of the contents. These contacts control electromotors, which bring about the supply of the various ingredients to the vessel, or their removal from it.—E. T.

Improvements in the Manufacture of Incandescent Lamps. W. Maxwell, London, and T. V. Hughes, Wales. Eng. Pat. 13,485, Nov. 7, 1885. 4d.

IN order to obtain a high vacuum without danger to the lamps, or discomfort to the operator, the former are enclosed during exhaustion in a vessel kept hot by a current of heated gases.—E. T.

Improvement in Thermo-electric Batteries. A. Burjorji, Gandevi, India. Eng. Pat. 14,037, Nov. 7, 1885. 8d.

METALS, when suddenly cooled, are changed mechanically, and therefore acquire different thermo-electric qualities at different points. To obviate this, pressure is put on the couple, by enclosing it in a strong casing with

a metal of a different co-efficient of expansion. This pressure is intended to effect a more homogeneous distribution of the particles of the couple.—E. T.

Improvements in Secondary Batteries or Electrical Accumulators. Jas. Y. Johnson. From S. Farbaky and Dr. S. Schenek, Hungary. Eng. Pat. 13,697, Nov. 10, 1885. 8d.

THE plates consist of lead grids, the interstices of which are packed with a special material; for negative plates this material consists of 95 parts by weight pulverised litharge and 5 parts granulated pumice stone, the grains being from 1 to 1½ mm. in diameter. Enough sulphuric acid is added to form a stiff paste; the mass is spread over the lead grids and "stroked with a brass bar until there is a visible sweat on the surface;" the material projecting above the lead frame being pared off with a long knife. The other side of the plate is treated in the same manner. The packing for positive plates consists of 95 parts by weight of litharge, 95 parts minium and 10 parts powdered coke. The coke and pumice stone give porosity, and thus facilitate the entry and escape of the electrolyte. The plates, when dry, are dipped into a bath of sulphuric acid diluted with 75 per cent. of water, rapidly removed and left to drain; after about 24 hours they are again dipped in the bath and left there for 12 hours. This treatment helps to maintain the packing in position. The plates are packed in airtight cells, the connecting rods projecting through the cover.—B. T.

Improvements in certain Elements for Electrical Batteries. J. T. Armstrong, London. Eng. Pat. 14,333, Nov. 24, 1885. 6d.

INSTEAD of using plates of similar metal, in both compartments of a battery, another metal, such as iron, is substituted for one of the plates in order to obtain equal or greater electrical power at a reduced cost. Laminated plates or bars of dissimilar metals are made use of. To make the working of a battery more regular and continuous, a small percentage of silver, lead, tin or other alloy is added to the zinc from which plates are to be formed.—B. T.

An Improvement or Improvements in Utilising Waste Products obtained in Galvanising Iron. R. Heathfield, Birmingham. Eng. Pat. 14,411, Nov. 24, 1885. 6d.

THE seum which is formed on the surface of the bath of melted zinc consists of chloride of zinc, ammonium chloride, oxide of zinc and some metallic zinc. The object of this process is to utilise the zinc contained in this seum. By treating with water, the chlorides of ammonium and zinc are dissolved out, leaving a residue consisting of oxide of zinc and metallic zinc, from which residue the zinc can be obtained in any ordinary way. The chlorides of ammonium and zinc are put into a bath, into which dip an anode of zinc or carbon and a cathode of the metal to be coated; a current of electricity is sent through the bath and pure zinc is deposited at the cathode.—B. T.

Improvements in the Production of Metallic Zinc from Products resulting from the Galvanisation of Iron, and the Recovery of Ammonia or Ammoniacal Compounds from the said Products. W. F. Richards, Swansea. Eng. Pat. 13,982, Nov. 16, 1885. 4d.

GALVANISERS' DROSS, consisting largely of zinc and ammonium chlorides, is dissolved in water with the minimum quantity of hydrochloric acid, evaporated to 25° Baumé and electrolysed till free from zinc, the residual liquors being treated for ammonia.—W. G. M.

An Improved Galvanic Battery. A. Dun and F. Hasslach, Frankfort-on-the-Main. Eng. Pat. 14,612, Nov. 27, 1885. 6d.

THIS cell consists of zinc and carbon (or other suitable substance), as electrodes, in a solution of a manganate

or permanganate mixed with a caustic alkali. It is claimed to have a high electromotive force and low resistance, to be very constant, being without local action; and its products are of marketable value. Its use as an accumulator is also claimed.—E. T.

Improvements in the Method of Supplying Liquids and Mixtures to Electrical Batteries. J. T. Armstrong, London. Eng. Pat. 398, Jan. 9, 1886. 8d.

AFTER a battery has been working for some time the electrodes usually become coated with a deposit which is deleterious to the working of the battery. In this method the exciting fluid is periodically withdrawn and a liquid passed in, which has the effect of reinvigorating the battery by removing the deposit. Two cisterns are provided, connected with the battery by flexible tubes, one cistern containing the exciting and the other the cleansing liquid; the connection between either cistern and the battery can be opened or closed by suitable plugs. These cisterns, which are fitted to a suitable framework, are capable of independent motion to positions above or below the battery, so that the fluid from either of them can be passed into the battery or that in the battery be withdrawn into either of the cisterns.—B. T.

Improvements relating to the Electro-deposition of Aluminium. W. R. Lake. From Count R. de Montgela, Philadelphia, U.S.A. Eng. Pat. 10,607, August 18, 1886. 4d.

ALUMINA is treated with hydrochloric acid and aluminium chloride obtained; this liquid is placed in a bath, into which dip a suitable anode and a cathode of brass or copper. On the passage of a current of electricity through the bath, the iron present in the liquid is first deposited, and as soon as this deposition ceases, which is apparent by the change of colour in the deposit, the liquid is decanted into a similar bath, and to it is added about fifty per cent. by weight of the oxide of either lead, tin or zinc. On sending a current of electricity through this bath, aluminium, together with the metal of the added oxide, is deposited at the cathode.—B. T.

Improvements in the Production of Aluminium and Aluminium Bronze. R. Grätzel, Bremen. Eng. Pat. 14,325, Nov. 23, 1885. 6d.

SEE p. 608.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Reactions of Brucine. H. Beckurts. Chem. Zeit. 10, 81.

BRUCINE dissolves in chlorine water with a red colouration due to the formation of a dichloro-derivative, obtained on evaporation as a red-brown amorphous powder. The colouration disappears on addition of excess of the chlorine water, but is restored when this excess is driven off. Bromine water forms when added to solutions of brucine salts a yellow amorphous precipitate of the tribromide, decomposed by warming with water into brucine hydrobromide and dibromobrucine.

The strychnine reaction—namely, the blue-violet colouration, with sulphuric acid and an oxidising agent—does not occur with brucine, as oxidation supervenes.

—V. H. V.

Pseudomorphine. O. Hesse. Annalen, 235, 229.

POLSTORFF has deduced for pseudomorphine or oxydimorphine the formula $C_{24}H_{36}N_2O_6$ from determinations of the quantity of it—namely, eighty per cent., formed by the oxidation of morphine by potassium ferri-cyanide in alkaline solutions. He did not, however, examine as to how far the specimens used were free from pseudomorphine, or as to the possibility of the conversion of morphine into pseudomorphine by exposure of the alkaline solution to the air. Avoiding these sources of

error the author has repeated the experiment, and found the yield of pseudomorphine to be 88.4 per cent. The reaction is as follows:— $2C_{17}H_{19}NO_3 + O = C_{17}H_{19}NO_3 + C_{17}H_{18}NO_3 + H_2O$.—V. H. V.

Saccharine as an Antiseptic. V. Adacco and H. Mosso. Gaz. Chim. Turin, 1886.

EXPERIMENTS are quoted to show that saccharine (benzoylsulphonicimide) acts as an antiseptic in fermentations of sugar, wine and milk. Peptonisation and diastasis are retarded. It possesses medicinal value in cases of *diabetes mellitus*, and also of abnormal processes in the stomach. It is also useful for certain disinfecting processes in the intestines.—V. H. V.

Improvements in Acid Bases for Aerated and other Beverages and Tonics. A. G. Brookes. Eng. Pat. 14,002, Nov. 7, 1885.

THIS invention consists in mixing lactic acid with 2 per cent. of lactate of lime and traces of gluten, gum, colouring matter and sulphate of lime with water, sugar, or syrups, for use as above.—T.

A Process for the Manufacture of Oxyquinoline Carbonates. J. Y. Johnson, Middlesex. From Dr. F. von Heyden, Nachfolger, Radebeul, near Dresden. Eng. Pat. 10,280, August 11, 1886.

THIS invention has for its object the production of oxyquinoline carbonates by treating alkaline oxyquinolines and earthy alkalis at a high temperature with carbonic acid under pressure—viz., 130° to 150° C. The conversion takes place quantitatively according to the equation—

—T.

XXII.—GENERAL ANALYTICAL CHEMISTRY.*

On the Testing of Brown or Pale Brown Mineral Oils. H. Hager. Pharm. C. H. N.F. 7, 397.

(1.) A MIXTURE of 2cc. of the mineral oil with 2cc. of petroleum spirit and 4cc. of water is vigorously shaken in a test glass at the ordinary temperature, and allowed to stand. If the oil is pure or is adulterated only with resin oils, an immediate separation occurs, and after a few hours two approximately equal layers are formed. The surface of contact of the layers may be turbid, but should not be more than 5mm. thick. If fatty oils are present, three layers are formed, the relative bulk of which changes after three or four hours. The lowest aqueous layer is very turbid, the uppermost layer oily and somewhat translucent, and the intermediate layer emulsive or milky. If the uppermost layer is also milky or emulsive, adulterations of a soapy nature are present.

(2.) In order to ascertain whether resin oils are present a mixture of 2cc. of the mineral oil, with 2cc. of petroleum spirit, 4cc. of water, and 1cc. of 10 per cent. ammonia, is vigorously shaken. If, after an hour or two, two equal layers are formed, of which the upper oily one is translucent or clear, and the lower aqueous layer has no milky appearance, the oil is pure. But if either two or three layers are formed, of which, after from five to ten hours, one or more possess an emulsive or milky appearance, then resin oils are present.

(3.) The fatty oils are saponified by heating with a caustic alkali and 60 per cent. alcohol. The soap is dissolved in 60 per cent. alcohol, the solution evaporated, decomposed with dilute sulphuric or hydrochloric acid, and the fatty acid collected on a moistened filter.

(4.) The separation of resin oils is effected by shaking with 89 to 90 per cent. alcohol at 25 to 30° . Twenty

* The woodcut on page 550 of the October number of this Journal was unfortunately placed upside down in arranging the type in pages.

parts of the luke-warm alcohol dissolve 1 part of resin oil. After evaporation of the alcohol the extracted resin oil has a specific gravity of 0.95 to 0.98, or is sometimes even heavier. Its composition may be ascertained by the usual methods.—S. Y.

Detection of Arsenic in Hydrochloric Acid and Metallic Copper (Reinsch's Test for Arsenic). H. Hager. Pharm. C. H. 1886, 7, 439.

METALLIC COPPER, used for the removal of arsenic from hydrochloric acid, must present a perfectly clean metallic surface; the presence therein of arsenic is not of importance, as the arsenide of copper is not attacked by the hydrochloric acid. In order to recognise the presence of arsenic in copper, a few drops of ammonia are poured upon the metal, and the action allowed to proceed for half-an-hour; the surface is then washed with water, and the stain formed is then dried with linen. Acetic acid is then poured upon the stain, and allowed to remain for 10 minutes; the surface is then washed, and the stain rubbed with linen. The presence of arsenic is revealed by the appearance of a grey stain, easily recognised under a lens.—V. H. V.

Detection of Free Sulphuric Acid in Aluminium Sulphate. H. Hager. Pharm. C. H. 1886, 7, 440.

IN order to detect the presence of free sulphuric acid in aluminium sulphate, the finely-powdered salt (about 0.25grm.) is added to a previously-warmed mixture of 2 drops of gurgun balsam and 3cc. of acetic acid; on warming, a bright blue, with traces of acid, or a dark blue colouration in the case of larger quantities, results. The presence of free aluminium hydroxide is detected by adding the crystalline salt to two parts of water; a milky solution is formed.—V. H. V.

Analysis of Peptone. G. Bodländer. Chem. Zeit. 10, 216—217.

THE author, after alluding to the criticism of König, describes his method for the estimation of peptones as follows:—5—10grms. of the substance are dissolved in 300cc. water and 5cc. of acetic acid added. The precipitate formed is collected on a weighed filter-paper, washed with hot water, dried, and weighed. This weight, less that of the ash obtained on incineration, gives the quantity of insoluble albumen. The filtrate and wash-water are collected and divided into two equal portions, of which one is saturated with sodium sulphate, which precipitates the soluble albumen or propeptone. The precipitate is collected on a weighed filter, washed with a saturated solution of sodium sulphate, dried, and weighed. The weight of the precipitate, less that of the ash, gives the proportion of the soluble albumen. The other half-portion is treated similarly with ammonium sulphate, whereby the proportion of mesopeptone is obtained.—V. H. V.

General Applicability of Kjeldahl's Method for Estimation of Nitrogen. C. Arnold. Arch. Pharm. 24, 785.

KJELDAHL'S method for estimating nitrogen is applicable to the case of substances containing nitrogen as cyanogen, or an oxygenated grouping, provided that the substance before treatment with sulphuric acid be boiled in the former case with sugar, and in the latter with some substance such as benzoic acid, which will combine with the nitric acid set free by the sulphuric acid. Experiments proved that in presence of the above-mentioned substances, or of mercury or copper sulphates, this process is applicable for all kinds of nitrogen compounds. Further, in the case of alkaloids, a preliminary oxidation by potassium permanganate is not necessary.—V. H. V.

Determination of Nitric Acid as Ammonia. E. Reichardt. Arch. Pharm. 24, 798.

IN the determination of nitric acid in the form of ammonia by reduction with zinc and iron in presence of

alkali, a difficulty is experienced in the presence in the alkali of nitrates, added by the manufacturer, to produce a white product. This may be obviated by fusion of the alkali and addition of a small quantity of zinc dust until a test portion removed no longer gives the brucine reaction of the nitrates.—V. H. V.

Determination of Carbon in Organic Substances in Aqueous Solution. Zeits. Rübenzucker, Ind. 36, 754.

THE values obtained for the carbon in organic substances when oxidised by chromic acid solution are frequently affected by the presence of chlorine compounds, evolving under these conditions chlorine, which is absorbed by the potash apparatus. This may be avoided by interposing in the calcium chloride tube of Rose's absorption apparatus a layer of dried and finely-powdered metallic antimony, and by conducting the analysis sufficiently slowly. Experiments with acetic, stearic, and phthalic acids gave satisfactory results.—V. H. V.

A New Apparatus for Determining Melting Points. C. F. Roth. Ber. 19, 1970—1972.

THE apparatus consists of a small, round-bottomed flask A, with a long neck B. The flask is 65mm. diam., the neck 200mm. long and 28mm. wide. Into the neck a glass tube C is sealed, closed at its lower end, which is 17mm. from the bottom of the round-bottom flask.

This tube has a diameter of 15mm. Near the top of the neck, a side tube D, 11mm. wide, is fused on, which has a small perforation at the side. A hollow stopper E fits into this with a similar perforation. Before use the flask is filled to the mark F with conc. H_2SO_4 . The hollow stopper is turned until the two side openings coincide. The sulphuric acid on heating rises in the outer vessel and converts the inner vessel in which the thermometer and the substance is placed into an air-bath of nearly constant temperature. From a series of experiments the author finds that with this apparatus no correction for difference of temperature of the mercury column is required.—J. B. C.

Dehydromorphine (Oxydymorphine). J. Donath. J. Prakt. Chem. 1886, 559—560.

AFTER giving a short history of dehydromorphine and its artificial preparation from morphine, the author adds his own observations on the properties of these two bodies. They may be distinguished by the following reaction:—Dehydromorphine is mixed with 8 drops of

H_2SO_4 (2 vol. conc. H_2SO_4 and 1 vol. H_2O) and gently warmed until acid vapours are evolved. The liquid assumes a bluish-green colour. Diluted with water the solution changes to rose-red, which, on the addition of an oxidising agent (1–2 drops conc. HNO_3 or 1 drop of a solution of 1 part NaNO_2 and 20 parts H_2O or 1 drop of NaClO solution), changes to deep violet. Morphine, on the other hand, treated in the same way, gives a red, on further heating a dirty brown, on dilution a reddish colour, and on oxidation a beautiful cherry red. The following reactions are common to both substances:— FeCl_3 gives a brownish-green; conc. HNO_3 a blood-red, Fröhde's reagent (conc. H_2SO_4 containing molybdic acid) a violet colouration. They also reduce iodic acid when other acids are absent.

The yield of dehydromorphine, according to Polstorff's method of preparation, is 63 per cent. Like morphine, it dissolves in hot amyl alcohol. The hydrochloride is soluble in water and alcohol, though less readily in hot alcohol than morphine. A 1-per-cent. aqueous solution of the hydrochloride dissociates on standing. The specific rotatory power of the anhydrous hydrochloride is -103.13° .—J. B. C.

Two Reactions for Morphine. J. Donath. J. Prakt. Chem. 1886, 563–565.

A SMALL QUANTITY (1mgm.) of finely-powdered morphine is rubbed with 8 drops conc. H_2SO_4 in a porcelain basin, a little potassium arsenate added, and the whole well mixed. On heating the mixture until acid vapours begin to escape, a violet-blue colour is formed which, on further heating, changes to dark-brownish red. On carefully diluting with water a reddish colouration is produced, which, on further dilution, changes to green. If chloroform is shaken with this liquid, the former is coloured violet. Ether acts in the same way. Dehydromorphine mixed with sulphuric acid and potassium arsenate produces a dirty-green colour, on heating a brown, and on dilution with water, a deep green. This latter solution, however, does not colour chloroform. Another reaction of morphine is as follows:—A small quantity of morphine is rubbed with 8 drops of conc. H_2SO_4 . On the addition of a drop of a solution of 1 part KClO_4 in 50 parts conc. H_2SO_4 , a beautiful grass-green colouration is formed, and at the edge of the liquid a faint rose red. Dehydromorphine under the same conditions gives a brownish-green colour.—J. B. C.

On the Diphenylamine Reaction in Milk Analysis. J. Szilasi. Rep. Anal. Chem. 6, 436.

THE author's method is a more rapid one than that of J. Herz. (*Chem. Zeit. Rep.* 10, 172). A little milk is dropped by means of a glass rod into about 1cc. of a solution of diphenylamine; colouration occurs at once or after a time, according to the quality and quantity of the water added to the milk. An addition of 25 per cent. of Buda Pesth water containing 10mgm. N_2O_5 to the litre, is not recognisable by this method, but 5 per cent. of a bad water gives a distinct reaction.—S. Y.

Method of Distinguishing between Genuine and Artificial Butter. C. Virchow. Rep. Anal. Chem. 6, 459.

WHEN butter is in an advanced state of decomposition the limits for the fatty acids, obtained by Meissl's method, and hitherto accepted as correct, are too high. Meissl has taken 25cc., Sendtner 24–25cc., Pirbaum 24–9cc., and the Society of Bavarian Chemists 26cc., of deci-normal caustic soda solution as the minimum. The characteristics of old artificial butter are: Tallow-like or hard consistency, slight smell and taste, the fat when melted remains turbid either permanently or for a long time, and is only imperfectly saponifiable, yielding a very fluid, milky soap; a solution in ether remains clear under conditions in which a similar solution of the fat of genuine butter would give a crystalline precipitate (*stearin, palmitin*). The rancidity is determined by titrating with deci-normal caustic soda and

phenolphthalein, a solution of 5grms. of the melted fat dissolved in 10cc. ether together with 20cc. of absolute alcohol. Samples which have a strong smell of butter, and which do not possess the characteristic properties of artificial butter, if very rancid contain comparatively little free fatty acid. Great rancidity is a sign of considerable decomposition of the glycerides of the so-called volatile fatty acids, and the quantity of butyric acid is lessened by volatilisation or further decomposition of it. Hence, very marked rancidity is a safe indication of old genuine as opposed to old artificial butter. No definite relation between the rancidity and amount of fatty acid could be found. In Switzerland the sale of rancid butter containing much mould and bacteria, is rightly forbidden as "spoilt," but it cannot be condemned as "artificial butter." If greatly decomposed, the rancidity of the sample should invariably be determined.—E. E. B.

Separation of Nickel and Cobalt. Pietro Gucci. Gazz. Chim. 1886, 207.

THE qualitative separation is effected by fusing the sulphides, precipitated by ammonium sulphide and insoluble in hydrochloric acid, with potassium nitrate in a porcelain crucible, boiling the fused mass with water-washing the oxides and treating them on the water, bath with dilute nitric acid (sp. gr. 1.2). The oxide of nickel is rapidly and completely dissolved, and the cobalt oxide left behind.—S. Y.

Determination of Phenol in Crude Carboic Acid. J. Tóth. Zeits. Anal. Chem. 25, 160–164.

THE method employed is a modification of Koppeschaar's (*Zeits. Anal. Chem.* 15, 233), which depends on the formation of tribromophenol, and is as follows: 20cc. crude carboic acid are placed in a beaker and treated with 20cc. concentrated potassium hydrate of sp. gr. 1.25–1.30, well mixed, and allowed to remain. At the end of about half-an-hour it is diluted with water to 250cc. This causes the tarry matters to separate out on the top of the liquid, and they can be easily separated by filtration. The residue is washed with luke-warm water, until the washings have no alkaline reaction. The filtrate and washings are very slightly acidified with hydrochloric acid, and diluted to three litres. The strong dilution is necessary, as the solution for titration must not contain more than 0.1grm. phenol in 25cc. 50cc. of this solution are then decomposed with 150cc. bromine solution (2.04grms. sodium bromate and 6.959grms. sodium bromide in one litre) and 5cc. strong hydrochloric acid. At the end of twenty minutes 10cc. iodine solution is added (125grms. in one litre), and after standing five minutes a little starch solution is added, and the excess of iodine titrated with sodium thiosulphate (9.763grms. in one litre = 5grms. iodine).—G. H. M.

Detection of Salicylic Acid in Beer and Wine. Röse. Archiv für Hygiene, 1886, 127.

IF beer or wine contains only a small quantity of salicylic acid, other substances are removed on shaking with ether, which hide the reaction of the acid with ferric chloride. This error may be diminished by shaking 100cc. beer, which has been acidified by the addition of 5cc. dilute sulphuric acid, in a separating funnel, holding 200cc. with a mixture of equal parts of ether and petroleum-ether. The aqueous layer is drawn off and the ethereal solution poured from the neck of the funnel through a filter into a small flask. The ether and the greater portion of the petroleum-ether is then distilled off, and the hot residue thoroughly shaken with 3–4cc. water. A few drops of a dilute solution of ferric chloride is then added, with gentle shaking, and the liquid filtered through a filter moistened with water, which only allows the aqueous solution to pass through. On addition of the ferric chloride the petroleum-ether is coloured deep yellow, owing to the formation of an iron compound with the resin of the hop. If salicylic acid is absent the

filtrate is almost completely colourless with a very slight tinge of yellow, showing that no trace of tannic acid is taken up. If, however, only a trace of salicylic acid is present, the filtrate is at once coloured the well-known violet. It is possible in this way to detect 0.0001grm. of acid in one litre of beer.

In examining a wine the mixture of ether and petroleum-ether takes up a small amount of tannic acid from the wine. The presence of salicylic acid can then only be detected, provided an extremely small trace of tannic acid is present. It is necessary, if the aqueous solution after addition of ferric chloride shows the tannic acid reaction, to again acidify with sulphurous acid, dilute with water to 50cc., and once more shake with an equal volume of ether and petroleum-ether. If salicylic acid is present the characteristic colour reaction is obtained by distilling off the ether mixture from the second agitation, and adding ferric chloride to the aqueous solution of the residue as before. The tannic acid remains entirely in the aqueous layer in the separator. With red wines containing a quantity of tannic acid 0.0002grm. salicylic acid per litre wine can still be detected.—G. H. M.

On some Simple Methods of Distinguishing between Silver, Nickel, and Tin when deposited in Thin Layers on Metallic Objects. L. Loviton. *J. Pharm. Chim.* **14**, 227.

THE detection of electro-deposited metals by the ordinary methods is frequently difficult on account of the very small quantity present, and the occasional presence of the deposited metal as a component of the alloy on which the deposit is formed. The following methods are recommended by the author:—

I. A small piece of the substance is held in the oxidising flame of a Bunsen burner and the changes of colour of the surface observed.

(1.) *Nickel*: (a), Greyish-yellow colour; (b), violet reflection; (c), blue colour with strong black reflection (characteristic); (d), uniform grey colour with green reflection.

(2.) *Tin*: (a), Faint greyish-yellow colour; (b), light violet-blue reflection, very transitory; (c), grey colour, spotted surface; (d), wrinkled surface with yellow spots.

(3.) *Silver*: (a), Nothing visible to naked eye; (b), small yellow spots; (c), more rapid change to uniform grey with white spots; wrinkled greyish-yellow surface.

II. The object is placed a few minutes in a boiling concentrated solution of common salt.

(1.) *Nickel*: Reddish-blue colour after ten minutes.

(2.) *Tin*: Almost imperceptible, faint grey colouration.

(3.) *Silver*: Unaltered.

Similar results are obtained with hydrogen peroxide to which a little powdered manganese dioxide is added.

III. The object is placed in warm dilute ammonium sulphide.

(1.) *Silver*: The surface is blackened.

(2.) *Tin*: The deposit is dissolved.

(3.) *Nickel*: Unaltered.—S. Y.

New Books.

COMMERCIAL ORGANIC ANALYSIS: A Treatise on the Properties, Modes of Assaying, and Proximate Analytical Examination of the various Organic Chemicals and Products employed in the Arts, Manufactures, Medicine, etc.; with Concise Methods for the Detection and Determination of their Impurities, Adulterations, and Products of Decomposition. By ALFRED H. ALLEN, F.I.C., F.C.S., Public Analyst to the West Riding of Yorkshire, the Northern Division of Derbyshire, and the Boroughs of Sheffield, Chesterfield, Doncaster, Wakefield, etc. Second Edition, Revised and Enlarged. Vol. II.: Fixed Oils and Fats, Hydrocarbons, Phenols, etc. London: J. & A. Churchill, 11, New Burlington Street. 1886.

THE notice of the appearance of the Second Edition of Vol. I. of this valuable work will be found in this

Journal, vol. iv. p. 420. The present issue of the Second Edition of Vol. II. takes the form of an octavo volume, bound in cloth, containing Preface, Table of Contents, and 573 pages of subject matter, Tables of Errata for Vols. I. and II., and an Alphabetical Index. The work is illustrated by seventeen woodcuts. The following concise Abstract of the Contents of this volume will give a sufficiently clear idea of the extent of the ground covered, as well as of the mode of treatment adopted:

GENERAL CHARACTERS OF FIXED OILS AND FATS.—Extraction and Purification of Fixed Oils and Fats; Physical Properties of Fixed Oils and Fats; Constitution and Chemical Properties of Fatty Oils and Waxes; Classification of Fatty Oils, etc.; Examination of Fixed Oils for Foreign Matters; Identification of Fixed Oils; Special Characters and Modes of Examining Fatty Oils, etc.; Examination of Lubricating Oils; Higher Fatty Acids; Soaps; Glycerin; Cholesterin. **HYDROCARBONS.**—Tabular Arrangement of Hydrocarbons in Series; Destructive Distillation; Crude Oily Products of Dry Distillation; Tars; Crude Hydrocarbons of Mineral Origin; Bitumens; Petroleum and Shale Products; Terpenes and their Allies; Benzene and its Homologues; Naphthalene and its Derivatives; Anthracene and its Associates. **PHENOLS.**—Monohydric Phenols; Dihydric Phenols.

REPORT ON EXPERIMENTS MADE TO TEST THE GERMINATION AND GROWTH OF FARM SEEDS IN VARIOUS MIXTURES OF GARDEN SOIL AND BASIC CINDER. By J. M. H. MUNRO, D.Sc., F.C.S., College of Agriculture, Downton, Salisbury. Eight pages 8vo. Middlesborough: *Daily Exchange Office*, 1886.

This report is supplementary to a previous one on the Manurial Value of Basic Cinder, by the author and Professor Wrightson, and contains experiments which tend to show that the popular belief in an injurious influence exercised on vegetation by protoxide of iron in the soil, has no basis in fact. An abstract is given on p. 437.

A SYSTEMATIC HANDBOOK OF VOLUMETRIC ANALYSIS ON THE QUANTITATIVE ESTIMATION OF CHEMICAL SUBSTANCES BY MEASURE, APPLIED TO LIQUIDS, SOLIDS, AND GASES. Adapted to the Requirements of Pure Chemical Research, Pathological Chemistry, Metallurgy, Manufacturing Chemistry, Photography, etc., and for the Valuation of Substances used in Commerce, Agriculture, and the Arts. By FRANCIS SUTTON, F.C.S., F.I.C., Public Analyst for the County of Norfolk; Corresponding Member of the Austrian Apotheker Verein, Vienna; Consulting Chemist in the Norfolk Chamber of Agriculture; etc., etc. Fifth Edition. London: J. & A. Churchill, New Burlington Street. 1886.

OCTAVO VOLUME, bound in cloth, containing Preface, Tables of Contents of the Atomic Weights of the Elements, and of Abbreviations and Explanations, followed by 483 pages of subject matter and eight pages of Alphabetical Index. With the text are interspersed ninety wood engravings. The work is divided into seven parts. PART I. deals with General Principles, Instruments employed, Preparation of Normal Solutions in General and Direct and Indirect Processes of Analysis. PART II. is devoted to ALKALIMETRY: Indicators used; Titration of Alkaline Salts; Alkaline earths; Ammonia; ACIDIMETRY: Estimation of Combined Acids in Neutral Salts, etc. PART III.: Methods of Analysis, mainly based on Oxidation and Reduction. PART IV.: Analysis by

Precipitation; Precision in Colour Reactions; The Colorimeter. PART V.: Antimony, Arsenic, Barium, Bismuth etc.; Chlorine, Bromine, Chlorine Gas and Bleach, Ferro- and Ferrihydrides, Sugar, Phosphoric Acid and Phosphates, Nitrogen as Nitrates, etc. APPENDIX to PART V.: Boric Acid and Borates; Oils and Fats, Glycerin, Phenol, Carbon Disulphide, etc. PART VI.: Analysis of Urine and of Potable Waters and Sewage; Water Analysis without Gas Apparatus; Table of Calculations, etc. PART VII.: Volumetric Analysis of Gases; Gases estimated Directly and Indirectly; Analysis of Air and Carbon Dioxide; Improvements in Gas Apparatus; Simpler Methods of Gas Analysis, etc.

DIE GLYCOSIDE. Von Dr. O. JACOBSEN, Prof. der Chemie an der Universität, Rostock. 1887. Breslau: Verlag von Eduard Trewendt. London: H. Grevel & Co., 33, King Street, Covent Garden.

8vo VOLUME, bound in cloth, containing 174 pages of subject matter, including also an Alphabetical Index and 9½ pages of Bibliographic Notices, giving the entire literature of the subject. This work is reprinted from the *Encyklopädie der Naturwissenschaften*. It commences with a definition, followed by methods for the isolation and purification of the glucosides, next following methods for the artificial preparation of certain glucosides. A concise work of this description, with complete bibliographic notices, seems calculated to render great service to manufacturing chemists interested more especially in dyewood extracts, dyewoods, fine chemicals and the vegetablealoids.

TRADE, TARIFF AND CUSTOMS NOTICES.

(Abstracted from "Board of Trade" and other Journals.)

HOLLAND.—Various changes relating to the quality of foreign "bastard" sugar.

SWITZERLAND.—(Quintal = 220 lbs.). Sulphuret potassium and myrtle wine (colouring) to pay 10 francs per quintal. Phosphate soda, 1 franc per quintal. Bromide potassium-sodium, 2 francs per quintal. Pyrites, duty free. Vaseline, 1 franc 25 cents per quintal. Extract of berries, analogous to syrups (not thickened), with the addition of sugar or alcohol in casks, etc., 16 francs per quintal. Chloride of antimony, 1 franc per quintal. Disinfecting powder, loose or in packets which can be examined, 2 francs per quintal.

ITALY.—Persulphate iron, with traces nitric acid, 2 lire per quintal. Seeds of colchicum, free. Benzene in jars, 36 lire per quintal net weight. Carmine acid saccharated for use as a syrup, 55 lire per quintal. Tannic acid, containing 1 or 2 per cent. impurity, 10 lire per quintal. Todolo (a new antiseptic and disinfecting powder), containing lime and an essence, 10 lire per quintal. Oxide of lead, containing an aniline producing a brilliant red, rendering it similar to cinnabar, 75 lire per quintal. British coal imports are 92½ per cent. of the whole.

SERBIA.—Spirits over 38 per cent. (151°), 50 francs per 100 kilos. Petroleum, 20 francs per 100 kilos; there are deductions according to the kind of packages. Matches, 100 francs per 100 kilos.

SPAIN.—	Per Cwt.

Artificial carbonate of lime, obtained by chemical process, and intended specially for industrial purposes, to pay 6cs. per 100 kilos, asbestos to pay 6cs. per 100 kilos, aurin to pay 3 pesetas (3½d.) per 100 kilos, scidletz powders to pay 1 peseta 85cs. per kilo., bismuth subnitrate to pay 10cs. per kilo., raw caramel, in barrels, same duty as foreign sugar, salicylate of soda (medicinal) 10cs. per kilo.

URUGUAY.—Machinery and plant intended for the manufacture of preserved meats will be exempt from all Customs dues; and, by decree of February 27 last, the proprietors of manufactories must apply for the necessary permit for such free admission to the Ministry of Finance.

TRADE STATISTICS FOR OCTOBER, 1886.

	1885.	1886.
Imports: Total value	£29,677,327	£29,054,399
Exports	18,674,198	18,221,823
Foreign and Colonial produce (partly estimated)	5,467,923	5,339,753
Imports: Chemicals, unenumerated	572,116	413,687
Dye stuffs: Tannins		
Exports: Chemicals and Medicinal Preparations	615,237	604,868

Below are the details affecting Drugs and Chemicals:—

Imports.

	Oct. 1884.	Oct. 1885.	Oct. 1886.
Chemical manufactures and products (unenumerated)	value £ 125,136	108,779	102,722
Alkali	cwt. 5,187	6,187	7,541
	value £ 5,722	5,014	4,578
Brimstone	cwt. 50,927	16,821	20,321
	value £ 12,880	4,559	5,907
Nitre (nitrate of soda)	cwt. 103,598	291,330	78,987
Nitre (nitrate of soda)	value £ 50,313	119,767	34,697
Nitre (nitrate of potash)	cwt. 27,615	31,759	23,038
Nitre nitrate of potash	value £ 24,812	26,099	20,060
Quicksilver	lb. 100,490	154,268	90,075
	value £ 7,505	11,382	8,060
Bark, Cinchona	cwt. 8,591	12,523	9,700
	value £ 69,751	74,251	47,390
Gum Arabic	cwt. 7,571	7,893	6,353
	value £ 22,122	29,166	29,161
Lac, seed, shell, stick, and dye	cwt. 10,438	9,768	11,124
Lac, seed, shell, stick, and dye	value £ 39,918	31,289	20,155
Dyes and tanning materials:—			
Bark (for tanners' or dyers' use)	cwt. 19,897	10,818	42,202
Bark (for tanners' or dyers' use)	value £ 8,079	2,765	18,506
Aniline dyes	" 29,411	22,371	21,649
Alizarin	" 15,201	25,807	19,778
Other coal-tar dyes	" 90	330	—
Cochineal	cwt. 1,087	1,128	1,381
	value £ 6,400	6,988	8,880

Nitre (nitrate of potash)	value £ 70	5,471	271

SPAIN.—That there is plenty of business to be done in Spain is well known, and is proved by the fact that in twenty years German exports to Spain have increased from £117,226 to £3,309,661. During the same period our exports to Spain have decreased from £7,284,633 to £6,831,000, simply because we have had to pay from 20 to 50 per cent. higher duties than the Germans. This unfair discrimination against us is now at an end; besides which, Spain is being largely developed in respect of railways (of which over thirty new lines are being surveyed), mines, and other enterprises. It is quite plain, therefore, that British manufacturers should make every effort to obtain their share of Spanish business.

RUSSIA.—Bicarbonate of nitre (potash) as well as all chemical products mentioned in the text of the tariff, irrespective of degree of purity even though they may be chemically pure, are to be included. A commission is now sitting at St. Petersburg to consider the limitation and control of the output of beet-sugar. The bounty on beet-root sugar is a failure. Russian Phosphorus is said to compete with the British and French article in European markets. The duty is heavy on imported Phosphorus, 114d. a pound, and the Russian manufacturers are estimated to pay 6000 roubles for a quantity yielding 1000 lb. Phosphorus. English manufacturers pay three times that amount, exclusive of carriage. The cost of bones is 104 per cent. in Russia, and 50 per cent. in England of sale price.

ITALY affords a field for the application of skill and enterprise, owing to the enormous waste of sulphur as sulphurous acid from the "calcaroni," and the prospect of economical utilisation in production of superphosphates—since immense layers of 10 to 60 per cent. phosphates are lying near to the sea at Gallipoli. The Italian authorities desire to foster trade whether initiated by foreigners or natives.

UNITED STATES.—"Manure salts" consisting of superphosphates or acid phosphates are to be exempt from duty, as substances expressly used for manure. There are great changes relating to oleomargarine and butter substitutes.

CUBA.—There is an average reduction of 25 per cent. on drugs and chemicals.

FRANCE.—A floating exhibition of French goods will sail from Marseilles *via* Havre, to various ports of South America. A similar undertaking is started at Bordeaux, to visit the West Indian and Northern Coast of South American ports. The port of Calais is now open to imports of mineral oils both raw and refined.

GERMANY.—Extract from a *prices* report from the German Commercial Chambers, on the development of German industry during the last twenty-five years. For facility of comparisons, the first year's product is taken at 100:—

Population	(1860=100 1885=124.1 1861=100 1885=412.5 =371.8 1871=100 1885=602.3 1872=100 1884=133.2 =94.8 1872=100 1884=190.7 =130.2 1866=100 1884=233.3 1872=100 1884=671.1

TRADE WITH JAPAN.—British trade in chemicals has decreased forty per cent. German has increased twenty-five to thirty per cent. In 1885, the consumption of heavy chemicals was—Chloride Lime, 81 tons; Caustic Soda, 675 tons; Carbonate Soda, 314 tons; Soda Ash, 125 tons; Soda bicarbonate, 140 tons; Chlorate Potash, 12 tons; Chromate Potash, 56 tons; Amorphous Phosphorus, 60 tons.

CHEMICAL IMPORTS IN JAPAN.—An Austrian Consular Report gives the following statistics of the imports of some leading chemicals and spices in Japan during the years 1884 and 1885. The quantities are given in metric centners of 100 kilos, and the values in dollars:—

ARTICLE.	1884.		1885.		Of which Value was contributed in 1885 by—
	Quantity.	Value.	Quantity.	Value.	
Acid (carbolic) ..	89.1	3,941	144.2	7,323	England, 100 p. c.

THE GERMAN POTASH INDUSTRY.—The circumstances of the Stassfurt potash trade are satisfactory, and likely to continue so during the existence of the convention now in force between the producers, but what will occur afterwards—that is, in two years—cannot be said. At present seven mines are comprised in the convention, and as three new works will be likely to join when a re-organisation takes place, it is evident that the working of the convention will in future be a very difficult and complicated matter.

The average length of the German working day, intervals of rest deducted, is 11 to 12 hours, but 10 hours is very common. The variations are considerable. Pomerania, 11 hours; Posen, 10 to 11 hours; Hanover and Schleswig-Holstein, 11 hours; Dresden and Bautzen, 11 hours; Zwickau and Meissen, 11 to 12 hours; Leipzig, 10 to 12 hours; Hamburg, 10 to 11 hours. In the Silesian district of Oppeln; 12 hours in blast furnaces, lead, silver and coke works, dyeworks, etc., in mining 12 hours continuous day and night working in 12 hour relays, 2 hours' rest included; Bavaria, 11 to 12 hours.

COMMERCIAL MUSEUMS are established in Austria-Hungary, 2; Belgium, 5; France, 19; Germany, 17; Holland, 3; Italy, 5; Portugal, 2; Sweden, 1; Switzerland, 3. Most of them have expert pattern samples and information bureaux.

THE CONTINENTAL PARCEL POST.—In consequence of the increasing number of parcels posted for Austria, Hungary, Belgium, Denmark, Germany, Heligoland, and Switzerland, a second daily parcel mail will be despatched to Belgium and to Germany and the other countries named, *via* Ostend, from London on the morning of every week-day. There will be corresponding additional parcel mails from the countries in question to the United Kingdom.

OPENING FOR BOTTLE MANUFACTORY.—There is good opening in New Zealand for a manufactory of bottles. The heavy freights and breakages make them cost here, on an average, three times the home price.

IMPORTATION INTO GERMANY OF CHEMICAL PRODUCTS MADE ELSEWHERE ACCORDING TO GERMAN PATENTS.

It appears that complaints have been made in Germany, and lodged with the higher authorities in Berlin, that chemical products made outside the Vaterland, according to German patented processes, are sent into Germany and sold there. The upshot of this plaint has been that the German Chancellor now sends forth a circular, which appeared in the official "Patent-blatt," No. 39, Sept. 29, 1886, directed to the different Courts of the Empire, showing that chemical compounds manufactured abroad according to methods patented in Germany must be considered as infringing these patents, if such chemicals are imported into Germany, and providing that no other process is known for their production. He further shows that, according to the German Patent Law, not only the manufacture of the article, but also its unauthorised sale, constitutes an infringement. The question that would at once arise as to whether the imported article or compound was manufactured under the German patent, or by some other method, is answered by an instruction to the Courts to consider the case proved, if no other but the patented process is generally known. The onus of proof is thrown upon the party charged with infringement, providing that there is no other process known besides the one patented.

It is almost unnecessary to point out that according to such ruling, if a German patent exist for the manufacture of a chemical substance A, and an English manufacturing chemist discover a new method, or employ a new method for making that substance, and choose to work it secretly, and his product A finds its way into Germany, that English manufacturer would be held to have infringed the German patent in question, and it is hard to see how he could clear himself of the charge and its consequences, whatever they might be, except by patenting his method, or else whispering his secret in German ears.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

- 13494 J. Dugdill, jun., Manchester. Improvements in alarm apparatus for indicating the level of water or other liquids. October 22
13565 J. Bonthron and R. B. Bonthron, Glasgow. Improvements in and connected with the admission of air to furnaces, also applicable for other purposes. October 23
13571 J. L. Honnart, London. An improved composition for preventing incrustation in steam boilers. October 23
13605 J. Cooke, Halifax. An improved composition for preventing and removing incrustation and corrosion of boilers. October 25
13671 D. M. Weston, London. Improvements in centrifugal machines. Complete specification. October 26
13687 J. Fyffe, Dundee. Raising liquids by compressed air. October 26
13753 J. Newton, Sheffield. Improvements in construction of furnaces. October 27
13789 F. Siemens, London. A combined evaporating and calcining furnace. October 27

- 13795 E. F. Daniel, London. Improvements in apparatus for drawing off liquids from the surface without removing sediment. October 27
13799 W. G. Gard, London. The manufacture of an improved liquid for preventing and removing incrustation in steam-boilers, and treating the product resulting from such manufacture. October 27
13851 J. H. Selwyn and E. Field, London. Improvements in rotary retorts. October 28
13861 J. Bernhardt, London. Improvements in or connected with apparatus for distilling, condensing, heating, cooling and extracting operations. October 28
13886 C. Blagburn and A. Thomson, London. Improvements in apparatus for distilling water for feeding boilers, for ships' use, and for other purposes. October 29
13917 T. G. MacEwen, London. A new or improved governor for the supply of gas or air. October 30
13919 W. Whittle, Smethwick. Improvements in the construction of condensers or vessels for the condensation of steam, and in the application of certain apparatus connected therewith for obtaining motive power. October 30
13959 J. Howie and T. Groves, Glasgow. Improvements in open kilns. October 30
13962 E. J. Pape, Liverpool. Improvements in and relating to the application of zinc to steam boilers and other structures for the prevention of corrosion. October 30
13964 J. A. Watson, London. An improved silica brick. October 30
14082 J. Conacher and O. L. Williams, London—From A. Conacher, United States. Improvements in refrigerating machines. Complete specification. November 2
14141 R. Cunliffe and J. Lund, London. Improvements in apparatus for calcining, drying, or roasting substances or materials, and extracting gases or acids therefrom. November 3
14162 H. T. Yaryan, London. Improvements in vacuum distillation apparatus. Complete specification. November 3
14190 P. H. Bracler, Liverpool. Improvements in or relating to apparatus for obtaining distilled water. November 4
14225 W. Ferguson and W. Hood, Glasgow. Improvements in and connected with liquid strainers. November 4
14261 H. H. Spotton, London. Improvements in meters for measuring liquids. November 5
14271 G. Burton, Birmingham. Improved draw-off taps for discharging in one stream two or more liquors simultaneously, and in any required proportion. November 5
14349 G. Dietrich, London. An improvement in apparatus for promoting consumption of smoke by means of air and steam jets. November 6
14379 W. Burnell, Liverpool. Improvements in furnace and fire bars applicable to marine boilers and every description of furnace. November 8
14415 E. A. Cowper, London. Improvements in filter-presses. November 8
14437 J. W. Hartley, Stoke-on-Trent. Improvements in triturating mills or cylinders. November 9
14468 E. Piot, London. Improvements in distilling apparatus. November 9
14471 H. E. Newton, London—From T. Main, United States. Improvements in steam generators. November 9
14535 C. A. Sahlstrom, London. Improvements in apparatus for burning oil, tar, and similar substances for generating steam and other purposes. November 10
14556 H. E. Edmunds and J. J. Hicks, London. Improvements in flexible chambers or containers to be used for air, gas, steam, water and other fluids, and as substitutes for pistons and cylinders. November 10
14575 F. Hughes, Cheltenham. An improvement in air-tight stoppers and covers for bottles, jars, pots and the cylindrical or oval apertures of chemical, mechanical, or sanitary appliances. November 11
14603 R. Kron, London. Apparatus for sifting granular or fibrous materials suspended in liquids. November 11
14606 J. Quiri, London. Improvements in refrigerating machines and novel binary liquids to be used therein. Nov. 11
14621 T. English, London. Means of maintaining heat and preventing condensation in the cylinders of steam-engines. November 11
14622 E. Taylor, London. Improvements in and relating to refrigerating machines and to the manufacture of ice. Complete specification. November 11
14613 T. Gilmour, Glasgow. Improvements in feed-heating apparatus for steam boilers. November 12
14616 W. E. Gedge, London—From J. E. Carroll, United States. Improved apparatus for heating and purifying feed-water before its introduction into the boiler. Complete specification. November 12
14649 R. Leigh, Bolton. Improvements in covering and protecting glass carboys. November 12
14680 J. Elliott, London. The employment of centrifugal force in combination with filtering pads for expressing fluids from substances and for compressing and moulding such substances. November 12
14690 A. M. Clark, London—From C. S. Wilcox, United States. Improved means of effecting the consumption of smoke in furnaces. Complete specification. November 12
14709 C. Billington and J. Newton, Longport. Improvements in filter presses. November 13
14710 J. Simpson and E. W. Parnell, Liverpool. Improvements in separating liquids from solids, and in apparatus therefor. November 13
14856 O. G. V. Sternberg, London. Improved means and apparatus for the generation and utilisation of motive fluid. November 16
14858 P. Jensen, London.—From Messrs. Hoy and Bussmann,

Hamburgh. Improvements in fire doors for boiler and other fireplaces. November 16

11873 H. H. Lake, London—From M. Hampford and C. C. Hampford, United States. Improvements relating to the cooling of liquids and to apparatus therefor. November 16

11887 D. George, Birmingham. An improvement in creating a draught in boiler flues or chimneys. Complete specification. November 17

11897 T. Bowen, London. Improvements in means or apparatus for facilitating the removal of mud or deposit from steam boilers or like vessels. November 17

11957 J. Barr, Glasgow. Improvements in and connected with valves for controlling the supply or passage of liquids. November 18

11967 E. O. Cooper and W. T. Cooper, London. Removing and preventing calcareous incrustations in steam boilers. November 18

15006 T. Routledge, London—From A. Abadie, France. Improvements in apparatus or appliances for crushing, grinding, triturating, disintegrating, reducing or preparing fibrous materials, or mineral, chemical, oleaginous or other substances. November 18

15022 J. Thomas, Newcastle-on-Tyne. Thomas's boiler incrustation preventor. November 19

15046 T. Lowe, London. An improved spiral mixing machine for liquidising or incorporating mixable ingredients. Nov. 19

15051 J. Lyle, Glasgow. Improvements in furnaces to be heated by the burning of oils or other hydrocarbon fluids in them, and in fittings or appliances connected therewith. November 19

15076 C. A. Sahlström, Aberdeen. An apparatus for projecting oil or other fuel into furnaces in the form of spray. Nov. 19

15125 F. L. Merritt, London. A retort fire-bar to generate water-gas as fuel in furnaces where the ordinary fire-bar is used. November 20

15132 W. Boggett, London. Improvements in evaporating fluids. November 20

COMPLETE SPECIFICATIONS ACCEPTED.*

1885.

11372 A. Bell. Apparatus for use in softening and purifying water. November 23

15282 R. Hammerschmidt. Apparatus for measuring or dividing liquids or gases under high pressure. November 2

15335 G. S. Ullathorne. Valves, etc., for prevention of waste of fluids. November 2

15898 J. T. Griffin—From J. W. Hatch. Improvements in furnaces and apparatus, and in using solid and gaseous fuel. October 26

15928 G. M. Cruickshank—From A. and G. Roth. Tuyeres for forges or hearths. October 29

15957 J. Easby. Improvements in water and other liquid taps. November 12

16016 T. Hudson. Consuming the smoke from the furnaces of steam boilers or evaporators. October 26

1886.

96 T. Fox. Apparatus for generating and utilising gases. November 16

183 E. White. Means for consuming furnace smoke. Nov. 5

397 H. Stockheim. Improvements in filtration and apparatus therefor. November 9

404 J. L. Sampson and J. Hart. Apparatus for feeding fuel to furnaces. November 12

561 J. M. Stanley. Smoke-consuming fireplaces. Nov. 16

699. C. M. Farrow. Taps for viscous fluids. November 16

737 W. Leggett. Apparatus for indicating the heat in ovens, etc. November 16

1001 A. J. Boulton—From G. A. Heiser. Smoke-consuming furnaces and boilers. November 23

1037 J. L. Wade. Compound for preventing incrustation in boilers. November 23

1793 F. Candy. See Class XVII.—B

2517 F. Candy.

11731 W. H. Twine, A. M. D. Churchill, and H. J. Honour. Cocks and valves for steam, water or other fluids under high pressure. October 26

12077 J. R. Alsing. Triturating cylinders. October 26

12112 W. P. Hoblyn. Smoke-consuming stoves and furnaces. November 2

12986 H. C. F. Storer. Apparatus for washing and absorbing gases and for evaporating liquors. November 12

13133 H. H. Lake—From S. Jonsson. Apparatus for limiting the speed of centrifugal apparatus. November 16

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

13501 A. E. Scott, London. An improvement in the manufacture of candles, combining safety, economy, cleanliness and ease in fitting. October 22

13513 D. C. Caddick and J. F. Wake, Middlesborough. The utilisation of waste ashes from all description of furnace grates, and also breeze or coke-dust in the manufacture of fuel blocks for household, steam and general heating. October 23

13578 H. H. Lake—From G. Godeffroy, Germany. Improvements in the preparation of fuel. October 23

13637 R. Combret, London. Improvement in the manufacture of blocks of artificial fuel. October 25

13674 G. T. Chimney, Newcastle-on-Tyne. Process by which the gases or smoke generated by the burning of mineral oils can be used for heating or lighting purposes. October 26

13752 G. T. Chimney, Newcastle-on-Tyne. Apparatus for inducing complete combustion of mineral oil-gases or smoke, to be used for heating or lighting purposes. October 27

13801 Sir E. Green, London. Improvements connected with scrapers for fuel economiser tubes. October 27

13823 F. V. Hadlow, Buxted. An improvement in the artificial manufacture of coal so as to render it comparatively smokeless. October 28

13824 A. Thomson, Glasgow. Improvements in gas fires. October 26

13897 W. T. Sugg, London. Improvements in apparatus for heating by gas. October 29

13922 W. H. Lindsay, London. Improvements in apparatus for moulding coal-dust or small coal into solid blocks. Oct. 29

13912 J. F. Waldie and R. Stewart, Glasgow. Improvements in washing coal, and in the mechanism and apparatus used therefor. October 30

13985 W. H. Lindsay, London. Improvements in the manufacture of artificial fuel. October 30

14077 J. C. Kent and G. Nash, London. Improvements in an apparatus for lessening the consumption of fuel in ordinary house fire grates, fire baskets, and other similar receptacles, while giving increased heat and perfect combustion. November 2

14097 A. Paget, Loughborough. Improvements in apparatus for producing light from gas by rendering incandescent what are known as "mantles," hoods, cones, cylinders, or coverings. November 2

14107 C. Andoy, London. A method and apparatus for manufacturing fuel blocks in form of bullets. November 2

14111 G. Seagrave, London—From P. Fougeron, jun., France. Improved construction and arrangement of carburetted apparatus, to be called "The Photogene." November 2

14191 H. H. Doty, London. Improvements in oxyhydrogen burners, and in the combustion of mineral oils and other hydrocarbons. November 4

14231 J. H. Johnson, London—From C. Goublier, France. Improvements in candles. November 4

14260 J. F. Wright and G. E. Wright, Birmingham. Waste heat extractors. November 5

14265 R. Stewart and J. F. Waldie, Glasgow. Improvements in washing coal or other material, and in the mechanism or other apparatus to be used therefor. November 5

14319 G. Dietrich. See Class I.

14567 G. E. Davis, Manchester. Improvements in the manufacture of gas retorts. November 11

14556 W. H. Bond, Aberavon. Improvements in gas hydraulic mains for displacing and replacing the seals. November 12

14795 J. F. Wright and G. E. Wright, Birmingham. Improvements in waste heat extractors for gas fires. Complete specification. November 15

14933 A. Cockey and W. Smith, London. Improvements in self-acting safety bye-pass gas valves. November 17

14958 W. Burns. See Class III.

14962 H. N. Box and H. Davison, Manchester. Smoke consuming and economising of heat and fuel in furnaces. November 18

14968 C. Y. C. Dawbarn, Liverpool. The improvement of the materials used in fire-lighters. November 18

15007 C. Estcourt, H. Vevers, and M. Schwab, London. An improved continuous process for the purification of coal-gas from sulphur compounds, by which the sulphur is recovered. November 18

15013 J. Lilley and F. Metgé, London. Improvements in the manufacture of artificial fuel. Complete specification. November 18

15081 H. Barclay and R. Simpson, Harrington Iron Works, Cumberland. A new method of treating coal to separate pyrites, shale, and other impurities therefrom, applicable to other industries. November 20

15125 F. L. Merritt. See Class I

15171 T. Richmond, London—From W. Wills, United States. Improvements in apparatus for the separation of smoke from the gases evolved during the combustion of fuel. November 22

15189 A. J. Boulton—From W. P. Lane and A. M. Sutherland, United States. Improvements in the manufacture of gas. Complete specification. November 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

13967 J. Roots. Rendering a liquid hydrocarbon gaseous. November 12

14771 S. Koerberthaler. Apparatus for regulating the supply of heat to rooms, etc. November 9

15614 W. Menzies. Combination of powdered and liquid fuel for furnaces. November 16

1880.

803 J. G. Dimelow, H. C. Parkin, and W. Stelfox. Improved heating and illuminating gas stove. October 26

9291 R. Ashton. Self-extinguishing candles. November 23

11063 Apparatus for burning liquid fuel. November 19

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

APPLICATIONS.

- 13929 H. Ellison and G. E. Davis, Manchester. A new and improved method for the distillation of coal-tar, the oils from coke-ovens, and other similar fluids. October 30
 14395 J. Hammond, London. Improvements to the method of and in apparatus for the utilisation of gas-tar. November 8
 14840 J. Young, Stoke-on-Trent. Improvements in coal carbonising or distillation. November 16
 14938 W. Burns, Leith. Improvements in the distillation of tar, oil, resin, and fats, and in the manufacture of illuminating and heating gases from liquid hydrocarbons, and in apparatus for that purpose. November 13

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

- 13780 C. D. Abel, London—From The Actiengesellschaft fur Anilin-Fabrication, Germany. Process for the production of azo colours from orthosulpho or orthocarbonic acid of benzidine. Complete specification. October 27
 14253 J. Annabehn, London. Methods or processes of treating oxynaphthol and aniline, or its homologues, obtaining certain products, and utilising the same in the manufacture of dyes. November 5
 14303 H. H. Lake, London—From K. Oehler. Improvements in the manufacture of azo dye stuffs. November 5
 14625 J. H. Johnson, London—From The Badische Anilin and Soda Fabrik, Germany. Improvements in the preparation of yellow, red, and purple colouring matters. November 11
 15146 T. Bang, Leeds. From Dahl & Co., Prussia. Improvements in the manufacture of red azo dye stuffs or colouring matters. November 22

COMPLETE SPECIFICATION ACCEPTED.

1886.

- 43 C. D. Abel—From C. Roth. Production of colouring matters. October 29

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

APPLICATIONS.

- 13497 G. Tolson and J. Illingworth, Batley. Improvements in machine for carbonising wool, rags, and the like. October 29
 13498 G. Tolson and J. Illingworth, Batley. Improvements in machine for carbonising wool, rags, and the like. October 22
 13606 J. Walker, Halifax. Improvements in apparatus for carbonising fabrics composed of animal and vegetable fibres. October 25
 13608 E. W. Serrell, jun., Paris. Improved process and apparatus for preparing silk cocoons for reeling. Complete specification. October 26
 13711 E. Edwards, London—From H. Wolff, Germany. Improvements in the method of and apparatus for treating hemp, flax, and other plants for the purpose of obtaining textile fibres. October 26
 14117 C. N. Waite, London. Compound for preparing starch or flour size for yarn, textile, or other fabrics. Complete specification. November 2
 14200 W. Scott, London. Improvements in the treatment of fibre and manufacture of textile fabrics. November 4
 14367 E. W. Serrell and E. Fougeirol, Paris. Process and machinery for preparing silk cocoons for reeling. Complete specifications. November 8
 14610 A. C. Henderson, London—From La Société C. Vignet, ses fils, et Cie., France. Improvements in the method of and in apparatus for dressing or sizing textiles. November 11
 14647 C. Halter and J. Halter, London. Improvements relating to the treatment of fibre and to the manufacture of imitation straw plait therefrom. Complete specification. November 12

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 15917 F. Candy. Preparation of Fuller's earth. October 29
 15918 F. Candy. Treatment and utilisation of a certain kind of Clay. October 29
 15953 A. Hieronimus. Size or dressing material for textiles and fabrics, and for polishing twine, etc. October 29

1886.

- 181 A. L. Cochrane, A. Cochrane, and W. Cochrane. Heat and drying fibrous and textile materials. November 5
 564 O. Chemin. Treatment of animal fibres to remove vegetable matters therefrom. October 29
 6357 J. Campbell. Method and apparatus for oiling wool and other fibre. November 19
 14755 E. Donner and E. Corssel. Treatment of cocoons preparatory to unwinding the silk therefrom. November 2

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

- 13598 J. Fletcher, Manchester. Improvements in dyeing tissue and other papers, and in apparatus therefor. Complete specification. October 25
 13814 A. Aykroyd, W. E. Aykroyd, and J. Smith, Liverpool. Improvements in aniline black dyeing or printing processes, for obtaining a fast aniline black in textile fibres and fabrics. October 28
 14316 A. S. Young, Manchester. Improvements in apparatus for printing upon calico and other similar woven fabrics. November 6
 14127 D. A. Louis, London. Improvements in bleaching vegetable fibres and tissues. November 9
 14673 E. Hernite, E. J. Paterson, and C. F. Cooper, London. Improvements in apparatus for the preparation of bleaching solutions by electrolysis. November 12
 14698 E. Edwards, London—From E. Decock, Roubaix. Improvements in machinery or apparatus for dyeing skeins or hanks of wool, cotton, jute, flax, silk, or other fibrous materials. November 12
 14971 E. Sutcliffe and G. E. Sutcliffe, Halifax. Improvements in machinery or apparatus for bleaching, damping, and dyeing loose fibre yarns, threads, or other fibrous materials. November 18

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

- 83 W. Bracewell. Apparatus for bleaching kiers. November 2
 359 F. W. Hudson and F. W. Schroeder. Scouring, washing, chroming and dyeing woven or felted fibre. November 9

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

- 15762 W. Bramley and W. P. Cochrane, Redcar. The manufacture of hydrated carbonate of magnesia, and other products. October 27
 14141 R. Cunliffe and J. Lund. See Class I.
 14247 J. B. Hannay, Glasgow. Improvements in the manufacture of sulphuric acid. November 5
 14343 L. Mond, Liverpool. Improvements in or relating to the manufacture of caustic soda or caustic potash from the respective carbonates. November 6
 14344 J. W. Kynaston, Liverpool. Improvements in or relating to the manufacture of chlorate of potash. November 6
 14372 W. Bramley, Middlesbrough-Tees. Improvements in and relating to the manufacture of alkaline carbonates and chlorine. November 8
 14414 W. Burns, Leith. Improvements in the manufacture of sulphuric acid under high pressure, with agitation, and in apparatus for that purpose. November 9
 14710 J. Simpson and E. W. Parnell. See Class I.
 14711 J. Simpson and E. W. Parnell, Liverpool. Improvements in apparatus for use in the treatment of sulphuretted hydrogen for the separation of sulphur, or for the production of sulphurous acid. November 13
 14732 D. B. Hewitt and Brunner, Mond & Co., Limited, Liverpool. Improvements in the manufacture of caustic soda or caustic potash. November 13
 14790 F. Bale, Droitwich. Improvements in the manufacture and production of ammonia, hypochlorous acid, and hypochlorites, and in the apparatus employed therein. November 15
 14875 J. R. Francis and F. F. Jones, London. An improved process and apparatus for obtaining sulphur and other substances from ores, for purifying such substances, and for similar purposes. November 16
 15007 C. Estcourt, H. Vevers, and M. Schwab. See Class II.
 15182 E. P. Alexander, London—From E. J. L. Delsol, France. A process for obtaining mother liquors free from magnesium salts in the manufacture of carbonate of potash by means of the double carbonate of potash and magnesia. November 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 15661 T. R. Shillito—From E. Hänisch and M. Schroeder. Separating substances from phosphate of lime. October 29

1886.

- 17 E. W. Parnell and J. Simpson. Manufacture of carbonate of soda, with production of sulphuretted hydrogen. November 2
 150 T. Robinson. Manufacture of alum and sulphate of alumina. November 9
 150 J. Addie and J. Addie. Production of sulphurous acid gas.
 227 N. Mathieson and J. Hawliczek. Manufacture of bicarbonate of soda and soda ash. November 12
 1050 W. Bramley. Manufacture of carbonates or bicarbonates of sodium or potassium from their sulphates. November 23

- 9276 E. Bohlitz and G. O. Heyne. Separating waste lye containing chlorate of magnesium into hydrochloric acid and magnesia, for producing carbon magnesia for use as a decolorising and disinfecting agent. October 29
 12255 T. Raynaud. Producing hypsulphite of soda. November 23

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

- 14216 A. M. Clark, London.—From E. Weis, Bohemia. An improved process for cutting very thin parts upon glass articles. November 1
 14239 G. Ingram, Wolverhampton. Improvements in the construction of crowns for glass furnaces. November 3
 14288 G. F. Chance, London. Improvements in or additions to machinery employed in the manufacture of sheets of rolled glass. November 5
 14330 W. Boulton, London. Improvements in the manufacture of various articles of pottery, having straight parallel sides. Complete specification. November 6
 14380 A. D. Brogan and A. M. Malloch, Glasgow. Improvements in the manufacture of chequered glass, and in apparatus therefor. November 8
 14727 H. M. Ashley, Ferrybridge. Improvements in the manufacture of bottles, and other articles of glass. November 13
 14779 W. H. Blessley, Middlesborough. The manufacture of iron stoneware. November 18
 15099 J. D. Watson, Glasgow. An improved method of annealing glass or articles manufactured therefrom. November 20
 15141 T. Kilner, Halifax. Improvements in the manufacture of bottle necks, and in apparatus employed therein. November 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 14168 T. Bolas. Imprinting devices on glass, stone, pottery, enamel, etc., which will stand the action of fire. November 5
 15743 H. Standen. Manufacture of glass for sanitary purposes. November 5

1886.

- 358 The Hon. D. Lawless. Producing designs on pottery, glass, etc. November 23
 13132 E. Moore. Improvements in connection with the annealing hear of a flint glass house. November 16

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

- 13511 R. Briggs and others. See Class X.
 13512 F. C. C. Hewett, E. P. Reeve, and W. P. Davis, London. Improvements in apparatus for turning and exposing drugs, grain, cement, and other materials, for the purpose of drying, cooling, or otherwise treating the same. October 22
 13616 R. Scholefield, London. Improvements in or relating to machinery or apparatus employed in the manufacture of bricks, tiles, and other forms. October 25
 13618 R. G. Burstenbinder, London. Improvements in saturating wood. Complete specification. October 25
 13881 W. H. Lindsay, London. Improvements in apparatus for moulding bricks or blocks. October 30
 14312 T. Arnold, Stockton-on-Tees. Improvements in the process of and apparatus for moulding briquettes of cement, or the like material, to be employed for testing the qualities thereof. November 6
 14434 G. Howard, London. Improvements in decorating wood. Complete specification. November 9
 14527 T. Cox, London. The following methods of fixing, without mortar and cements, panels, tiles, bricks, borderings, fillets, cornices, etc., so that they can be fixed to ceilings, frames, walls, etc., so that there are no nails, screws, or cement mortar joints shown on the fronts; to be made with all kinds of clay, slugs, glass, woods, etc. November 10
 14674 W. Scott, C. Swan & Co., W. Whamond, and T. Gibb, London. Improvements in the manufacture or treatment of Portland and other hydraulic cements. November 12
 14972 T. C. Fawcett, Halifax. Improvements in machinery for pressing bricks, brickettes, tiles, and other articles. November 18
 15012 H. Macevoy, H. Holt, L. White, and W. Wilders. Improvements in the manufacture and burning of Portland cement. November 18
 15211 J. Y. Johnson, London.—From E. Coignet, France. Improvements in the preparation and treatment of beton or concrete, and in the apparatus employed therein. Complete specification. November 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 15877 J. Dejaiffe. Process and apparatus for dressing, squaring and polishing stone, etc. November 9

1886.

- 31 W. Joy. Utilisation of the waste heat from cement and lime kilns. October 29
 616 J. Howie. Chambers for drying bricks and clay ware. November 16
 8418 W. G. Woodson and R. Skeoch. Manufacture of bricks, ridge tiles, etc. November 9
 14091 J. C. Anderson. Manufacturing bricks, tiles, etc., from pulverulent materials.
 14629 C. J. Heaton. Manufacture of ornamental cloisonné work, specially applicable to building purposes. October 29

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

- 13481 W. Galbraith, Glasgow. Improvements in the treatment of and in the separation and recovery of iron from phosphatic slags and minerals. October 22
 13483 B. H. Thwaite, Liverpool. Improvements in the pneumatic process of manufacturing steel ingots and castings. October 22
 13502 E. Wheeler, London. Improvements in the production of compound ingots. October 22
 13503 E. Wheeler. Improvements in the production of metal bodies or ingots, and in the method of producing the same. October 22
 13511 R. Briggs, J. Briggs, T. S. Briggs, and R. W. Briggs, London. Improvements in kilns for burning limestone and calcining metallic ores, cement, and other substances. October 22
 13531 A. G. Greenway, Liverpool. Improvements in the manufacture of iron and steel. October 22
 13539 S. Morley, Horsforth, Yorks. Safety of miners after an explosion from the effects of after-damp. October 22
 13562 P. M. Justice, London.—From W. B. Spear, United States. Improvements in and connected with the coating of metal sheets with metal. October 23
 13561 W. Martin, Glasgow. Improvements in and connected with the manufacture of malleable iron. October 23
 13572 W. Banks and S. Brierley, London. A new or improved miner's safety lamp. October 23
 13590 J. Macnab, London. Improvements in safety lamps for miners and other purposes. October 23
 13654 L. Grabou, London. Improvements in the manufacture of fluoride of aluminium, and the double fluoride of aluminium, and an alkali. October 25
 13658 W. Elmore, F. E. Elmore, and A. S. Elmore, London. Improvements in and apparatus for the treatment of tin scrap and the like, and the obtainment therefrom of oxide of tin and oxide of iron. October 25
 13680 B. C. Tilghman, London. Improvements in drawing iron and steel bars through dies, to produce a smooth surface suitable for shafting. October 26
 13682 J. R. Turnock, Loughor. Improvements in machinery for coating metal plates or sheets. October 26
 13686 J. Laidler, Durham. Improvements in safety or miner's lamps. Complete specification. October 26
 13793 E. J. H. E. Whitehouse, London. Improvements in annealing pots. October 27
 13869 H. Levetus and M. Wilkins, Birmingham. An improved metallic alloy. October 29
 13920 T. Nordenfelt, London. Improvements in the manufacture of castings in iron and steel. October 29
 13928 J. E. Baugh and C. Hinksman, London. Improvements in the humid reduction of gold and other ores. October 30
 13938 J. Butler and J. Evans, Manchester. Improvements in and in apparatus for forming moulds in which articles or frames of polyhedral, cubical, or other analogous forms may be formed by casting. October 30
 14009 J. A. Ramsay, London. Improvements in purifying the atmosphere of coal mines. November 1
 14020 J. T. Dunn, London.—From A. Schaag and Messrs. Flurscheim & Bergmann, Germany. An improved method of galvanising iron and steel. November 1
 14022 A. Brin and L. Q. Brin, London. Improvements in and apparatus for the treatment of tin scrap and the like, and the obtainment therefrom of oxide of tin and oxide of iron. November 1
 14061 J. B. Hannay, Glasgow. Improvements in obtaining gold from refractory ores or other auriferous substances. November 2
 14136 E. H. Cowles, London.—From the Cowles Electric Smelting and Aluminium Co., United States. Improvements in separating aluminium from tin, silver, and other metals and alloys. November 3
 14156 A. Wylie, London. Improvements in machinery and appliances for the manufacture of pipes or rods from metallic alloys or compounds thereof. Nov. 3
 14169 T. Nordenfelt, London. In part from C. G. Wittenstrom, E. Faustman, and P. Ostberg, Sweden. Improvements in Bessemer converters and in the manufacture of castings thereby. Nov. 3
 14220 R. W. Lindsay and W. Darwen, London. Improvements in the manufacture of tubes of copper or alloys of copper. Nov. 4
 14258 A. Schmole, Berlin. A method of separating the injurious ferruginous alloys of tin contained in baths of tin in tinning iron articles. Complete specification. Nov. 5
 14281 R. K. Boyle, London. Improvements in and means for electro-plating or coating metallic surfaces with metals. Nov. 5

14297 J. Nicholas, London. An improved method of smelting and recovering metals from ores and dross. Nov. 5
 14398 J. Harris-James, Cornwall. An improved process of crushing and dressing tin and other ores, and improvements in machinery therefor. Nov. 6
 14432 E. C. Ibbotson, Sheffield. An improved system (connected with mining) for the separation of free metals from their ores, or from debris, or from foreign matter connected therewith. Nov. 6
 14333 R. Began, London. Improvements in cleansing tin andterne plates, and in machinery therefor. Nov. 6
 14385 E. Patterson and W. H. Strype, London. Improvements in miners' safety lamps. Nov. 8
 14386 T. H. Rees, London. Improvements in the manufacture of metal tiles, and method of fixing the same in position. Nov. 8
 14397 A. L. Underwood and A. E. Carroil, London. Improvements in the manufacture of steel or malleable castings and forgings. Nov. 8
 14407 O. M. Thowless, London. Improvements in the manufacture of aluminium chloride and in the extraction of aluminium therefrom. Nov. 8
 14405 O. M. Thowless. Improvements relating to solutions for use in the electro deposition of aluminium and to substances for use in the preparation of such solutions. Nov. 8
 14419 J. Morrison, Stockton-on-Tees. An improved blast. Nov. 9
 14559 G. L. Brückmann, London. Improvements relating to the manufacture of iron and steel. Nov. 10
 14568 A. Howat, Manchester. Improvements in electric safety lamps. Nov. 11
 14600 J. E. Bennet, London. Improvements in the treatment of metallic chlorides for the extraction of metals therefrom. Nov. 11
 14612 F. W. Paul, Glasgow. Improvements in making steel. Nov. 12
 14639 J. E. Brooks, Glasgow. Improvements in blast furnace charging apparatus. Nov. 12
 14714 C. Todd, London. Extraction of gold from crushed quartz. Nov. 13
 14760 H. H. Lake, London—From R. de Montgelas, United States. Improvements relating to the preparation of metallic magnesium by electrolysis, and to solutions therefor. Complete specification. Nov. 13
 14772 J. Whitehead, Manchester. An improvement in the manufacture of composite wrought iron and cast steel forgings. Nov. 15
 14799 G. W. Wade, London. An improved blast or exhaust fan. Nov. 15
 14833 C. M. Pielstickier, London. Improvements in machinery for the production of metal plates and bars direct from the molten metal. Nov. 16
 14843 W. Thornycroft, Glasgow. Improvements in the treatment of certain kinds of slag to convert the same into a valuable product. Nov. 16
 14903 J. G. Cranston, Newcastle-on-Tyne. Improvements in machinery for drilling rock, coal, and other minerals. Nov. 17
 14921 A. N. J. Contarini, London. Improvements in safety lamps for coal mines. Nov. 17
 14927. J. R. Whitney, London. Improvements in and connected with "chills" employed in casting metals. Complete specification. Nov. 17
 14928 J. R. Whitney. Improvements in and connected with the casting of metals. Complete specification. Nov. 17
 14952 D. Edwards, R. Lewis, and P. Jones, Swansea. Improvements in apparatus used in coating iron, steel, and other metal plates with tin or other metal or alloys. Nov. 17
 14974 M. Settle, Manchester. Improvements in electric safety-lamps for use in mines and other places. Nov. 18
 14988 P. Higgs, London. Improvements in the amalgamation of gold and other ores. Nov. 18
 15001 A. M. Clark, London—From H. A. Brustlein, France. A process and apparatus for hardening shells and other hollow articles of steel. Nov. 18
 15010 P. Rogers and J. Player, Swansea. Automatic machines for coating metal plates and sheets with tin, lead, or other metals, or any alloys of the same. Nov. 19
 15097 D. P. G. Matthews, Newport. Improvements in and connected with the manufacture of ingot moulds, together with improvements in the treatment when in operation of all ingot moulds at present in use, and apparatus in connection therewith. Nov. 20
 15123 G. C. Sillar and L. S. Powell, London. Improvements in incandescence lamps for use in mines or other places. Nov. 20
 15154 J. T. King, Liverpool—From H. Kennedy, United States. Improvements in the manufacture of mineral wool and in apparatus therefor. Complete specification. November 22
 15205 G. A. Dick, London. Improvements in the manufacture of tubes and rods from copper and certain alloys thereof, and in apparatus therefor. Nov. 22
 15205 B. C. Molloy, London. Improvements in apparatus for amalgamating gold and other precious metals. Nov. 22
 15209 T. Fenwick, London. Improvements in the electro deposition of metals.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

11732 J. Woods. Furnaces for forging. Oct. 29
 15355 J. Spencer and C. Robinson. Apparatus for turning steel ingots or slabs in connection with cogging or rolling mills. Oct. 26

1886.

608 H. F. Dale—From The Tabor Concentrator Co. Ore concentrators. Nov. 9
 785 R. C. de Walcher-Myrdal. Apparatus for facilitating mining and quarrying minerals. Nov. 19
 1027 T. J. Greenway. Separating the precious metals from lead. Nov. 16
 2560 A. T. Davies, T. H. Griffiths, and D. Griffiths. Manufacture of tin and other coated metal plates, and apparatus therefor. Nov. 2
 2816 T. Longmore and J. Tibbitts. Means for forging certain articles of metal, especially applicable in the case of T's, plags, flanges, etc. Nov. 19
 9741 A. J. Boulton—From E. Hamelius. Improvements in cupolas and blast furnaces. Nov. 5
 11089 H. Saek. System of rolls for rolling H and similar iron. Oct. 26
 12302 J. Whitley. Construction of bronze guns and other ordnance. Nov. 9
 12371 W. H. Follett. Plant for casting steel ingots. Nov. 5
 12326 H. H. Lake—From J. Illingworth. Moulds for use in the manufacture of armour plates. Oct. 29
 12541 R. Miller and N. E. Maccallum. Furnaces for the manufacture of steel.
 12636 B. J. B. Mills—From N. W. Perry. Detectors for marsh gas and other hydro-carbon gases. Nov. 5
 13265 E. Walsh, jun. Blast furnaces. Nov. 19

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

13765 J. Stott, London. Improvements in apparatus for straining oil and other analogous liquids. October 27.
 13865 A. Macalister and W. Stuart, Glasgow. The preparation of iodised oil. October 29
 13979 A. G. Wass, London. An improved lubricant. October 30
 14046 F. Walton, Twickenham. Improvements in the manufacture of moulded articles in oxidised oil compounds. November 1
 14053 A. Macalister, and W. Stuart, Glasgow. Improvements in the manufacture of soaps and glycerine. November 2
 14382 H. Mackay, London. Improvements in the preparation of oils for medicinal purposes. November 8
 14629 C. A. Gosnell and C. P. Gosnell, London. Improvements in branding or marking soap. Complete specification. November 11
 14729 H. Mackay, London. Improvements in the preparation of oils for medicinal purposes. November 13
 14835 F. T. Archer, G. W. Hardy, and F. J. Archer, London. An improved lubricating composition. November 16
 14884 A. Macarthur, Glasgow. An improved wash or dip for sheep and other animals, the same being applicable for washing fabrics and other materials. Complete specification. November 18

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

326 C. D. Abel—From The Fabrik Chemischer Produkte Actien Gesellschaft. Preparation of lanolin and anhydrous lanolin from waste liquors of wool washing and from wool fat. November 9
 419 J. G. Johnson—From C. L. Baillard. Preparation of oils for treating wool, and the manufacture of soap, lubricants, and mordants. November 19
 510 A. Brimstein. Method and apparatus for obtaining alizarin oil from oleaginous seeds. November 23
 1026 R. Hutcheson. Manufacture of lubricants. November 16
 1113 R. Park and J. E. Park. Manufacture of soap. October 26
 4625 T. B. Harrison. A wash or compound for cleansing painted or other articles. October 26
 11138 T. Berliner. Method and apparatus for extracting fat from bones. October 29

XII.—PAINTS, VARNISHES, AND RESINS.

COMPLETE SPECIFICATION ACCEPTED.

1886.

11688 H. Mason. Varnish for boots and shoes. October 26

XIII.—TANNING, LEATHER, GLUE AND SIZE.

APPLICATIONS.

13636 T. Palmer, London. Improvements in purifying and graining hides and other skins, and in apparatus employed therein. October 25
 13775 C. J. Palmer, London. Killing the lime, fat, grease, and other deleterious compounds in hides, kips, or skins. October 27
 13833 J. R. Tussaud, London. Improvements in obtaining the separation of wool, hair, feathers, or other covering from the skins of animals, and in securing the same in position when separated. October 28

14683 J. W. Aborn and J. Landin, London. An improved method of tanning hides and skins. November 12
14916 E. A. Brydges, London. Treating and preserving hides and skins. Complete specification. November 17
15200 H. H. Lake, London—From A. Millochau and F. Chailly, France. An improved process of tanning. Complete specification. November 22

XIV.—AGRICULTURE, MANURES, ETC.

APPLICATIONS.

14301 H. H. Lake, London—From Terceclin, Briart, & Co., Belgium. Improvements relating to the manufacture of chemical manures. November 5
15019 D. Smith, Inverness. An improved self-feeding kiln fire apparatus for drying corn, using the husks as fuel. November 19

XV.—SUGAR, GUMS, STARCHES, ETC.

APPLICATIONS.

13566 W. T. Crooke, London. Improvements in the method of cleansing pockets or bags employed in the manufacture of sugar, and in the means employed therefor. October 20
14117 C. N. Waite. See Class V.

COMPLETE SPECIFICATION ACCEPTED.

1886.

1820 L. Cuisinier. A new diastase saccharine substance, and method of making the same. October 26

XVI.—BREWING, WINES, SPIRITS, ETC.

APPLICATIONS.

13678 J. Bonthorne and R. B. Bonthorne, Glasgow. Improvements in the washing of malt for brewing and distilling, and in the machinery therefor. October 26
13738 H. H. Lake, London—From J. W. Free, United States. Improvements relating to the manufacture of malt, and to apparatus therefor. Complete specification. October 26
14079 F. Faulkner and W. Adam, London. Improvements in vessels for use in brewing beer, porter, and other like malt liquors, and applicable also for use in the manufacture of vinegar and other like analogous processes. November 2
14092 G. P. Wheeler and F. Ritter, London. An improved non-alcoholic beverage. November 2
14191 J. H. Woodward, London. Improvements in apparatus for drawing off and aerating wort, in the manufacture of vinegar, and in brewing and other like and analogous processes. November 4
14257 J. Williamson, Glasgow. Improvements in preparing yeast for the better preservation of the same. November 5
14302 A. G. Fraser and G. Epstein, London. Improvement in the treatment of distillers' and brewers' worts. November 5
14342 A. J. Boulton, London—From C. F. Elze, Germany. Improvements in beer refrigerators. Complete specification. November 6
14360 S. Fulda, London. Improvements in preserving and clarifying ale, beer, porter, stout, cider, cordials, water and other sweetened and unsweetened, fermented, and unfermented beverages and liquids. November 6
14390 Messrs. Gottsmann Brothers, London. Improvements in or relating to the refining of lager beer. November 8
15175 J. C. Mewburn—From L. Teilliard. See Class XX.
15188 H. H. R. Jensen, W. B. Mears, and J. Brunt, London. Improvements in the treatment of yeast. November 22

COMPLETE SPECIFICATION ACCEPTED.

1886.

783 D. A. F. Bang and M. C. A. Ruffin. Process and apparatus for the purification of alcohol. November 9

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

APPLICATIONS.

A.—CHEMISTRY OF FOODS.

13734 E. Serrant, London. Manufacture of a biscuit bread. October 26
13742 H. H. Lake, London—From P. B. Rose, United States. The manufacture of an article of food. Complete specification. October 26
13758 J. Marshall and T. A. Marshall, Glasgow. Improvements in preparing a nutrient or digestive and medicinal substance from malt. Complete specification. October 27
13955 H. Stockman, North Sunderland. Improvements in the processes of curing articles of food and disinfecting. October 30

14285 R. Low, London. Improved mode of preparing food from cereals. November 5
14391 B. J. B. Mills, London—From S. S. Serrier, Belgium. An improved apparatus and process for making coffee. Complete specification. November 8
14472 S. Pitt, London—From J. M. Hughes, United States. A new and useful mixture of salt and phosphate of lime for table use as a condiment for seasoning food. Complete specification. November 9
14610 S. French, London—From T. J. Richman and A. M. Plumb, United States. A process for extracting butter from milk, and for manufacturing butter. November 12

B.—SANITARY CHEMISTRY.

13791 P. A. Ames, London. Deodorising sewage in large quantities at its outfall, known as the "Ames" process. October 27
13829 F. Candy, London. Improvements in the manufacture of materials for use in the treatment of sewage in order to the separation or removal by precipitation or otherwise of the matters in suspension and solution in the water thereof, and in the clarification and purification and deodorisation and decoloration by precipitation or otherwise of other polluted water, and certain other liquids. October 28
14138 T. Hewson, Leeds. A cheaper and better means of destroying or rendering innocuous by fire the combustible refuse of towns usually collected by local authorities. November 3
14221 T. Donnithorne, London. Improvements in the treatment of sewage. November 4
14109 A. Forrest and W. Walsh. Machines for drying and powdering blood, sewage, etc. November 2
14820 G. H. Leane. Use of carbon in the compression of sewage sludge. November 2
530 J. C. Bothams. Apparatus for extracting sewage sludge from tanks in which it is precipitated. November 19
775 C. Blagburn. Vessels for carrying sewage, etc. Nov. 23
907 A. Howatson. Methods of arranging plates, etc., in vessels for separating solid impurities from liquids. Nov. 23

C.—DISINFECTANTS.

14684 H. E. Harris, London. Improvements in the method of applying and manufacture of antiseptic, disinfecting, curative, and healing agents. November 12
15201 J. Watt, London. An improved deodorising material. Complete specification. November 22

COMPLETE SPECIFICATIONS ACCEPTED.

A.—CHEMISTRY OF FOODS.

1886.

9322 F. P. Warren. Improved food for animals. November 9
14732 A. B. Lester and A. Meaby. Preparing malted wheat and other cereals (barley excepted), and employing them in the manufacture of food. November 9

B.—SANITARY CHEMISTRY.

1885.

15861 F. R. Conder. Application of iron compounds for the purification of water, and other sanitary purposes. November 16
15895 C. D. Abel—M. M. Rotten. Apparatus for purifying effluent waters from factories, sewers, etc. November 5

1886.

1793 F. Candy. Filtering media for the purification of liquids and gases. October 29
2517 F. Candy. Filtering materials and precipitants. October 29
8871 J. Bannehr. Treating sewage and other polluted waters. November 2
9276 E. Bohlilg and G. O. Heyne. Process for manufacturing carbon magnesia from lyes of magnesium chlorate, for cleansing spent lyes and sewage and rendering same innocuous. October 29
12075 G. E. Leane. Apparatus for filtration of sewage, etc. October 29

C.—DISINFECTANTS.

1886.

591 T. Bradford. Disinfecting, and apparatus therefor. November 16

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

13515 E. J. Houghton, London. Improvements in charging accumulators by dynamo machines. October 22
13529 R. Oakley, London. Improvements in apparatus for filling and emptying the cells of batteries. October 22
13591 M. Bailey and J. Warner, London. An improved method of preventing the escape of noxious fumes from batteries used for electrical purposes. October 23

13592 M. Bailey and J. Warner. Improvements in primary batteries. October 23
 13618 W. H. Johnston, London. An improvement in the manufacture of carbons for electrical and other purposes. October 25

13665 G. Quarrie, London. Improvements in and apparatus for producing electricity for lighting, motive power, and other purposes. October 26

13712 A. M. Clark, London—From the Electrotechnische Fabrik, Caunstatt, Germany. An improvement in dynamo-electric machines. October 26

13910 G. Quarrie, Liverpool. Improvements in or relating to the production of electricity and apparatus therefor. October 29

13987 J. G. Statter, S. L. Branton, and J. W. Kempster, London. An improved collector or brush for dynamo-ormagneto-electric machines or motors. October 30

14033 C. D. Abel, London—From Messrs. Siemens and Halske, Germany. An improvement in electrolysis. November 1

14101 A. B. Holmes and J. C. Vaudrey, London. Improvements in frictional gearing for driving dynamo electrical machines. November 2

14211 G. Sengrave, London. Improvements relating to the preparation under partial vacuum of organic substances, in order to render them capable of being electro-plated. November 4

14269 R. E. B. Crompton, London. Improvements in galvanometers. November 5

14280 W. H. Tasker and T. J. Jones, London. Improvements in voltaic batteries. November 5

14286 A. Wunderlich and O. Eisele, London. A new or improved galvanic battery. November 5

14345 H. Tudor, Liverpool. Improvements in electrodes for accumulators or secondary batteries. November 6

14352 J. Wolicka, London. Improvements relating to the armatures of dynamo-electric machines and electro-motors. Complete specification. November 6

14398 L. Bollmawa, Vienna. Improvements in dynamo-machines and electric motors. November 8

14408 O. M. Thowless. See Class X.

14521 J. J. C. Rappard, London. Improvements in dynamo-electric or magneto-electric machines. November 10

14533 J. S. Sellen, London. Improvements in secondary batteries. November 10

14673 E. Hermite, E. J. Paterson, and C. F. Cooper. See Class VI.

14757 W. Lahmeyer, London. An improved dynamo-electric machine. November 13

14760 H. H. Lake—From R. de Montgelas. See Class X.

14765 C. Lever, London. Improvements in dynamo-electric machines and electro-motors. November 15

14937 M. Bailey and J. Warner, London. An improved method of preventing the escape of noxious fumes from batteries used for electrical purposes. November 17

15039 G. Hookham, Birmingham. Improvements in dynamo-electric machines with slotted armatures. November 19

15031 G. Hookham. Improvements in the commutators of dynamo-electric machines. November 19

15202 L. Grabat, London. Improvements relating to the smelting or reduction of ores and similar materials by means of electricity, and to apparatus therefor. November 22.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

13422 W. A. Barlow—From M. Sappey. Galvanic battery and apparatus for automatically supplying liquids thereto. November 2

13594 J. P. Reeves and T. D. C. Parker. Voltaic batteries. November 5

13951 G. Tolman and H. Deaton. Dynamo-electric machines. November 16

15268 C. J. Bosanquet, W. Cameron, and W. A. Tomlinson. Appliances for regulating the electro-motive force of currents and the speed of motors. November 9

15421 O. E. Woodhouse, F. L. Rawson, J. H. Davies, and E. J. Moynihan. Apparatus for measuring electric resistances. November 23

1886.

335 D. G. FitzGerald. Voltaic batteries. November 9
 611 O. Imray—From A. Khotinsky. A secondary voltaic battery. November 16

1054 J. H. Noad and R. Matthews. Improved formation of plates with composition for electric batteries. November 23
 7028 G. F. Rose. Primary electric batteries. November 2
 12169 G. C. Tricker. Dynamo-electric machines. November 12

XIX.—PAPER, PASTEBOARD, ETC.

APPLICATIONS.

13533 A. Schmidt, London. Improvements in the manufacture of certain kinds of fancy paper. October 22

13827 B. Makin, London. An improvement in fitting cylinders with blades used in the process of macerating materials for pulp in the manufacture of paper, millboards, and kindred products. October 28

13855 G. Bodlander and J. ranbe, London. Improvements in the manufacture of copying paper. October 28

14271 W. Rogers, Liverpool. Improvements in the preparation or treatment of paper for copying written letters, documents, and the like, and chemical preparation or compound therefor. November 5

14300 A. G. Hehre and O. G. Hehre, London. Method of and machinery for pressing paper pulp into long ornamental and other mouldings. Complete specification. November 5

14580 H. A. Perry, Brighton. Sizing paper hangings, or varnishing same. November 11

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

13770 S. Travado, London. Toilet purposes called the "Oriental aromatic salts." October 27

14617 O. Imray, London—From the Society of Chemical Industry, in Basle, Switzerland. Manufacture of the ethylether of a new acid. November 11

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 12.—VOL. V.

DECEMBER 29, 1886.

Non-Members 30/- per annum; Members
21/- per Set; Single Copies 2/6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S. ..	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S. ..	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.

COUNCIL FOR YEAR ENDING JULY, 1887.

President: David Howard.

Vice-Presidents:

Sir I. Lowthian Bell, Bart., F.R.S.	Sir H. E. Roscoe, M.P., F.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
Dr. Peter Griess, F.R.S.	E. C. C. Stanford.
Dr. Ferdinand Hurter.	J. C. Stevenson, M.P.
E. K. Muspratt.	John Williams.
Dr. W. H. Perkin, F.R.S.	Philip J. Worsley.

Ordinary Members of Council:

John Calderwood, F.R.S.E.	John Pattinson.
Eustace Carey.	S. A. Sadler.
R. Forbes Carpenter.	Sir Bernhard Samuelson,
Henry Doulton.	Bart., M.P.
Dr. John Evans, F.R.S.	Sir Chas. Tennant, Bart.
S. H. Johnson.	Lewis T. Wright.
Ivan Levinstein.	

With Sixteen Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

NOTICES.

The supply of copies of the Journal for January, 1887, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of that number, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the number will be reprinted.

Members are hereby advised that the Subscription of 25s. for 1887 is now due, and should be paid as early in the year as possible. Cheques and orders should be made payable to Mr. E. Rider Cook, and forwarded either to him at the East London Soap Works, Bow, E., or to the General Secretary.

Authors of communications read before the Society or any of its Local Sections are requested to take notice that, under Bye-Law 43, they cannot receive the prescribed 50 copies of their communications unless they comply with the condition laid down in that Bye-Law—viz., that they give notice of their desire to receive such copies upon their manuscript before sending it to the Editor. Mention should also be made as to whether the Discussion is to be included in the reprint.

CHANGES OF ADDRESS.

H. Rumby, 1/o Ebbw Vale; Solway Iron Works, Maryport, Cumberland.
A. C. Claudet; Journals to 5 and 6, Coleman Street, London, E.C.
C. S. A. Collyns, 1/o Barton Street; 47, Park Street, Greenheys, Manchester.

Hon. Local Sec. and Treasurer: Thos. Tyler,
Garden Wharf, Church Road, Battersea, S.W.

The meetings of the London Section will be held on the first Monday in each month.

SESSION 1886-87.

Prospective Arrangements.

Jan. 3.—Mr. Watson Smith, "On the Explosive, 'Kinetite.'"
" Mr. J. W. B. Mumford, "Some Notes on Grinding and Separating Hard Substances."
Feb. 7.—Mr. W. Jago, "On Fermentation in its relation to Bread Making."
" Mr. J. Maclear, "A New Method of Elevating Liquids, especially applicable to Acids."
" Mr. C. Napier Blake, "Notes on the Stassfurt Industries."

Notices of Meetings and Papers will be found in the Scientific Journals.

Notices of papers and communications to be made to the Local Secretary.

Meeting held December 6, 1886.

THE PRESIDENT IN THE CHAIR.

ON THE MANUFACTURE OF HYDRATE OF STRONTIUM.

BY E. F. TRACHSEL.

HYDRATE OF STRONTIUM has only been manufactured in quantities during the last few years, the demand for it having sprung up through its use in the making and refining of beet-root sugar, and in the extraction

of crystallised sugar from molasses. Its advantage in the manufacture of sugar from the beet is derived from the fact that it is possible by its usage to obtain a pure white sugar direct from the beetroot, whilst in refining beetroot sugar it has been found to be far superior to lime. As for the extraction of crystallised sugar from molasses, lime alone is not sufficient to separate the crystallisable sugar from the uncrystallisable sugar and the various salts contained in the molasses, unless alcohol be used in conjunction with the lime.

Oxide or hydrate of strontium, on the contrary, effects this separation without the aid of alcohol, and it is here that its principal advantage is found. It is the tendency of oxide of strontium or its compounds with water—viz., monohydrate of strontium and hydrate of strontium—to combine with sugar by forming saccharates easily decomposed by carbonic acid, which renders it useful for the purposes mentioned.

It is not my aim to give a full and exhaustive account of the manufacture of hydrate of strontium in all its details, but to put before you a general view of the subject, supported by the description of some of the processes used. The minerals at our disposal for the manufacture of hydrate of strontium are: The native carbonate of strontium, or strontianite, found chiefly in Westphalia; and the native sulphate of strontium, or celestine, the chief supplies of which are in Sicily and in Gloucestershire. The native carbonate of strontium is converted into oxide by being burnt in kilns similar to lime-kilns, care being taken to raise the temperature of the charge as high as possible, the carbonate of strontium parting with its carbonic acid with much more difficulty than carbonate of calcium does. The resulting oxide of strontium is dissolved in boiling water, the solution clarified and allowed to crystallise, when hydrate of strontium crystallises out. The manufacture of hydrate of strontium from the sulphate is of a more complicated nature, and has been attempted in different ways. One process consists in boiling the finely-powdered mineral with a solution of carbonate of sodium, when carbonate of strontium and sulphate of sodium are formed. The carbonate of strontium is then burned as before described, being mostly made into bricks with the addition of sawdust. The sulphate of sodium can be reconverted into carbonate by the Leblanc process.

Another process consists in furnacing together a mixture of sulphate of strontium and carbonate of sodium, with the production of carbonate of strontium and sulphate of sodium.

In a third process, carbonate of ammonium is used to convert the sulphate of strontium into carbonate, the conversion being accomplished in closed vessels provided with a stirring apparatus. All these processes, however, are indirect, inasmuch as they only yield carbonate of strontium, which has to undergo the operation of calcining in order to turn it into oxide of strontium. I have therefore devised and patented the following process, which does away with this disadvantage, and which, provided it is carried out in a rational manner, and with the aid of the improved apparatus now at our disposal in the domain of manufacturing chemistry, bids fair to supersede the indirect methods previously mentioned.

In order to give you a clear view of the process, it might be well to put before you the reactions on which it is based.

1. Sulphide of strontium solution when treated with caustic soda yields hydrate of strontium and sulphide or sulphydrate of sodium thus:—

It will be seen that the second formula is most advan-

tageous, as it used only half the quantity of soda, and it is this the proportion adopted by me.

2. Sulphydrate of sodium (as also sulphide of sodium) is converted into carbonate by treatment with carbonic acid, sulphuretted hydrogen being given off—

3. Carbonate of sodium treated by caustic lime yields caustic soda and carbonate of lime, the presence of sulphydrate of sodium in the liquor, if any, not interfering with the reaction.

We have here all the elements for a complete and continuous process, the carrying out of which I will now endeavour to describe. The sulphate of strontium as it comes from the mine is passed through a crushing apparatus (fluted rollers, disintegrator, or such like), preferably mixed with the necessary quantity of coal, which I found best as 7cwt. of coal to 20cwt. of sulphate. The mixing of the coal beforehand ensures a more uniform mixture of the two materials. After passing the crushing apparatus, the mixture of sulphate of strontium and coal is calcined in a furnace (either a so-called plus-pressure furnace or a revolving furnace), when the sulphate of strontium gives off its oxygen to the coal and is converted into sulphide of strontium, the conversion taking from three to four hours, according to the heat attained in the furnace, the fineness of the material, the character of the coal, and divers other circumstances. After reduction the mixture is carried to the lixiviators, which are of different designs, the following arrangement being one of the simplest. A round or square vat made of boiler plate is provided, at the distance of about 6in. from the bottom, with a removable grating of iron bars: on this grating a filter is spread, which can consist of sugar bags. Fragments of brick or other suitable material are placed on the top of this filter, to protect it from the action of the red-hot charge drawn from the furnace. In the middle of the grating a cast-iron pipe is fixed in an upright position, passing through the grating but not quite touching the bottom of the vat, and bearing on the top a flat or umbrella-shaped plate, between which and the pipe an interstice is left for the escape of the liquor which is forced up by the steam entering through a steam pipe placed in the centre of the cast-iron pipe at the bottom of the vat, over which it projects several inches.

In these lixiviators the charges of sulphide of strontium, as they come from the furnace, are covered with boiling water or weak liquor from a former operation, as the case may be, and the steam is turned on, which not only keeps the liquor boiling but also circulates it energetically, the steam forcing the liquor, which has percolated through the false bottom, upwards in the cast-iron pipe, when it falls back upon the charge. After the liquor has attained a strength of 24° Twaddle it is allowed to settle and then run off to the crystallising tanks, where it is treated with a strong solution of caustic soda. This causes the greatest part of the hydrate of strontium to fall down at once, another quantity crystallising out on cooling. The mother-liquor, which consists chiefly of sulphydrate of sodium, is drained off the crystals and run into the evaporating pans, where it is concentrated to about 30° Twaddle, and then run into other crystallising tanks. In these tanks the mother-liquor is allowed to cool, whereby it deposits practically all the hydrate of strontium still held in solution. After cooling, the mother-liquor is transferred to the carbonators, in which carbonic acid gas of as great a strength and purity as possible is forced through it.

The crystals of hydrate of strontium are dried and washed in hydro-extractors and twice recrystallised,

which makes them ready for packing. This repeated crystallising is connected with a serious loss, caused chiefly by the formation of carbonate of strontium during the dissolving and the crystallising in the tanks, and I have succeeded in making one crystallisation sufficient to get pure crystals by the following treatment. The impure hydrate of strontium, after being once dried and washed, is thrown into a muffle furnace, where it is gently heated and stirred about in the meantime. During this operation part of the water of crystallisation is driven off, the double sulphide of iron, which chiefly causes the discolouration of the crystals, is oxidised, and any sulphide of strontium retained in the crystals is changed into sulphite, sulphate, and hyposulphite, whilst a small part of the hydrate is converted into carbonate, through the action of the carbonic acid of the atmosphere. This carbonate, together with the carbonate already contained in the crystals, is sufficient to throw down all the iron, now in the state of oxide, when the furnace product is dissolved in boiling water. The impure crystals of hydrate of strontium contain before this treatment about 37 per cent. of oxide of strontium, and I found it best to continue the heating until the mass shows a percentage of from 60 to 70 per cent. of oxide of strontium. After the furnace product is dissolved in boiling water, the solution is clarified and allowed to cool, and the crystals after going through the hydro-extractor are ready for packing. It will be seen that this simple treatment of the crystals not only dispenses with one crystallisation and the losses connected therewith, but that it also is the means of turning over the crystals in a much shorter time, which, from a manufacturer's point of view, is important. It is the means of doing in six days what otherwise would require a fortnight. I must now return to the mother-liquor of sulphydrate of sodium. Through this mother-liquor, as I have stated before a current of carbonic acid gas is forced which, acting on the sulphydrate of sodium, turns it into carbonate of sodium, whilst sulphuretted hydrogen is given off.

It has been proved by others that sulphide of sodium is decomposed by an equivalent of carbonic acid, so that I need not dwell upon this part of the process particularly. I may, however, observe that by using strong solutions of sulphydrate of sodium, as I always do, the action of the carbonic acid is so energetic that the liquor becomes quite hot, and that if the conversion is carried far enough the whole mass on cooling becomes one solid lump of carbonate of sodium.

The sulphuretted hydrogen is passed through a Claus-kiln, which contains a layer of hydrated oxide of iron or of manganese, and at the same time a small quantity of air is blown through the oxide sufficient either to turn the sulphuretted hydrogen into sulphur and water, or else into sulphurous acid and water. The operation presents no difficulty, even with dilute gases, and it is possible to recover nearly all the sulphur either in the elementary state or as sulphurous acid capable of being used for the manufacture of sulphites or of sulphuric acid. It is best to keep the carbonators warm, so as to prevent a crystallisation of carbonate of sodium in them, and when the conversion of the sulphydrate of sodium is deemed to be sufficient the liquor is run into the causticiser to be causticised by lime in the well-known manner. It is, indeed, not necessary to continue the treatment of the sulphydrate of sodium liquor until the whole of it is converted into carbonate of sodium, because, as I have mentioned before, the presence of sulphydrate of sodium in the liquors does not interfere with the causticising. The liquor, after having been causticised, is again used in the first part of the process, thus

making it possible to use the same quantity of soda over and over again, and rendering the process a continuous one by which all the sulphate of strontium is converted into hydrate of strontium.

DISCUSSION.

Mr. B. E. R. NEWLANDS : The author had said that it was impossible to remove glucose from sugar by lime alone. That was a mistake, because lime would remove every trace of glucose. He should like to hear more from the author on the rapidly developing uses of strontia. It was very interesting to see a substance like strontia, formerly regarded as of very little use, become so intimately connected with a large and important industry. It was more interesting still to sugar refiners to know that their old friend lime was being rapidly displaced not only by strontia but by another competitor, baryta. Baryta was generally regarded as "very poisonous," and strontia had been also described as "poisonous"; but with regard to the latter, he could answer for it that small animals, such as mice, could take it without any ill effects. Therefore he considered strontia as far preferable to baryta for sugar refining. Baryta, however, had recently been introduced into the Paris sugar refineries, and he expected that the public analysts here would have something to say about it before long. He had tested sugar refined by means of baryta in conjunction with phosphate of ammonia, and had found it quite easy to detect traces of baryta in sugars so manufactured. It would be very desirable that public analysts should have their attention drawn to this subject. Had the author succeeded in getting a complete reduction of his sulphate of strontium? He himself had experimented with it some years ago, and had found great difficulty in getting a reduction beyond 60 per cent. If one-third or thereabouts of the sulphate were lost in working, that would make a serious difference in the expense of the process. He would like to know also, if the process had been used commercially.

Mr. J. MACTEAR, before discussing the paper, drew the attention of the meeting to a remarkable fact in connection with strontia and baryta processes for recovering sugar from molasses. In such processes a considerable proportion of the sugar underwent a change of character, and came out of the solution in needle-shaped crystals. These needle crystals polarised 108 per cent., and this appeared to have a higher sweetening power than they really possessed. Difficulties have constantly arisen in France in estimating the sugar present in them; the sugar merchant naturally objecting to pay for 108 per cent. when he gets only 100 per cent. In the paper just read, Mr. Trachsel had described a reaction which did not actually take place. The reaction which really does take place is not between caustic soda and strontium sulphide as such, but between caustic soda and strontium sulphhydrate in a mixed solution of strontium hydrate and strontium sulphhydrate. The process described by Mr. Trachsel being based on the reaction between caustic soda and a solution of strontium sulphide, was much the same as that patented in connection with baryta by Brooman in 1863. As now proposed, the process appeared to be a very ingenious one and ought to work well. But he thought that the author should alter his statement of the decomposition so as to include the water which played a part in it, since it was an undoubted fact that directly one treated sulphide of barium or strontium with water it split up into nearly equal portions of hydrate and sulphhydrate, and that the reaction with the caustic soda was with the sulphhydrate of strontium, and not with the sulphide.

Mr. W. B. GILES said he had had some experience with the various methods of producing strontium hydrate alluded to by Mr. Trachsel. In the first place, he had tried on a large scale the decomposition of strontium sulphate by carbonate of sodium, and had found it go very well. It took very little more than an equivalent of carbonate of sodium to decompose an equivalent of finely-ground native celestine. He had also worked on a considerable scale a process for treating native strontium sulphate by carbonate of ammonium. The method consisted in passing gas liquor fresh from the tower through Bristol celestine. The carbonate of strontium thus obtained was very pure. It was intended for pyrotechnic use, and the flame it gave when converted into nitrate was far superior to that obtained by means of carbonate of sodium. He had noticed a curious fact in respect of nitrate of barium, in the manufacture of which soda had been used. He had taken a considerable quantity of that body and had recrystallised it six times successively in distilled water, and had found the last crop of crystals to contain apparently as much soda as the first. He had never seen this fact noticed; though, doubtless, the same experience had occurred to others.

Mr. SULMAN wished to ask Mr. Trachsel a few questions about his process, especially with respect to carbonating the sodium sulphhydrate liquors obtained as a by-product. The commercial success of the process would depend largely on the practicability of utilising this sodium sulphhydrate again and again in a continuous round of operations. He feared it would be found too expensive to carbonate this residual sulphhydrate by carbonic acid derived from lime-kilns. It had been attempted also to use waste gases from furnaces for the carbonation of these liquors; but the oxidation which took place was so great as to convert a large proportion of the sodium sulphhydrate into sulphate and hyposulphite. He feared, therefore, that this proportion of the sodium hyposulphite must be regarded as lost, as it could not be causticised, and that this probable loss would have a most important bearing upon the future of the process.

Mr. TRACHSEL, in reply, said that, in the first instance with respect to the comparative values of lime, baryta, or strontia processes for the extraction of sugar from molasses, he had said in his paper that the superiority of the strontia process consisted in the fact that it did not require the use of alcohol, whereas in all lime processes the use of alcohol was absolutely necessary.

Mr. B. E. R. NEWLANDS observed that that statement was right so far as the extraction of the salts was concerned, but no further.

Mr. TRACHSEL thought his argument was proved by the fact that, so far as he was aware, no lime process was in actual use which did not in some way include the use of alcohol.

Mr. B. E. R. NEWLANDS rejoined that the Steffen process did not require alcohol, and that that process was in actual work on a large scale at Cologne.

Mr. TRACHSEL replied that if such were the case it would materially affect the value of his strontia process. He had not spoken of other processes for the purification of sugar, for the simple reason that they did not appear to come within his limits. He knew that several new processes had been started recently and were, he believed, going well. It was always the case that, when a new chemical process for getting a particular result was started and succeeded well, other processes sprang up in a short time and attained the same result more or less successfully. With respect to his own process, he could say

that several manufacturers were already working it, and, as far as he knew, successfully. Someone had inquired whether the decomposition of strontium sulphate into sulphide was complete. That depended very much on the temperature of the furnace, and also on the fineness of the material treated. The specimen of sulphate handed round during the reading of this paper showed that, though the mineral as a whole was rather friable, the individual crystals were pretty hard. The rapidity and completeness of the reaction depended entirely upon the degree of fineness to which the mineral was ground.

Mr. NEWLANDS inquired to what extent the decomposition was possible?

Mr. TRACHSEL replied up to about 90 per cent.

Mr. CRESSWELL asked whether a high or low temperature was preferred?

Mr. TRACHSEL replied that he preferred a high temperature.

Mr. NEWLANDS observed that he understood that coal was mixed with the sulphate, and that then a 90 per cent. reduction was got.

Mr. TRACHSEL said that was correct; and the better the coal the better were the results. The process had been used for about six months, and, from a chemical point of view, was quite successful. He was not, however, in a position to go further into details at that moment. Mr. Maclart had combated his statement of the reaction which took place between strontium sulphide and caustic soda. No doubt practically it was as Mr. Maclart had said; but chemically regarded he thought that when strontium sulphide was dissolved in water the reaction was really:

There would always be found a small quantity of hydrate in excess of the sulphhydrate, and he thought it was this small excess which gave the initial movement to the decomposition. [Some further discussion ensued upon this point, and it eventually appeared that Mr. Trachsel and Mr. Maclart were at one on the subject.] Mention had been made of a process for the decomposition of sulphate of strontium by carbonate of sodium. He knew that such a process had been tried, but believed it had been dropped because it was found impracticable to regenerate the sodium carbonate for use again. He had been asked if the decomposition of his residual sulphhydrate of sodium by carbonic acid was really profitable. He was quite aware that the decomposition of sodium sulphide by carbonic acid had been often attempted and often patented. But it had always been proposed to start from solid sulphide of sodium. Now it was practically impossible to obtain solid sulphide of sodium on a large scale. The late Mr. Weldon had tried to manufacture carbonate of sodium in this way; and his best endeavours had failed, not because of the difficulty of the decomposition, but because of the difficulty of getting the sulphide. In the strontia process that difficulty did not occur, for the sulphide of sodium was ready made to their hands. It had been suggested that flue gases might be used as the carbonating agent; but he did not think that would be profitable. The gases contained at most about 12 per cent. of carbonic acid, and lime kiln gases contained about 24 per cent. He thought it would be found of great advantage to use the latter, as the decomposition would be not only more rapid but more complete also.

Mr. NEWLANDS inquired whether, seeing that Mr. Trachsel had shown them by one of their reactions which he had formulated on the blackboard that strontic hydrate was practically insoluble in water, and strontic sulphhydrate very soluble, it would not

be practicable to run off the supernatant liquor and use the hydrate at once?

Mr. C. T. KINGZETT said that by his reference to the experiments of the late Mr. Walter Weldon, he supposed the author to mean the experiments in obtaining carbonate of soda from sulphide of sodium which he had conducted at St. Helens on Mr. Weldon's account many years ago. They had roasted salt cake with fine coal in a muffle furnace, obtaining a very impure sulphide of sodium. Carbonic anhydride was passed through a solution of this sodium sulphide in water, and the result was that they obtained about 90 per cent. of sodium hyposulphite, and only about 10 per cent. of sodium carbonate. This result was probably due partly to the unavoidable admission of air into the muffle, and partly to the presence of air with the carbonic anhydride.

Mr. TRACHSEL explained that even if hyposulphite were present with the soda used to decompose the strontium sulphide, it would make no difference in his process, since a double decomposition would take place—viz., $\text{SrS} + \text{Na}_2\text{S}_2\text{O}_3 = \text{Na}_2\text{S} + \text{SrS}_2\text{O}_3$, which latter would immediately decompose into $\text{SrSO}_3 + \text{S}$, therefore any hyposulphite present or formed would be rendered harmless.

NOTE ON THE VOLUMETRIC ESTIMATION OF NITROUS ACID.

BY A. G. GREEN AND F. EVERSHED.

IN the *Chemical News*, vol. xlix. p. 173, A. G. Green and S. Rideal describe a process for the volumetric estimation of nitrous acid by means of aniline. Although the results obtained by this process are very accurate, it is somewhat too tedious, and requires too much care in manipulation to be generally available for technical purposes. In the modification now to be described, we have greatly simplified and shortened the operation by substituting normal for decinormal solutions. The employment of the diazo-reaction for the estimation of nitrous acid instead of an oxidation process has the great advantage, apart from its accuracy and convenience, that most oxidisable substances which may also be present are not affected. In fact by this means nitrites may be determined under conditions which would entirely preclude an oxidation method.

The normal aniline solution contains 93grms. of pure aniline (freed from water by redistillation), and about 450cc. of hydrochloric acid in 1 litre. Of this solution, 25cc. is placed in a small stoppered bottle, together with a little ice. The solution of the nitrite (about normal) is run in from a burette, with continual agitation. From time to time a drop is taken from the bottle and mixed on a white slab or dish with a drop of a solution of potassium iodide and starch. The immediate production of a blue colour indicates the presence of nitrous acid. When this point is reached, the bottle, with stopper replaced, is left to stand, surrounded with ice. If after some minutes another testing shows that the nitrous acid has been taken up, another drop is added from the burette, and so on, until there is an excess after the solution has stood for an hour. In testing with the starch solution, account must only be taken of the colour which is produced *at once*, as, on standing, the drop almost always becomes coloured even when no excess of nitrous acid is present. By the quantity of the nitrite solution used, omitting the last drop, its value in HNO_2 or NaNO_2 is indicated.

We have not found time to test the process directly, but we have compared its results with those given by a slight modification of the improved

permanganate process described by Kinnicutt and Nef in the *American Chemical Journal*, vol. v. p. 388, and reprinted in the *Chemical News*, vol. xlviii. p. 274. For this purpose a portion of the same nitrite solution was diluted to one-tenth the strength, and 10cc. of this solution placed in a flask with 40cc. of water and a drop of ammonia. A considerable excess of decinormal permanganate (about 25cc.) was run in, then immediately 10cc. of pure concentrated sulphuric acid, then decinormal oxalic acid in slight excess, and lastly, permanganate, until the solution had a permanent pale pink colour, due to an excess of 0.02—0.05cc. A correction was made for this excess, and for an impurity in the sulphuric acid, which, in blank experiments, reduced about 0.1cc. of permanganate. The quantity of oxalic acid used was then deducted from the corrected quantity of permanganate, and the percentage of nitrite thence calculated. The following results were obtained by the two processes:—

DISCUSSION.

The CHAIRMAN said the method now described by the authors appeared to him to be a very good modification of the original process for testing nitrites.

Mr. CROWDER asked whether the authors considered this method was an improvement upon the old permanganate test for vitriol in the chambers. It seemed to him to be very difficult to hit the mark with this new method of testing, whereas any boy in the laboratory could use the permanganate of potash test.

Mr. EVERSHED replied that the advantage of using the aniline test instead of the permanganate test consisted in the fact that the former was much more accurate. Permanganate of potash would oxidise other substances besides nitrites; and in many instances there might be impurities present which would cause the results to appear higher than they really were. It was of course quite possible that the permanganate test might be equally or more suitable as the aniline test for vitriol, especially if used with modifications introduced by Messrs. Kynaston and Rideal. But he thought the ordinary permanganate test would be found to give somewhat varying results, and to be altogether unsatisfactory where accuracy was required.

Mr. J. W. LEATHER asked how long it was considered necessary to allow between adding the different portions of the nitrite from the burette, as that was a matter of importance.

Mr. EVERSHED replied that he was not aware that it mattered. So soon as the nitrite had disappeared more was added. It was often a matter of guess-work. One would get perhaps 80 or 90 per cent. of the nitrate run in, and then find a blue colour produced. He would leave it for a few minutes, and if it were not then all absorbed he would leave it again. If it stood for a considerable time—say half an-hour—and still did not give a blue colour, one might consider the thing done. He did not pretend that the test was an absolutely accurate one.

Thanks were given to the authors of all the papers for their contributions.

Meetings will be held at the Chemical Laboratory, Brownlow Street, on Jan. 5, Feb. 2, March 2, April 6 (Annual Meeting), and May 4, and the following papers have been promised:—
Mr. James W. Westmoreland, "On the Determination of Sulphur in Pyrites."
Mr. V. C. Driffield, "On Boiler Management."
Dr. George Archbold, "On the Manufacture of Starch."
Mr. G. Watson Gray, "On the Estimation of Tin in Wolfram Ores."
Mr. A. Norman Tate, "On Melting Points."

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

A Meeting was held in the Chemical Theatre of the University College, Brownlow Street, on Wednesday evening, December 1, 1886.

PROFESSOR CAMPBELL BROWN PRESIDING.

ON HEISCH AND FOLKARD'S PYROMETERS.

BY F. HURTER, PH.D.

THE Publication Committee asked me to report upon a new pyrometer by Messrs. Heisch and Folkard, with a view to insert a notice of the instrument in our Journal.

I have had considerable experience with many varieties of pyrometers, or "high temperature thermometers," as they are now called, the old name having got into bad repute. There is hardly any phenomenon caused by increase of temperature which has not been made the basis of a pyrometer. We have great choice. We have contraction pyrometers and expansion pyrometers in great variety; we have dissociation tension and vapour tension pyrometers; optical and acoustical pyrometers; thermo electric and electric resistance pyrometers; but in spite of this choice a good pyrometer is still wanted. Those who interest themselves in pyrometers will find a valuable paper on the subject in *Dingler's Journal*, 225, 272, by Dr. Fischer, and several papers on special instruments in our Journal, vols. iii. and iv.

Dr. Fischer's conclusion is that the most practical pyrometer now known is the calorimetric pyrometer, and the best pyrometer is Siemens' electric resistance pyrometer. I quite agree with him from the scientific point of view. But from a practical working man's point of view, Siemens' electric pyrometer is too troublesome to keep in order, and vastly too expensive. It is a good instrument for an investigator; but it is very little use in works. A new modification of it has been proposed by Spohr (*Dingler's Journal*, 257, 315), who substitutes an induction coil and telephone arrangement for the voltameter or galvanometer of

Siemens' instrument; but I doubt whether the instrument so modified has any claim to being an improvement on the galvanometer arrangement. For the working man there is nothing yet but the calorimetric pyrometer, and the ordinary differential expansion instrument, unless Mr. Murrie's thermometers prove satisfactory.

The calorimetric pyrometer—the only one at present known which will give satisfactory results at all temperatures—has, I believe, been first described in this country as a technical instrument by Mr. Wilson, of St. Helens. One form of the instrument is also sold and known as Siemens' pyrometer. Another modification of it is described as Fischer's pyrometer, in the "Alkali Makers' Pocket Book." It is so well known that I refrain from describing it.

The calorimetric method requires, however, the use of tolerably extensive tables, or rather tedious calculations, if the temperature must be labelled correctly, as Professor Dittmar expresses himself—*i.e.*, if the temperature must be given in a number corresponding to one of the recognised scales.

For working purposes I have always dispensed with labelling the temperatures correctly—*i.e.*, I take no notice of the variations in the specific heat of the metal or the water into which it is plunged. I am thus enabled to make a little slide rule arrangement which saves all calculations, and thus makes the calorimetric method available for the working men, many of whom could not be trusted to make the calculation. It must, however, never be forgotten that by neglecting the variation in the specific heat, great differences arise between the real and the apparent number of degrees. At higher temperatures the results are much too high; at lower temperatures than the one for which the specific heat is the correct one, the results are much too low.

Professor Codazza proposed a method by which the troublesome calculation of the temperature with the variable specific heat of metals is avoided. The method consists in making with the same calorimeter two experiments, using two pieces of metal of different weight. Starting with the same initial temperature of the calorimeter, the final temperatures will be different, say t and t_1 , because the quantities of heat Q and Q_1 , transferred by two pieces of different weight p and p_1 , will be different, although the temperature T of the pieces of metal before being plunged into the calorimeter is the same. If c is the mean specific heat between T and ordinary temperature, we should have—

$$Q = c p (T - t) \text{ and } Q_1 = c p_1 (T - t_1)$$

By elimination of c we obtain—

$$T = \frac{Q p_1 t_1 - Q_1 p t}{Q p_1 - Q_1 p}$$

$$Q p_1 - Q_1 p.$$

The method is ingenious, but in my hands has not given satisfactory results.

As trustworthy as the results are, as inconvenient is the calorimetric method. In the first place, observations can only be made at intervals of at least thirty minutes. An iron cylinder of 50 grms. takes nearly half-an-hour to assume the temperature of the furnace. In large apparatus, where changes of temperature within that period are not noticeable, this is of no consequence, but in very small apparatus, with only a few tons of mass, this length of time becomes an objection when the operation to be carried out in the apparatus is at all delicate. Moreover, the frequent calorimetric determination of the temperature becomes a tedious business, and makes one long for a self-indicating instrument where a temperature has to be kept within narrow limits. I consequently use, in conjunction with the calorimetric method, an ordi-

nary expansion pyrometer, made of metallic rods, on the Gauntlet principle. We often extemporise these arrangements, using part of the apparatus itself. For instance, when ascertaining the temperature of superheated steam, we use a straight length of the steam pipe itself as the expanding metal.

Much has been said against these ordinary metal pyrometers. They have been expected to do too much. A range beyond red heat is usually marked on their dial, leading to the belief that they may be used to any degree. They are utterly worthless while new; they are ruined by any temperature close to visible red heat; but up to 900° F. they are not bad. My experience has shown me that newly-drawn metal rods rapidly change, undergo some kind of annealing, but after some time give tolerably uniform results. But every time they are cooled they require resetting. It is the cooling which spoils them.

By means of these two kinds of pyrometers I have hitherto managed to solve all technical problems requiring a knowledge of temperature, the expansion

FIG. 1.—HEISCH AND FOLKARD'S AIR PYROMETER.

pyrometer indicating constantly the direction of the change and the calorimetric pyrometer giving a reliable record of the actual temperature.

It would be a great boon if we had a pyrometer which would combine both these properties—*i.e.*, which would indicate correctly and continuously.

It is generally accepted that the air pyrometer is the only one which would do that with certainty. Many forms of air pyrometers have consequently been constructed, but not any of them have been able to find their way into workshops. Dr. Fischer, who mentions most of these air pyrometers, came to the conclusion that for technical purposes air pyrometers are generally inapplicable.

I also have designed and tried various forms of air pyrometers, but have abandoned them all. I use one in the laboratory occasionally of similar form to that described in our Journal, vol. iv. 45, by Mr. Beilby. For checking other pyrometers I simply

insert into the air-bath or oil-bath in which the pyrometer is to be tried a glass tube sealed at one end, drawn out at the other. When the temperature has become constant I seal up the capillary end of the glass tube, note the barometer, open under mercury, and ascertain thus the volume of air left in the tube. The rest is a simple calculation. But for works' purposes I had to abandon air pyrometers.

I looked with sceptical eyes on the new air pyrometer of Messrs. Heisch and Folkard, of Brentford. It consists of a bulb *a* (see Fig. 1) which contains rarefied air, and which, by means of a fine capillary, is connected to a mercurial vacuum gauge *b*. (At a temperature of 40° F., at which the bulb of the instrument on the table was sealed, the vacuum was 94mm. of mercury). When the bulb *a* is heated the rarefied air begins to exert a greater pressure and the mercury rises in *b*. The space above the mercury is as perfect a vacuum as can be made. The novelty and the great feature of this instrument is the use of rarefied air and a vacuum gauge. By these means Messrs. Heisch and Folkard have succeeded in reducing the dimensions of the gauges to reasonable limits. In

lation of the degrees is tedious, and is not worth the trouble. Mr. Folkard therefore constructed another instrument on similar principles, but in which the air is always at constant volume. This instrument (Fig. 2) is also before you. Mr. Folkard lent it me for the occasion. He calls it his standard thermometer. The method of keeping the air at constant volume is simply this: The same length of column of mercury is always supported by the pressure of the air in the bulb, but this column is inclined, and as the temperature increases, the mercury is not allowed to move upwards, the inclination of the pressure tube is altered so as to keep the mercury exactly at the same point. The pressure exerted by the mercury is proportional to the length of the column multiplied by the sine of the angle of inclination. By means of a movable vertical scale *c* the length of a vertical column of mercury which would exert the same pressure as the inclined one can be readily read off; thus angular measure and references to trigonometrical tables are avoided. The instrument is simple enough, but would not answer as a practical pyrometer. By means of it the

FIG. 2.—HEISCH AND FOLKARD'S STANDARD THERMOMETER.

the instrument before you, the whole range from 0° to 1000° F. is only 17 centimeters long, and as you see the degrees are equally divided, the sensitiveness is equal throughout the range. Of course where a larger degree is required it is only necessary to make the gauge longer and not to exhaust the bulb so much. But I find that for all my requirements, a range from 16 to 20mm. per 100° F. is sufficient, and this is obtained with a vacuum of from 90 to 110mm. at ordinary temperature. The theory of this instrument has been published, I believe, in 1875, by Pfandner as a special case of differential thermometers, but not having access to the journal in which his paper is published, I do not know whether Pfandner really made any practical proposal in this direction. I have found no indication of such a vacuum pyrometer elsewhere.

If the air in the bulb remained at constant volume, which it does not, the degrees of the instrument would be theoretically all equal, but as the air in displacing mercury from the gauge expands, the degrees become somewhat smaller theoretically for the higher temperatures than for the lower ones. The exact calcu-

technical instrument can be graduated. In the first instrument I made I found that the graduations so obtained differed from the graduations calculated on the assumption that the air was at constant volume so little, that I was induced to calculate dimensions of an instrument such that the deviations should remain less than, or amount at the outside to, two per cent., so that by substituting the calculated scale for the real scale I should commit no greater error than 20° F. in 1000° F. I find that with a pressure tube of 2mm. bore and a bulb of 30 to 40cc. capacity, with a vacuum of 100mm. mercury, the deviation is less than two per cent. provided that all noxious space, excepting that of a very fine capillary connecting tube, is avoided. I thus succeeded in making the instrument so that I can calculate the scale, which is readily done by the ordinary formula:—

$$\frac{Pt}{Po} = \frac{275 + t}{275}$$

where *Pt* is the pressure corresponding to temperature *t* in Centigrade, *Po* the pressure at zero and $\frac{1}{275}$

the coefficient of expansion of air in glass. There are various little errors, but the whole of them may, for technical purposes, be neglected. Whether a temperature is labelled 980° or 1000° is, for technical purposes, immaterial.

Now, as to the performances of this instrument. I had one which I heated at intervals of several days for some hours to 500° F., simply to ascertain whether it would change its zero. Within six months it has not changed visibly. Then the next question was, At what temperature will the glass bulb collapse? Clearly a glass tube will not stand a temperature much higher than 1000° F. I have had one of these instruments made of ordinary test tube glass at 900° F. for 24 hours; it has not collapsed and has not changed its zero. I consider that Messrs. Heisch and Folkard have provided us with an instrument which is applicable in many cases, and which, if properly made, is reliable and labels temperatures tolerably accurately, even if a calculated scale is adopted instead of empirical graduations. For scientific purposes I would prefer an instrument with open gauge, but for works the very small length of the gauge is its recommendation. The instrument is, of course, fragile and rather difficult to transport, but it is not expensive, and should not cost many shillings. But for higher temperatures we shall still have to use the calorimetric method, unless Messrs. Heisch and Folkard see their way to substitute a different material for the glass bulb, which, I am afraid, they will find very difficult.

IVAN LEVINSTEIN, ESQ., IN THE CHAIR.

THE MANCHESTER JUBILEE EXHIBITION.

THE CHAIRMAN, referring to Sir Henry Roscoe's remarks at the opening meeting, with regard to the forthcoming Jubilee Exhibition in Manchester, and to the section of the exhibition in which the members are more particularly interested—viz., that devoted to chemical and allied industries, said that all the large amount of space kindly allotted to this section by the Executive Committee had been applied for. Indeed it had been found impossible to entertain all the applications that had been received. It might be expected, therefore, that that section would not be behind any other section in the importance and interest of its exhibits. Marvellous progress had been made in the erection of the elegant structure which is intended for the exhibition. On looking carefully over the ground and the drawings he was strongly impressed with the belief that it would be a very great pity, after the successful termination of the exhibition, to break up these commodious and well-constructed

buildings, which appeared so admirably adapted for conversion into a great technical institute in conjunction with a technical museum and dépôt for samples and patterns of goods required by foreign nations. A comprehensive and thoroughly-well equipped technical institute, supported by a first-class teaching staff, and guided by a chief of real attainments, experience, and high position in science, would be, in his opinion, of the greatest value to the many branches of industry established in this neighbourhood. The utilisation of the exhibition buildings for such a purpose as that which he suggested would confer everlasting fame on the Jubilee Exhibition of Manchester.

ON THE DEVELOPMENT OF BLACK SPOTS ON PAPER IN WHICH WOOLLEN GOODS HAD BEEN WRAPPED.

BY WILLIAM THOMSON, F.R.S.E.

THE black spots in question appeared as if they had been caused by ink, most of them having a perfectly definite outline; there were some, however, round which there appeared a faint brownish tinge. Some of the spots were cut out and macerated in water for comparison with an equal weight of unstained paper which was similarly treated. The black spots gave a much more distinct acid reaction than the unstained, and this reaction was due to sulphuric acid. This led me to suppose that the black spots might be due to free sulphuric acid which had got spirted on to the paper, and which on drying had charred it. Experiments were made with sulphuric acid of different strengths, put in a similar manner on the same paper and heated, but the black spots thus formed were very different in character from those in question. They had a much more strongly acid reaction to litmus paper, besides being different in appearance, and in their behaviour towards reagents.

On treating one of the spots in question with nitric acid, the black colour disappeared, giving place to a greenish colour, and on adding ammonia a deep blue was at once developed. Some of the spots were cut out and an equivalent quantity of the unstained paper taken for comparison; both were burned to ash, which was then dissolved and tested: a large quantity of copper was found in the stained parts, whilst none was contained in the unstained portions.

The questions now arose, How did the particles of copper oxide which originally existed in the paper get there? and then, How did that greenish oxide become converted into a black compound? It was evident at first that the paper was free from black spots, but when some woollen goods were wrapped in them the black spots gradually developed. I found, on putting a piece of bibulous paper containing lead acetate among the woollen materials, that the paper soon became brownish-coloured and ultimately black by the sulphuretted hydrogen which was liberated from the wool, and it seems clear that the objectionable smell which new woollen materials possess is due in some degree, if not entirely, to the liberation from them of sulphuretted hydrogen or of some volatile organic sulphides. Possibly the use of sulphurous acid in the bleaching process tends to the formation of some sulphur compounds, which slowly decompose, yielding sulphuretted hydrogen, or somewhat similar substances.

The particles of copper oxide have evidently come from the oxidation of some brass buttons which had been left on some of the rags introduced into the rag machine during the manufacture of the paper, as it was only a comparatively small portion of this paper which was thus affected. The pale greenish particles of copper oxide were not easily seen at first, but

when the sulphuretted hydrogen from the woollen goods came in contact with the copper oxide, it formed the sulphide of copper, and so brought into existence these mysterious black spots. Part of the sulphuretted hydrogen thus arrested was evidently converted into sulphuric acid, which gave the acid reaction to litmus paper.

DISCUSSION.

Mr. H. GRIMSHAW: I should like to ask Mr. Thomson how he accounts for the copper spots in the paper?

Mr. W. THOMSON: The only reason than can be given for the copper spots being on the paper, is that some of the rags which had been used had had some brass buttons on them, and in the process of manufacturing the paper the surfaces of the metal oxidised and produced oxide of copper, which got mixed with the paper, and it was not observed until the paper was used for wrapping up the woollen goods, when the sulphuretted hydrogen came in contact with it, converting the oxide into sulphide of copper, and so developed the spots.

CHLORIDE OF SULPHUR: ITS PROPERTIES AND REACTIONS, WITH ESPECIAL REFERENCE TO ITS USE AS A VULCANISER, AND ITS ANALYSIS.

BY CHAS. A. FAWSITT.

THE discovery of Parkes, in 1846, that indiarubber could be vulcanised by merely immersing it for a few seconds in a solution of chloride of sulphur in bisulphide of carbon, gave birth to the manufacture of chloride of sulphur. Although its consumption is small it is nevertheless an article of great importance to the indiarubber manufacturer, who in very many instances has little idea of its properties. For this reason I thought that a few notes which I had gathered might be of interest to this Section, in which the rubber industry is so strongly represented.

I shall (1.) briefly describe the different chlorides of sulphur supposed to exist, and the commercial varieties.

(2.) Show that their decomposition by water is not as simple as is generally supposed.

(3.) Mention the principal uses of chloride of sulphur, with special reference to its employment as a vulcanising agent.

(4.) Describe a method for the estimation of the sulphur and chlorine in the chlorides of sulphur.

Firstly, There is evidence to show that three distinct chlorides exist: Sulphur monochloride, S_2Cl_2 ; sulphur dichloride, SCl_2 ; sulphur tetrachloride, SCl_4 . It is the first and second that we have to deal with more particularly to-night.

Sulphur monochloride, S_2Cl_2 , is a yellow liquid, having a sp. gr. 1.7044 at 0° C., and 1.6822 at 15.5° C., boiling at 136–137° C. at 755mm. I arrived at these numbers after bestowing great care on the samples taken, and they are the mean of several determinations. This chloride is a well-defined stable compound.

Sulphur dichloride, SCl_2 , is a dark red, unstable compound existing in the pure state only at temperatures below 10° C. It has, according to Dumas, sp. gr. 1.62, but no constant boiling point.

In the *Phil. Mag.* 1871, 309, Thorpe and Dalzell state that a dark red liquid, supposed to be a mixture of S_2Cl_2 and SCl_2 , is obtained by passing chlorine into the monochloride, and which on heating begins to boil at 64° C., but that the temperature gradually rises until it reaches 136° C., where it remains stationary. I repeated this experiment and found

that by heating the flask in an oil-bath cautiously the liquid began to boil at 49° C., and gave off 10 per cent of a distillate under 64° C. A naked flame causes more rapid dissociation. Sulphur tetrachloride, SCl_4 , exists only at 22° C., and its properties have not been well determined.

Perhaps some of you may have noticed in a patent taken out by Parkes, in 1846, that mention is made of solid chloride of sulphur; now, as no solid chloride of sulphur is known to exist, I think the substance referred to must have been oxy-tetrachloride of sulphur, $S_2O_3Cl_4$, which no doubt, with the imperfect apparatus in use at that time for the manufacture of chloride of sulphur, would be produced in considerable quantity.

In commerce, the term "chloride of sulphur" comprehends all the kinds usually sold, and samples of which you have before you. The only difference you will notice on looking at them is one of colour, which varies from pale yellow to dark red. We will now inquire as to the difference in their composition and properties. Nos. 1, 2, 3—i.e., the light coloured varieties—have approximately the same properties and composition; they differ in colour slightly, and this is accounted for by their different modes of preparation. The following are their specific gravities referred to water at 15.5° C.:

No. 1 = 1.6820
No. 2 = 1.6826
No. 3 = 1.6816

The boiling points vary very little from one another:

No. 1 = 136–137° C.
No. 2 = 136–137°
No. 3 = 135–137°

Below you have a boiling point determination in full of No. 2, which will show you how little the temperature varies, and serve as a comparison for that of the dark varieties (100cc. taken; first drop 132° C.):—

10cc. thermometer in vapour	135° C. ..	in liquid	136.5° C.
20	136	..	137.0
30	136.5	..	137.5
40	136.5	..	138.0
50	136.5	..	138.0
60	137.0	..	139.5
70	137.0	..	—
80	137.0	..	—
90	137.5	..	—

An analysis of Nos. 1 and 3 gave the following numbers:—

	No. 1.	No. 3.	Calculated S_2Cl_2 .
Sulphur	47.33	48.30	47.41
Chlorine	52.09	51.27	52.59

You will notice that No. 3 contains 48.3 per cent. of sulphur, being 1.1 per cent. above the calculated quantity, but as this sulphur cannot be removed by distillation, it cannot be termed free sulphur. From the above numbers—i.e., those from specific gravity, boiling point, and analysis—you will see how nearly these varieties approximate to S_2Cl_2 .

Now as regards the darker varieties, Nos. 4 and 5, the numbers for specific gravity will be:—

No. 4 = 1.671 at 15.5° C.
No. 5 = 1.657 ..

Occasionally for special purposes this variety is prepared as low as 1.640.

This dark chloride has not a fixed boiling point, as you will see from the numbers below for sample 5. I select 5 as being very generally used (100cc. taken; first drop 62° C.):—

10cc. thermometer in vapour	73.5° C. ..	in liquid	84° C.
20	81.0	..	90.5
30	89.5	..	101.5
40	117.5	..	123.0
50	133.0	..	136.5
60	131.0	..	137.5
70	134.0	..	—
80	131.5	..	—
90	135.0	..	—

The thermometer in this case rises quickly until 50 per cent is distilled over, when it remains tolerably steady to the end.

You will observe that the numbers are widely different from those obtained with the yellow varieties, and we shall have to speak of them again.

An analysis of this No. 5 gives the following numbers :—

	No. 5.	Calculated SCl_2 .
Sulphur	39.67	31.07
Chlorine	60.03	68.93

The above numbers, taken in conjunction with each other, prove that this dark chloride is a mixture of S_2Cl_2 and SCl_2 , and that it has not such a definite composition as the yellow variety.

Secondly, The decomposition of chloride of sulphur with water.

As is well known, chloride of sulphur fumes strongly when exposed to the atmosphere, on account of the aqueous vapour in the latter causing its decomposition. The fumes consist chiefly of hydrochloric acid.

It is generally stated in text-books that the monochloride in contact with water decomposes according to the following equation :—

Taking this as correct for the yellow chloride, it struck me that in the case of the dark variety more SO_2 would be produced, and if such were the case it would be less suitable for vulcanising, as the SO_2 produced would oxidise gradually to H_2SO_4 , and this would be objectionable. I tested the idea by decomposing a known weight of both the yellow No. 2 and the red No. 5, with water, and sought to estimate the SO_2 produced with standard iodine solution, but failed owing to the difficulty experienced in catching the end point of the reaction. I eventually placed the matter into the hands of Professor Dittmar, and he, after having tried the iodine method, and failed, for the same reason as I had done previously, devised the following, which he says worked exceedingly well :—

A known weight of chloride was, together with a quantity of cold boiled-out water, placed in a tubulated retort connected with an inverted condenser, which was joined at the other end to an absorption apparatus containing a solution of permanganate of potash. The whole apparatus was filled before starting with CO_2 , and a slow stream of the same gas passed through the apparatus whilst the experiment lasted. After the chloride had stood for some time in contact with the water, heat was applied to the retort, and the SO_2 formed passed through the condenser into the absorption apparatus, where it was oxidised to H_2SO_4 , and finally precipitated and weighed as BaSO_4 .

The solution remaining in the retort was tested for H_2SO_4 , and, on giving a positive result, the H_2SO_4 was determined.

I was astonished to find that there was slightly more SO_2 produced in the case of the yellow than with the dark chloride, and the results were as follows :

Yellow = 3.74 per cent. sulphur given off as SO_2
Red = 3.43 " " " "

You will note that the above equation demands much more. Another fact was brought to light—viz., that in the case of yellow chloride much less H_2SO_4 was produced in the decomposition than in that of the dark. The numbers are as follows :—

Yellow = 2.08 per cent. sulphur given off as H_2SO_4
Red = 9.31 " " " "

No doubt by varying the proportion of water to chloride, and also the temperature, this result would be slightly altered, but it is of the utmost importance for a rubber manufacturer to bear in mind, as whenever moisture is presented to chloride of sulphur,

either in rubber or prepared cloth, etc., a reaction analogous to this must take place, and must have a damaging effect, especially in the case of the dark variety.

There is evidence which points to the formation of other sulphur acids in this decomposition, especially at ordinary temperatures. For instance, H_2S is always produced in small quantity, and if, after allowing the aqueous mixture to stand, you draw off a small quantity and add a little NaHO solution, you get a large precipitate of sulphur, which, taken in conjunction with the evolution of H_2S , indicates, I should say, tetrathionic or pentathionic acids.

Thirdly, The uses of chloride of sulphur, with special reference to its employment as a vulcanising agent.

Its two principal uses are for the vulcanisation of indiarubber, and the manufacture of indiarubber substitute. As is well known, when rubber is dipped into a solution of chloride of sulphur in bisulphide of carbon, it is vulcanised by a small quantity of sulphur replacing hydrogen. The evolution of hydrogen can be plainly seen by making the chloride solution strong.

Now, suppose we take the different commercial varieties of chloride of sulphur, and proceed to vulcanise in precisely the same manner, shall we get the same results ; and, if not, wherein lies the difference ?

There are two processes in which chloride of sulphur is used as the vulcanising agent—viz., the wet process and the vapour process.

The Wet Process consists in passing through or dipping into a solution of chloride of sulphur, in bisulphide of carbon or petroleum spirit, rubber goods of various kinds ; and in order to obtain some idea as to the relative merits of the different kinds of chloride, I procured some "cut sheet" of fine quality, and proceeded in the first instance to determine the amount of sulphur retained by rubber when the different kinds of varying strengths of solution were used.

For the trials I selected Nos. 1 and 5, and also distilled the more volatile portion off a sample of No. 5 in order to see what effect a chloride having an approximate composition to SCl_2 would have, only collecting the portion which came over under 64°C .

The following was my method of procedure. The pieces of cut sheet were warmed so as to free them from moisture, and were then dipped into a carefully prepared solution of one or other of the chlorides in bisulphide of carbon, the duration of the immersion being in each case 15 seconds. After taking out of this solution they were, with one exception, twice in succession immediately plunged into pure bisulphide of carbon, so as to remove the chloride which was on the surface. They were finally dried in an air-bath at 60 – 65°C . (140 – 150°F).

The experiments were conducted with great care to ensure uniform results. You have the results in Table I. on next page.

The rubber contained 0.06 per cent. of sulphur. These results show that chlorides containing a greater proportion of volatile constituents act more quickly on the rubber—i.e., for equal strengths and time they give up a larger per cent. of sulphur to the rubber. Again, by noting the numbers for 1 and 2 we see that the act of washing after having treated with chloride removes the excess of the latter from the surface, which must have a beneficial effect in practice, as it will prevent hardening. Again, by using 1 to 30 there is roughly 1.75 times as much sulphur retained as when 1 to 60 is taken.

I will now pass round a few samples in order that you may compare the effect of the different varieties.

For these trials Nos. 1, 3, 5, and the volatile portion distilled from 5 were used. (See Table II.)

These samples (see Table II.) show on examination that the yellow chloride acts quite differently from the dark; there is no tendency with the former to harden the rubber, even although used as strong as 1 to 15, whilst with the latter 1 to 60 has such a tendency, and renders the rubber inelastic.

For equal per cent. of sulphur—*i.e.*, 1 in 60 dark, Nos. 7 and 8, and 1 in 30 light, 10–13, you will notice that the former has a damaging effect, whilst in the case of the latter the rubber is almost completely vulcanised.

with the least colour has the least damaging effect on the rubber.

There is another point in connection with the use of chloride of sulphur in the wet process which I should like to mention.

When bisulphide of carbon evaporates in the air it produces cold and condenses the moisture in the atmosphere, and this is eventually left as water when the bisulphide has all evaporated; whilst, if the evaporation be conducted in a close vessel, not a trace of water would remain.

This has an important bearing on the use of chloride of sulphur in bisulphide of carbon for vulcanising

TABLE I.

16	Light 1	1	15	15 "	" " "	Soft and elastic

In using the dark variety the action will I think be analogous to its properties shown on heating, the sulphur combined with the more volatile portion will be taken out more quickly at first than that existing as S₂Cl₂, and after the process has gone on for some time the solution will approximate closely to one of the yellow chloride.

From the above experiments taken in conjunction with amount of sulphuric acid formed, when mixed with water, I should conclude that the dark chloride is not so well suited for vulcanising rubber as the yellow; in fact the chloride

prepared cloth, as the solution is often contained in open troughs. The same action must necessarily go on, and the water produced will decompose the chloride with results the reverse of beneficial.

I had two cases brought under my notice lately in which the last batch of goods was damaged, and the above would, I think, account for it.

The Vapour Process.—A process for vulcanising by the vapour of chloride of sulphur was patented in 1878, by Abbott, and is I believe worked by several firms. The goods are passed through a chamber in which chloride of sulphur is evaporated, and you will readily see that to make this process work

smoothly the chloride should have a fairly constant boiling point. Now, as we have before seen, this is the case with the yellow varieties, whilst the dark kind would for this reason be unsuitable. It would be also more difficult to work, owing to the temperature having to be constantly increased to keep up a steady supply of vapour, and I should not be surprised to see the first batch of goods come out blistered.

Fourthly, a method for the analysis of chloride of sulphur.

In the analysis of chloride of sulphur a precaution to be attended to at the outset is not to expose the samples too freely to the atmosphere, as they soon change in their composition, and to avoid this in weighing the best plan is to partly fill a small thin glass

bulb with drawn out end  by warming gently and then allowing a little to be drawn in as the air cools. This is boiled, and when the bulb is deemed full of vapour the end is immersed in the liquid, which then rises and almost completely fills it; the bulb is now sealed and weighed. In the case of the dark variety care should be taken to boil out completely before filling for the last time, as if any were left in the bulb it would have a different composition to the sample.

To determine the Sulphur.—Measure into a small flask about 25cc. of strongest HNO_3 ; the bulb containing the chloride is now dropped in and broken, and to moderate the reaction the flask is kept immersed in cold water. If any undecomposed sulphur now remains, the flask is gently warmed in a slanting position and a crystal of chlorate of potash added occasionally until it is all oxidised; the contents of the flask are transferred to a basin, the excess of HNO_3 removed by evaporating in a water bath with HCl ; taken up with water, and the H_2SO_4 precipitated and weighed as BaSO_4 .

For Chlorine.—A bulb containing about 2grs. is broken under water or weak NaHO solution in a 250cc. stoppered flask, the contents well shaken, and when the decomposition is complete allowed to settle. A weighed or measured portion is transferred to a flask, and the liquid, if acid, made alkaline with Na_2CO_3 ; it is now boiled, HNO_3 added, and if any sulphur has separated out, filtered, the HCl in the filtrate is precipitated and weighed as AgCl .

DISCUSSION.

Mr. H. GRIMSHAW: I think that most indiarubber manufacturers will agree with me that the chief point about Mr. Fawsitt's paper is not that he has made any absolutely new discovery with regard to the properties of chloride of sulphur, or its action upon indiarubber, but he has given a rational explanation of the effects which the chloride of sulphur produces in its various modifications. The results which most skilled indiarubber manufacturers have observed in their experience are explained in the chemistry of the subject as placed before us by Mr. Fawsitt, and for this his paper is useful.

Mr. THOMSON: The study of the chemical composition of these chlorides, and of their actions upon indiarubber, is an important step in the right direction, in reducing to scientific accuracy and method the use of an important substance employed in the indiarubber industry, which has hitherto been used by "rule of thumb," and I think indiarubber manufacturers will be much indebted to Mr. Fawsitt for his paper. It seems interesting and remarkable that the lighter coloured samples of chloride of sulphur are more serviceable for vulcanising, and that they produce less injurious effects upon indiarubber than the darker samples, although the former contain a greater percentage of sulphur than the latter. Mr. Fawsitt pro-

poses that after the rubber goods are treated with chloride of sulphur, they should be passed through bisulphide of carbon for the purpose of removing the excess of chloride of sulphur. Perhaps he can tell us whether this would not be a somewhat objectionable proceeding, and if it would not probably at the same time remove some of the normal oily or semi-liquid constituents of the rubber. I have observed that when these substances have been removed, the rubber tends to harden afterwards by undergoing oxidation more rapidly than it would do if the oily constituents were allowed to remain in their normal proportions.

Mr. H. PHILLIPS: I have recently had a sample of chloride of sulphur to analyse of which not more than 60 per cent. distilled at 136°C . The rest seemed to be sulphur.

Mr. H. L. TERRY: As regards the composition of chloride of sulphur, these are not sufficiently understood in vulcanising, and this led to mistakes. Possibly that is the cause of the so-called "blooming." In a "bloomed" piece I have found three times as much sulphur as in a sound piece, and probably the difference in the quality of the sulphur chloride would account for this.

Mr. BELL: I had a case brought before me of some indiarubber cloth which had "bloomed," and I traced the cause of it to the adulteration of the chloride of sulphur with sulphur.

Mr. ROWLEY: I have known cases of "blooming" which have arisen from badly prepared bisulphide of carbon, and not from the chloride of sulphur at all. In all cases the bisulphide of carbon had been of foreign manufacture of a low price, and without careful preparation the same difficulty might arise with any manufacture of this article. As a matter which has engaged the attention of indiarubber manufacturers, I should like to ask whether our chemists could not discover some means by which they could deodorise in some measure the bisulphide of carbon? Thus a very great benefit would be conferred upon those who have to use it. I have known of cases of insanity produced by men inhaling these vapours.

Dr. WATSON: I should like to ask Mr. Fawsitt if he could tell us whether the bisulphide of carbon takes any part in the reaction of vulcanising? It appears very strange that the chloride of sulphur which contains the least percentage of sulphur should cause vulcanising to take place more rapidly. Perhaps the greater amount of absorption of sulphur is connected with the reaction between the chloride of sulphur and the bisulphide of carbon.

Mr. GRIMSHAW: I think it simply arises from the higher chlorides, although containing less sulphur, being more unstable, and therefore more easily decomposed when in contact with the rubber; and it does not follow that chloride with the largest amount of sulphur would necessarily part with it more readily.

Reply.

Mr. FAWSITT: As regards Mr. Thomson's remarks it is well known that indiarubber is composed of a viscous and fibrous constituent, the former of which slowly dissolves in bisulphide of carbon, ether, etc., but for the short time to which it is exposed to the bisulphide of carbon in vulcanising, it would not, I think, have an injurious effect in hardening the rubber. With reference to the damage caused by "blooming," I think this question has been already answered by Mr. Bell and Mr. Rowley. It can be caused by the chloride of sulphur containing an excess of sulphur, which can be got rid of on distillation; and also when the bisulphide contains free sulphur. In reply to Dr. Watson, the bisulphide of carbon plays no part at all in the vulcanising. It is all removed on the warming of the goods,

NOTES ON COTTON SILK OF THE GOLD COAST, CAMEROONS, AND MALABAR.

BY WATSON SMITH, F.C.S., F.I.C.,

Lecturer in Chemical Technology of the Victoria University, etc.

THIS so-called "Cotton-silk," of which I show a specimen, as well as a pod with the beautiful fibre bursting through, has been the subject of some attention lately, perhaps partly in consequence of its appearance in the Indian and Colonial Exhibition in London. It may be interesting to give a brief general account of the botanical nature and occurrence of the tree bearing this form of fibre, and then to allude to the experiments that I have tried.

The fibre-bearing plant belongs to the *Salmaal*, a genus of Malvaceæ, consisting of one or two species generally included in *Bombax*, from which they are recognised by their bell-shaped calyx being divided into three or five unequal blunt lobes; by their egg-shaped more erect petals; by the tube of the stamen being inflated or bulged out, and composed of numerous filaments in several series; and by the stigma being divided into five sharp-pointed spreading lobes. Both species are large trees, natives of tropical Asia, and have large hand shaped leaves, composed of from four to nine leaflets, and large red flowers, either solitary or several together on the naked branches. Their fruits resemble those of *Bombax*, and are filled with seeds enveloped in silky cotton. *Salmaal malabarica* or *Bombax malabarica*, the Simool-tree of India or Malabar Silk-cotton tree, attains a height of 70 or 80 feet, and has a prickly trunk and branches, leaves composed of five to seven leaflets, and clusters of flowers. The Silk-cotton of the Simool, though very beautiful, is said to be like other Silk-cottons, not adapted for spinning. It is chiefly used for stuffing cushions, and a kind of quilt or thick cloth is manufactured from it in Assam. The trunk yields a very pure gum and light porous wood, and the bark possesses emetic properties. Another species, without prickles on trunk or branches, is an inhabitant of Burmah.

I find that the tensile strength of the cotton-silk is very feeble, and hence I can quite coincide with the opinion of the botanists, already quoted. But I was led to suppose that this fibre was extremely weak after a microscopic examination, in which I viewed some of it through an immersion lens. On glancing at the fibre under the microscope, under the wet lens, and also under a dry lens, it will be seen that in the former case water will have got into the little tubes, and almost filled them, leaving bubbles of air, which can be easily seen. On glancing, in the latter case, at the dry tubes, nothing of such appearance can be seen in the tubes. Now, as these bubbles seemed so large, I concluded the fibre-walls must be correspondingly thin, and this before I made any trials of the strength. Not only did I subsequently find my conclusion confirmed, but in a recent number of the *Chemiker Zeitung*, 10, 1335, I observe some chemist has been trying a few experiments with the species found in the Cameroons, in which he also finds the tensile strength very feeble, and the fibre unsuitable for spinning. I have recently heard that attempts have been made to use this beautiful fibre, either alone or in mixture with wool or fur, for the making of hats. The result was signal failure, and a brief comparison of these two classes of fibres under the microscope will make such failure fully intelligible, when the process of felting is properly considered. Under the microscope the fibre resembles thin smooth transparent tubes without the longitudinal markings seen in the silk-fibre, and it differs from cotton by having none of the twists and irregularities of that fibre, and not being composed of

flattened, but perfectly round tubes. The appearance in the water (immersion less) is, in fact, very like what one would expect to see with the naked eye in the case of a number of bits of glass-tubing used for laboratory connections, partly immersed in the water. There are present no bamboo joint-like appearances as with flax-fibres (linen) viewed under the microscope. It is further easily distinguished from silk by merely holding a fibre to the flame, when the former at once burns with a faint flash close up to the finger, whereas a silk fibre, like one of wool, fuses to a minute head where contact with the flame has taken place; there is also more of the empyrenmatic smell peculiar to burning animal fibre. The cotton-silk fibre is very sensitive to the action of dilute acids, and it cannot be dyed with the basic aniline colours without the intervention of mordants. If some cotton-silk fibre be warmed up with a dilute solution of a basic dye, such—e.g., as methyl violet, I find the colour is very quickly taken up, whilst the dye-solution loses colour. It is possible thus to leave only a light-coloured violet solution, whilst the cotton-silk becomes coloured a very deep violet tint. I have good reason to believe, however, that this is not attraction of the colour in the true dyeing sense, but only such a kind of capillary attraction as we observe often in the case of the ground glass stopper of a bottle, for example, which latter, if filled with a solution of methyl violet, could be easily washed free from dye again with warm water, whereas the ground portion of the stopper retains it obstinately, and, as I have found sometimes, needs treatment with hot alcohol to cleanse entirely. Now, in the case of the cotton-silk tubular fibres, the wider these tubes the greater the relative area of attractive surface, and it is probable this wider surface is of a porous nature, and so exerts capillary attraction; the tubes themselves are also capillary tubes, and thus we have a greatly multiplied capillarity. In support of this theory, I must say that ordinary cotton-wool treated in a similar manner with methyl-violet solution did not show so strong a capillary attraction for the dyestuff as that shown by the cotton-silk, and the cotton tubes are certainly not nearly so wide as those of the cotton silk. By washing the cotton-silk coloured fibres with boiling water, the colour is abstracted, but I did not succeed in abstracting it all without the use of a very little soap in the water, when the fibre was quickly reduced almost to whiteness again.

I consider the cotton-silk is merely a cellulose fibre, and its silky appearance is simply due to the delicacy and thinness of its fibre walls and their consequent relatively increased transparency. In fact, in holding up a thin layer of cotton-silk, and looking at a bright gas-light through it, prismatic colours are observed just as with finely-spun glass or soap-bubble films, and this will not be seen if either cotton or silk fibres be taken and examined in like manner. The prismatic colours, I take it, are just those of thin plates in the case of cotton-silk, and are due to the extreme tenuity and transparency of the tubular walls of the fibre. The fibres are larger than those of ungnomed silk. Molisch's reagent gives, with cotton-silk, the reaction characteristic of all vegetable fibres. This test is applied as follows:—A very small quantity, about 0.01 grm. of the well-washed fibre is treated with 1 cc. of water, 2 to 3 drops of a 15 to 20 per cent. alcoholic solution of α -naphthol are added, and then an excess of concentrated sulphuric acid; on agitating, a deep violet colour is developed. In the case of a small fragment of animal fibre, such as wool or silk, merely a yellow or greenish solution is obtained.

I would strongly recommend this cotton silk as a cheap and efficient substitute for eider-down for quilts and cushions, etc.

INVESTIGATION OF AN ALLEGED REACTION, ON WHICH IS BASED A RECENTLY-PATENTED PROCESS FOR MANUFACTURING CARBONATE OF SODA DIRECT FROM SULPHATE OF SODA.

BY WATSON SMITH AND W. B. HART.

A FEW months ago a patent was taken out by A. Kayser, A. B. Young, and J. Williams, of Buffalo, New York, and communicated to H. H. Lake, of this country, for the manufacture of sodium carbonate direct from the sulphate by passing a mixture of carbonic acid and carbonic oxide over the latter, maintained at a certain high temperature. In the reaction which is said to ensue, sulphur dioxide is expelled, and carbon dioxide takes its place, forming sodium carbonate. The sulphur dioxide it is proposed to pass into Hargreaves' cylinders, charged with salt, and thus form sodium sulphate, again completing the cycle of operations.

On paper, this discovery seemed to us a brilliant one, and we proceeded to endeavour to investigate more precisely the conditions under which the reaction took place. We were further impelled to publish our results obtained some months ago, by the fact that in *Dingler's Polyt. J.* 262 [7], a prominent place is accorded to an abstracted report of this invention.

The reaction that, according to the patenters, should take place, is that the carbonic oxide reduces the sulphate at the high temperature employed, and at the same expels the sulphurous acid of the resulting sulphate forming carbonate, thus :

The carbonic acid, it is said, takes no part in this reaction, but simply acts as a diluent, preventing the formation of sodium sulphide. At least one volume of carbonic acid should be present for each volume of carbonic oxide, in order that the reaction may take place. If the proportion of carbonic acid be less than this, sodium sulphide will be formed and sulphur expelled; whereas, if the proportion be greater, simply unnecessary dilution will be the result.

In our experiments, we prepared our mixture of carbonic oxide and carbonic acid by heating to decomposition oxalic acid, and collecting the gaseous mixture for use in a gas-holder. Thus we obtained equal volumes of the two gases required.

The mixture of gases was passed over the sulphate contained in a hard-glass combustion tube heated in the ordinary gas combustion furnace. The resulting gases were passed into dilute sodium hydrate. The sulphate used was the Hargreaves' salt cake, quite free from acidity. It was broken up into small bits about $\frac{1}{8}$ th in thick.

Experiment 1.—The mixture of gases was dried by sulphuric acid, and then passed over the sulphate, which was previously heated to expel moisture. The temperature used was one of low redness, and was continued for five hours. No sulphur dioxide was evolved, and the residue in the tube was perfectly neutral to litmus paper. No carbonate was found.

Experiment 2.—The mixture of equal volumes of the gases was passed in the moist state over the sulphate heated to low redness, as in *Experiment 1*, for four hours. Negative result.

Experiment 3.—The mixture of gases was now passed in the moist state over the sulphate, heated to bright redness for three hours. Sodium sulphide was produced, hydrogen sulphide evolved, and sulphur sublimed. On examination of the mass in the

tube, no carbonate was detected, although an alkaline reaction was manifested to litmus. This alkalinity was due to sodium sulphide formed in small quantity.

Experiment 4.—In this experiment the carbonic acid was used in excess, the gaseous mixture containing one-third carbonic oxide and two-thirds carbonic acid. This mixture was passed over the sulphate in presence of moisture, at a bright red heat for four hours. Here again sodium sulphide was formed, but no carbonate. Alkaline reaction merely due to sulphide.

Experiment 5.—The mixture of gases containing slight excess of carbon dioxide was passed in the dry state over the sulphate heated to bright redness for five hours. Neither sulphide nor carbonate was produced, nor was sulphur dioxide evolved. Neutral reaction of the mass in the tube. In none of the foregoing modifications was any carbonate formed. The only product was a little sodium sulphide.

In the next experiment the gases were passed separately over the sulphate.

Experiment 6.—Carbonic oxide in the moist state was passed for five hours over the sulphate at a bright red heat. A certain small amount of sulphide was thus formed.

The carbonic acid was now passed over alone, and in a moist state, below a dull red heat. Hydrogen sulphide was evolved, but no carbonate was formed. The residue was alkaline, and this was no doubt due to the presence of sodium sulphide.

Experiment 7.—The first part of the previous experiment was repeated for four hours. Carbonic acid was then passed over at a low red heat, in presence of moisture, till hydrogen sulphide was no longer evolved; this continued for two days. The temperature was now increased to a bright red heat. No further hydrogen sulphide was evolved, but sulphur was deposited at the further end of the tube. No carbonate was produced, but the residue had a stronger alkaline reaction from the presence of a small amount of sodium sulphide.

In this experiment it was now clearly seen that the glass tube had been attacked, and the sodium silicate thus being formed would, of course, increase the alkalinity of the residue. The deposit of sulphur at the higher temperatures can be explained as follows :—A portion of the sulphate is partially and wholly reduced by the carbonic oxide to sulphate and sulphide respectively. The silica of the glass at the high temperature would attack the sulphide, sulphite, and also the sulphate to some extent. Sulphur dioxide and hydrogen sulphide would react to yield free sulphur.

As regards the apparently anomalous case of the second part of *Experiment 6*, we think this is to be explained as follows :—Some sulphur was contained in the tube as a residue from the first stage of *Experiment 6*; this, by the action of moisture at the lower heat, would yield hydrogen sulphide and sulphur trioxide to a small extent, which latter would react on the sodium silicate,

(It is a known fact that sulphur boiled with water will yield sulphuric acid after continued action.)

But free sulphur might be formed otherwise under certain of the conditions named, and so two further experiments were now tried.

Experiment 8.—A mixture of carbonic acid, carbonic oxide, and sulphur dioxide was passed moist through a red-hot glass tube containing pumice-stone fragments without dust. The temperature was one of bright redness. Sulphur was separated and sub-

lited to the far end of the tube. The mixture of CO and CO₂ was prepared from oxalic acid as before.

Experiment B.—The above mixture was now passed, perfectly dry, through the tube, otherwise just as in *Experiment A*. Some sulphur was also sublimed, but the quantity separated was not quite so much as in *Experiment A*.

This separation of sulphur only took place at the highest temperatures.

SUMMARY OF RESULTS.

From the foregoing it would appear—

1. No action takes place at a dull-red heat, even in presence of moisture, when carbonic oxide comes in contact in a glass tube with sodium sulphate.

2. At a bright red heat, in presence of moisture, carbonic oxide reduces sodium sulphate to sodium sulphite and sulphide.

3. At a bright red heat, moreover, the silica of the glass reacts, especially in the presence of moisture, on the sulphite and sulphide, yielding silicate, SO₂ and H₂S. These gases react to yield free sulphur.

4. From the fact that no sulphur dioxide could be detected, but only hydrogen sulphide, it may be argued that reduction by carbon monoxide tends under the circumstances named, for the most part, to carry the sulphate direct to sulphide.

5. The amount or proportion of this reduction is very small, even at a bright red heat, a temperature at which siliceous materials, like glass, commence to be attacked by sodium sulphate, sulphite and sulphide.

6. No carbonate was formed under any of the circumstances named.

7. In absence of moisture, and with carbon dioxide in slight excess over that necessary to form a volume equal to that of the carbon monoxide in the gas mixture, a bright red heat being employed, *no reduction of sulphate took place.*

8. Carbonic oxide at a bright red heat, and in presence of moisture, reduces sulphur dioxide to sulphur.

9. This reduction does not proceed quite so easily if moisture be excluded.

University of Glasgow.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

The Second Meeting of the Session was held in the Rooms, 207, Bath Street, Glasgow, on Tuesday, December 7, 1886.

PROFESSOR E. J. MILLS, D.S.C., F.R.S., IN THE CHAIR.

A SYSTEM FOR THE NATURAL PURIFICATION OF WATER FOR DOMESTIC USE, AND FOR SOFTENING AND OTHERWISE TREATING WATER FOR TRADE PURPOSES.

BY W. H. HARTLAND.

BEFORE bringing to your notice this system of liquid purification, I will make a few remarks anent the practice in use, and recent proposals for purifying water on a large scale, for no system can be of interest unless it shows an advance on sand filtration and fulfils the requirements of scientific research in the elimination of germ life and other features of impure water.

Sand filtration was sufficiently criticised in a paper read before the Society, which appeared in the July issue of the Journal, describing a process of filtration invented by Dr. Gershon.

On page 416, the paper referred to reads:—"However, the result (*i.e.*, of sand filtration) in many cases was not in proportion to the cost, and the excellent report of the Rivers Pollution Commissioners in 1874 has clearly shown that the sand filters do not remove the soluble organic matter from the water: but it has been reserved to the last few years to discover something even worse than this. It is the undeniable fact that the water contains a large amount of micro-organisms, the originators of epidemic disease.

"Where sand filters are used, the water from the supply is found to have a distinct taste and odour of organic matter in a state of putrefaction in warm weather; as, for instance, in Manchester, rendering the water almost unfit for a beverage. In consequence of this we find in all the houses of the better class, special carbon filters, through which the water is again filtered. But these small filters are only for the classes which can afford to pay for them, while the poorer people have to be satisfied with the water as it issues from the sand filters containing certain quantities of suspended organic matter."

There can be little doubt these remarks accurately represent the case, and clearly show that something else is required than sand filtration, and Mr. Steiger, who read the paper referred to, lays down four conditions as necessary for a perfect system of filtration (p. 417). These conditions are—

1. The filters must purify the water "chemically and mechanically."

2. They must destroy the life of germs and micro-organisms.

3. Their cleansing must be made easy, and without causing great expense.

4. They must be more economical with regard to space and cost.

With the conditions stated no fault need be found; but this does not apply to the mode in which they profess to be obtained, or to the calculations on which the statements are based. It will be generally admitted that from a sanitary point of view the filter bed falls far short of what is required for the effective purification of water; but so far as the mechanical action of filtration is concerned, I venture to think there is no great difference between this process and the ordinary filter bed.

The first condition of purifying water "chemically and mechanically," means that the sponges and other filtering media are impregnated with tannate of iron, and the claim put forward on this account is that the pores of the sponges, etc., are hermetically sealed,

and decomposition prevented. This substance then gives rise to the claim of chemically in addition to mechanically, or the process possible to sand filtration. I do not propose inquiring further into the merits of tannate of iron for this purpose, but venture to express the opinion that the British public at least will never submit to use artificial or chemically treated water so long as a natural product can be obtained of reasonable quality; besides it would be equally impossible to fix and maintain a standard of purity by such means as it is by ordinary sand filtration.

The second condition: They must destroy germ life, etc., I need not enter into further than to say this condition in the Gershon process depends solely on the chemical and mechanical action described.

The third condition: Their cleansing, which must be easy and without causing great expense, deserves notice. For instance, the water to be treated is forced, under a pressure of from 13 to 14 feet, into the bottom of a cylinder, and so up through the sponges, etc., contained in trays, and passes out at the top—in fact, “upward filtration” through closely-packed filtering media, treated with tannate of iron; and owing to the action of this substance the passage of organic matter or microbes, etc., into the body of material is impossible, so much so that it was only found necessary to take out and wash these materials once in about two years. The cleansing out of the cylinders and contents is said to be easily accomplished by reverse currents of water; but how this operation is achieved is not very clearly shown; it is rather left to the reader to infer that the matter arrested in the cylinder bottoms, assuming that Mr. Steiger's statement is correct, and that that matter cannot enter the body of filtering media, can be effectually flushed out by gravitation alone, or without pressure at all. This assumption is opposed to all experience. Under similar circumstances, equally so is the possibility of filtering water under pressure opposed to experience; taken together these facts render it doubtful if cleansing of the cylinders would be easy or without great expense.

The fourth condition, or economy of space and cost, also requires notice, as on this feature alone I venture to think depends whatever value the Gershon process possesses over the ordinary filter bed; at the same time there can be no doubt of the abstract value of the preliminary filtration, in place of the direct action of the filter bed. It is possible the claims put forward under this head are due to mis-calculation or want of knowledge as to the average capacity of filter beds in relation to space and quantity for a given period, at all events in Great Britain.

Fig. 4, the article reads, represents a battery of preliminary filters, with six pairs of cylinders, which take up only a space of 1050 square feet, while the secondary filtration is performed in a tank of 1016 feet of surface. This plant was erected for the city of Astrachan some years ago, and corresponds to a capacity of 5000 cubic metres, or 1,120,000 gallons per 24 hours.

It is stated (page 417) that the preliminary filters working under a pressure or head of 13 feet are in capacity for a given period 200 times greater than the ordinary filter bed. How this assertion squares with the fact is seen from the following figures, based on the area given for the Astrachan filter of 1050 square feet.

$1050 \times 200 = 210,000$ square feet of filter beds. The capacity of the former is given as 1,120,000 gallons in 24 hours, whilst the capacity of the latter for effective work is generally accepted at 500 gallons per square yard in 24 hours, so that the capacity of the filter bed is $210,000 \div 9 = 23,333\frac{1}{3}$ square yards, which totals no less than 11,666,666 gallons in 24

hours, or nearly $10\frac{1}{2}$ times the capacity of the Astrachan filter at Mr. Steiger's own calculation.

The real fact is, that for the quantity given—viz., 1,120,000 gallons per day—the areas required respectively are as follow: for the process of preliminary filtration, 1050 square feet, or $116\frac{2}{3}$ square yards, against 2240 square yards for the whole process for ordinary filter beds, or a little over 19 times in favour of the former in place of 200 as claimed.

Were this all it would still show much in favour of the preliminary process over the ordinary filter bed, but confining the question to capacity only, we have still to take into account the surface required for the secondary filter, which according to the Astrachan plant as shown, for example, is a space of 1016 square feet. This, then, further brings down the difference of 19 times, as previously shown between the two processes, to less than 10 times.

But there is a wide discrepancy between the area given as required for the Astrachan secondary filtration, and the later description giving particulars of the general features of the process (on page 417). The article reads: “The secondary filters, which remove the fine organic matter suspended in the water, can, according to local circumstances, be worked either under high or low pressure. In the first case, their capacity is about half the capacity of the preliminary filters, and the total pressure for both filters 25 to 29 feet; while in the second case, under low pressure—namely, about 32 inches—they require 10 times the surface of the preliminary filters, but still exceed the capacity of sand filters 25 times.”

Leaving this assertion for the moment, it appears that the Astrachan secondary filter surface should be given at double the area of the preliminary filters, or instead of the area being as given—viz., 1016 square feet—it should be 1050×2 , or 2100 square feet. This further reduces the difference of 10 times by one-half, or down to five times, and then taking the space given by Mr. Steiger as required for low pressure—viz., as 10 times that of preliminary filtration under high pressure—it seems doubtful where the advantage exists, as regards space, between the process and the ordinary filter bed for any given quantity per day.

It seems equally problematical where the advantage would be under high pressure, putting aside the fact that economical filtration under pressure is opposed to fact and experience, for against the five times saving in space must be put one of the following conditions—i.e., to either mechanically raise the water a height of 25 to 29 feet, or otherwise lose that height or head in gravitation level.

Looking now at the process from a purely sanitary point of view, in its comparison with the filter bed, we get at the following facts, if we are to allow Mr. Steiger but a portion of what he claims. On page 416 he refers to the nature of the Manchester supply, and quotes the well-known feature more or less of all surface-collected water—that is, the odour resulting from putrescent organic matter.

He is perfectly correct in saying that sand filtration does not affect to any appreciable extent the removal of this odour, and he might have gone further, and said that no amount of filtration under existing circumstances would remove it sufficiently; still there can be little doubt that the removal of this condition, common to all partially stagnant water, is the one thing required to restore not only the Manchester supply, but, generally speaking, all our public water supply, to a sufficient degree of purity.

The comparison to be drawn between the two systems under notice is this, that sand filtration, in even a short period, is decidedly injurious to the

water, from its having to percolate through the accumulated or arrested matter on the surface, this arrested matter to a large extent giving to the water the odours to which Mr. Steiger refers.

If this is admitted, then it is obvious that unless the cylinders were washed out at very short intervals, the same effect to a greater degree would occur from the water being forced through a solid stratum of filth, collected or arrested in the cylinder bottoms, assuming it to be correct that this matter, from causes mentioned, cannot enter into the body of filtering materials to a greater extent than necessitates their washing out only at intervals of a year or two. Such a supposition as this is entirely opposed to all experience, and is equally opposed to the conditions required by recent scientific research and experiment in the purification of water.

Taking the Astrachan example as a case in point, the only conclusion to be drawn by any one conversant with the principles of filtration is this, that the water treated there by the Gershon process requires but the simplest treatment, and is, moreover, a totally different quantity from such a water as the Manchester supply; equally so it may be considered doubtful, if applied to such a water, the process would much exceed in quantity alone for a lengthened period the capacity of the ordinary filter bed, though it may be freely admitted that the process, by dividing filtration into a preliminary and secondary process, is a step in the right direction.

The proportion to space of water filtered by the two processes mentioned is for sand filters—without pressure—about $2\frac{1}{2}$ gallons per square foot in one hour for an average of 500 gallons per square yard in 24 hours; but it is obvious this quantity in no sense represents the actual work done, as the filter area immediately it is put in operation is reduced, by reason of the blocking up of the sand by arrested matter. 10 days are generally considered the *limit* during which it remains effective under favourable circumstances, and we may safely assume that in the later period of its existence especially, to obtain this average of 500 gallons for the whole period the quantity will vary from the minimum of $2\frac{1}{2}$ to a maximum of 20 or 25 gallons per square foot in an hour. This condition of increased quantity, and necessarily in the inverse ratio *a decrease* in the mechanical action of the filter, combined with the contamination of the water by arrested matter, explains the unsatisfactory state of our water supply in connection with sand filtration.

The proportion of space and quantity of water filtered under pressure according to the Astrachan example is about 45 gallons per square foot an hour, but the proportion is on the assumption that the space given, 1050 square feet, for 120,000 gallons per day, is that of the cylinders themselves. If it means the space occupied by the plant, then the proportion given would be increased three or four times, or approaching 200 gallons per foot in an hour. It requires a robust faith to believe that a satisfactory degree of purification would be obtained by means of filtration with either proportion given on water previously forced through a more or less solid stratum of arrested filth; and this would necessarily be the case if the one principle on which the process depends for success achieved its object, and that for a much shorter period than two years. The feature mentioned is simply a more concrete example of the same condition attendant on sand filtration. The most recent experiments of British and American experts relative to the purifying effect of filtration, prove conclusively, at all events so far as the elimination of germ life is concerned, that in no sense can it be said that sand or other filtration is sufficient to purify a water contami-

nated with other than the simplest forms of suspended matter. My own contention will be that a sufficient degree of agitation by air under pressure is the natural remedy for eliminating impurity, whether soluble, gaseous, or germ life foreign to natural pure water, leaving filtration to perform that part of the process of liquid or water purification for which only it is fitted—the arrest of suspended matter. The proportion of space and quantity in the system I shall propose will be a maximum of 17 gallons per foot in an hour, or probably about the actual work done by filter beds for the greater period of their existence.

The question of water supply is one that of late years has occupied the attention of scientific experts, principally on account of the new terror of the discovery of germ life and its connection with epidemic disease. Great interest has attached to the investigations, and especially so in Britain and America. You no doubt are aware of Professor Pampelly's experiments at Newport, for the National Board of Health of America, and also of Dr. Frankland's experiments in the same direction. These experiments have thrown much light on the subject of bacteria and the means for their removal from water. Drs. Tidy and Dewar are continuing the experiments, but practically Dr. Frankland's paper on the purification of water, contained in the proceedings of the Institute of Civil Engineers, vol. 85, part 3, may be considered the most authoritative textbook of science on the subject.

As regards filters, Dr. Frankland is much more favourable to their efficiency as a means for the removal of germ life from water than are most other observers, in fact his conclusions are in direct contradiction to American views, as Professor Pampelly found that water, after being filtered through several feet in thickness of sterilised sand, contained living micro-organisms. Dr. Frankland reports that a filter of ferruginous sand six inches thick entirely removed micro-organisms at first, and that coke and animal charcoal were efficient in straining out bacteria. He concludes that it is no very difficult matter to construct filters which shall remove micro-organisms for a time at all events, and which will do this without exerting any special chemical action on the organic matter in the water, but that even in the case of the best filtering materials there is a necessity for frequent renewal.

Dr. Frankland's experiments in agitating water with suspended particles of spongy iron, etc., showed that while over 90 per cent. of germ life may be removed in this way, yet the process is unreliable, and in some cases the number of organisms was actually increased by the process; but he does not appear to have experimented in agitation with air, or bringing it into contact with every part of the fluid. This view of the case is strongly held by American experts, and such a process is known to have a powerful effect in destroying the vitality of micro-organisms, and good reasons exist for supposing that this destructive effect is exerted more powerfully and promptly upon the more dangerous forms of germ life than it is upon the more harmless forms. It is easy to understand that bacteria, which only flourish in the absence of oxygen, would be destroyed by a thorough process of aëration and removal of odour. The results described by Warrington in connection with sewage point to the same conclusion, and in further confirmation Dr. Frankland points out that it is more difficult to remove from water some kinds of organisms than others, and that those bacteria which cause liquefaction of gelatine, among which are some of the most dangerous forms, are more readily destroyed than those which do not effect such liquefaction.

With regard to precipitation methods, Dr. Frankland's conclusions are that chemical precipitation is attended with a large reduction of micro-organisms present in the water, but if agitation or precipitation be continued too long, the organisms first carried down may again be redistributed in the water. For this and various other reasons, then, this process does not appear to me as worth consideration, or at all events in connection with potable water. But in the fourth or last process of purification by natural agencies, Dr. Frankland's conclusions are of the highest value, and I quote the conclusion of the report which deals with the subject:—

"Finally, it should be observed that processes for the purification of general water supplies are desirable, not only for the removal of dangerous micro-organisms, but also for the removal of matters which are offensive to the senses—to clarify water from suspended particles of clay, etc., which make it unfit for bathing, to remove algae, and to oxidise and destroy certain matters which cause offensive odours. For all these purposes simple sand filters are useful, and if these are constructed of ferruginous sand and combined with means for agitation and thorough aëration at certain times, the results will probably be satisfactory."

In the system of liquid purification I shall lay before you, I shall claim that every condition laid down by Dr. Frankland is fully achieved. I may remark that the only difference is that I propose *constant* in place of occasional aëration. I venture to attribute this to the fact that I have in my mind the purification fit for potable use of a class of waters not anticipated by Dr. Frankland; and to the same cause may be attributed the reason why the system of purification to be described "seems" to go further than the conditions of Dr. Frankland require. Practically speaking, these conditions are complied with by, say a preliminary and secondary process of filtration. Means being provided by which a frequent renewal of the materials may be obtained at reasonable cost, the condition of agitation and aëration I suggest will best be obtained by agitation with air. I claim this process, in the way it is obtained, has a threefold effect in comparison with aëration superficially or by injection. These effects are (1) elimination of the original gas or odour; (2) revivication and natural disinfection by each particle of water being washed in fresh air; lastly, the destruction or development of soluble impurity foreign to naturally pure water, the same terms applying to the destruction of germ life, the full process rendering soluble matter and germ life amenable to the general law of subsidence or the process of filtration.

I venture to think the conclusion put forward complies with the conditions required by the most recent scientific discovery, which shows that a high temperature in water is conducive to the propagation of microbe life, whilst a low temperature has an opposite effect; and surely, so far as drinking water is concerned at all events, we cannot conceive a more rational or natural process of cooling than that of aëration, besides the fact that by natural law aquatic animal life seems equally impossible in presence of an abnormal quantity of air, as non-aquatic life is, we know, impossible in presence of an abnormal quantity of water.

In briefly describing the system and apparatus employed for your consideration, I will, for convenience, divide it into four sections. The first pre-preliminary, the second preliminary, and the third I will call the geological section. These sections I propose to employ for the purification of water for domestic use, the fourth section being devoted for the purpose of artificial or chemical treatment of water for trade purposes.

The whole of the sections named may be either embodied in one system, or each may in itself be used separately for the purpose in which it is employed in the system under notice, so that the treatment only may be employed which circumstances require, with economy in both space and cost.

For the sake of brevity I will ask you to assume that gravitation is the only motive power employed, except the generation of a forced current of air, and also to consider that between the first and third sections a drop of about four or five feet occurs in the gravitation level; but, allowing for this fall, then the purified water is discharged from the third or geological section at the same or about the same level at which the water enters the pre or preliminary section. It will be readily understood this feature would modify in many cases the expenses of pumping, and that water by gravitation alone would reach a higher level than is possible with the ordinary filter bed in use.

1st Section. The first or pre-preliminary section consists of a tank or vessel that may be, say either 2 feet or 2000 feet in length; in fact, of just sufficient size according to the quantity required, which is determined by a sufficient syphonage effect produced on the particular water passing. The tank is provided with an inlet and outlet at each end. This allows of the water traversing the filtering media in reverse directions, or from right to left as required, the labour achieving this result being simply moving a valve or shuttle. The filtering or syphonage materials are contained in strong, open, iron-work frames, which are fitted in slides or columns, and so are withdrawable as occasion requires for the renewal of filtering material. I propose not less than two lines of filtering stratum in this section, the first acting as a guard or a preliminary filtration to the second. The general features are two lines of filtering stratum, which divide the body of water into three columns or strata, the vertical strata of water being three or four inches wide. This brings into play not only the rapid syphonage through the filtering media of the water as it traverses longitudinally the faces of the filtering stratum, but also that of friction on the side of the tank. The depth of the filtering stratum is governed by the rule as to quantity, but in all cases I propose the bottoms should be a greater depth, to be governed by circumstances, than the bottom side of the filtering stratum, so that provision is made for the collection of suspended impurity below the filtering media, which admits of the law of subsidence taking place. The element of cleanliness is provided for by the tank bottom, if small or medium in size, sloping from back to front, the front being the inlet side, and to one end, or if large, then from the centre to both ends, at which a sludge door or valve is provided to discharge the accumulated deposit, whether existing on the bottom or sides or on the face of the filtering media. The vertical columns or strata of water at the moment standing on both sides and between the filtering stratum will automatically flush them out in any part by the rush of the water to escape at the valve opened at the lowest point of the tank for the purpose; it will be observed that by the water traversing the face of the filtering stratum the collection of matter on the surface is reduced to a minimum. Further, the collection of matter is always subject to removal by the action of, the current of water, which, although in itself slow would have a tendency to remove it and cause its deposit on the bottom; again, it must be remembered that provision is made for subsidence of matter, and that the current of water may be reversed at pleasure. With these features of keeping the filtering media effective as long as possible, must also be taken into account the fact that, although the

accumulation of matter on the filtering surface would have to take place during the slow gravitation of liquid, yet by the feature of cleansing out its removal is effected by a violent discharge backwards of the water standing between and behind the two strata of filtering surface: the water in the inlet or front side of the filters having no impediment would immediately rush out at the valve, carrying the deposit with it, but the water in the centre and back strata must come back through the filtering media, and cannot fail, under the circumstances described, to automatically dislodge and flush out any matter accumulated either on the surface or in the body of material. Shortly, I propose the defilement of filters shall occur "without pressure," but their cleansing and flushing out be effected under considerable pressure in the opposite direction.

I should mention here that the loading of the filter frames is, by a simple contrivance, made an easy matter, and may also be made use of for exposing the water to the action of other substances than sand; for the first line I should generally propose a coarse sand, but there seems no reason why the second line should not be, say charcoal, for instance, nor need this be of any great quantity, as by the contrivance mentioned a frame may be loaded in a few minutes with, say two or three different strata of material, for instance, two outer strata of fine sand, enclosing a stratum of charcoal or other substance; in this way it is quite possible to carbonise public water at a slight increase of cost over sand.

The general features and process of this section may be called the process of syphonage in combination with subsidence and gravitation, coupled with reasonable means to ensure cleanliness and efficiency of work, and may be considered as sufficient for a pre-preliminary purification of water; the function of this section in the system proposed is the arrest or filtration of suspended matter.

The second section consists of two tanks or vessels, one corresponding to the first section in capacity, the other, which varies in size according to the quantity of water purified per hour or day, stands between the two; the water, after undergoing the process described, enters this apparatus, when a fall or alteration in the gravitation level takes place; by an arrangement of spray plates the stream of water is converted into a shower or spray, which is arranged to fall in a circle. The inner part forms a funnel, and communicates with an outlet in the cover, which is extended on by pipes away from the site of the works; the floor of the apparatus is the gravitation level of the water, and immediately above this level are the inlets for the forced or induced current of fresh air, which passes through the falling spray into the funnel or inner circle, and out by the opening at the top; as, except this, there is no other outlet.

The process, then, is seen to correspond to some extent with the most perfect, because natural, process of aëration, or a shower of rain in a high wind; and in consequence, as every drop of water must be affected or aërated, so must the original odour contained in the water be blown out and replaced by fresh air. It must be noticed that the falling spray is subjected to the freshest air immediately before reaching the gravitation level, and necessarily carries with it a certain quantity, so that the water at this point is doubly aërated by falling through and being washed in air, and afterwards undergoing the reaction attendant on the process or oxidation as hitherto applied for this purpose.

I venture to think Dr. Frankland's essential conditions of thorough agitation and aëration are fully achieved by the process described; in fact, with a

sufficient pressure of aërating current, the water is literally broken up into vapour; but this would only be necessary for an exceptionally foul-smelling water, that by ordinary means would be utterly unfit for potable use; for ordinary water—such, for instance, as the Manchester supply—a sufficient degree of aëration would be obtained by the induced current of air generated by the falling water. This, aided by ventilation, would in most cases be sufficient to disinfect and remove odour, and to revivify the partially stagnant water of most reservoirs, wells, and similar sources.

The second tank of this section is similar in construction, and in filter area is exactly the same as the first section; the filtration is primarily a guard against the intrusion of matter into the third section, and the same features as to cleanliness and automatic flushing-out of the second tank and filtering stratum apply as already mentioned.

The general features and process of this section are the extraction of foul gas or odour and the process of filtration, combined with subsidence and gravitation, coupled with reasonable means to ensure cleanliness and efficiency of works. The function of this section in the system proposed is the production of a neutral or pure water, by reason of the elimination of gaseous and soluble impurity, and destruction of germ life.

I venture to suggest that the system described up to this point is in accord with, and meets, Dr. Frankland's conditions to produce satisfactory results in purification by natural agencies, the process being—first, filtration through two strata of sand or other material, six inches thick, and renewable at reasonable cost as often as required; secondly, thorough aëration and agitation, and again filtering through two strata of sand, and renewable as often as required.

Assuming the water, after undergoing the process described, is to some extent a pure or neutral liquid, corresponding in some degree with rain-water, then it is peculiarly fit and amenable to the impregnation of mineral salts, or, in other words, to receive the constituents of natural spring-water, and this process is the function of the third, or geological section, which consists of two tanks, or vessels of similar capacity to those of the other section mentioned, and possessing the same features with respect to reversing the current of water at pleasure, and also the feature of flushing-out or cleanliness. The tanks are connected by a syphon placed a certain distance above the sloping floor, the inlet and outlet ends being protected with an iron grating. The water below the syphon being still, allows of the subsidence of any matter or particles of material falling below its mouth, and of being flushed-out as occasion requires. I should remark here that each section may be flushed-out separately, as by simply moving two valves the inflowing and outflowing stream is cut off.

The formation and nature of the impregnating strata admits of endless variety; in fact, the chemist in this direction has the whole geological and some portions of the vegetable world to choose from.

I do not propose to enter largely into this subject, although, from every point of view, the section and its function in the system proposed is the most interesting, and which is, practically speaking, the artificial production of spring-water by using the same means, *in comparison to the effect of the lower stratum of the filter-bed.*

I may perhaps be permitted to show a typical form of strata, and briefly point out how this section seems to meet a recent scientific communication by Dr. Tidy to the Royal Society touching the subject of water purification and its effect on lead pipes, and

how the full effect of the suggestion could be obtained in this system of water impregnation.

Assuming, then, the two tanks are empty, I first propose to fill them up to the level of the connecting syphon with rough lumps of limestone or other stone. This is to allow of a comparatively free rush of the water to the flushing valve when open. Then on this rough substratum of loosely-packed rock may come chalk, for instance, then sandstone, then charcoal, then sandstone again, and lastly, a stratum of filtering sand, on to which the water from the second section would discharge. It would then pass downwards, percolating through the impregnating strata to the opposite end of the tank; and then passing through the syphon into the second tank, it commences to rise or spring gradually until it reaches the outlet at the opposite end, the process being downward and then upward filtration governed by the law of gravitation.

At the recent Birmingham meeting of the Royal Society, Dr. Tidy communicated a paper on the subject of silicising water by bringing it in contact with old red sandstone, for the purpose of neutralising the effect on some water in corroding lead pipes, expressing the opinion that its effect would be to minimise the danger to health from lead poisoning, and to also purify the water. I believe this idea has been mooted in connection with Loch Katrine supply, and it was proposed to bring the water to Glasgow in a red sandstone conduit. It will readily be understood that, had this idea been carried out, the effect could not have been more than very slight under the circumstances named. But taking the geological section of the system proposed, it is equally obvious that the strata could be either wholly or partially of this material, and consequently the degree of impregnation may be that found most desirable by experiment or experience. The same rule applies, of course, to all other substances under similar circumstances, and I respectfully suggest that there seems no good reason why the geological chemist should not supply, under the conditions named, a water for public use in the largest quantity, possessing to a degree the characteristics and constituents of almost any favourite natural spring water, and produced under, practically speaking, similar circumstances and the same natural means.

But if I may be permitted to say so, is the fact just stated with respect to Loch Katrine water, and its effect on lead pipe, the only one of importance or interest to the city of Glasgow? I venture to think it is not. I refer to the generally accepted idea as to increase of infantile deformity, which by many people is rightly or wrongly put down to the use of this water in a large measure; or, shortly, it may be said that Loch Katrine water is a magnificent water for most trade purposes, but for domestic use is deficient in one at least of the attributes of a health-giving and wholesome water. This idea may or may not be true, but assuming that it is, then I confidently assert it would be an easy matter to give to this water, by the means proposed, that constituent or attribute in which it is deficient.

I venture to ask you to consider the facts put forward in the light of showing how it may be possible, by the means proposed, for the chemist to fix standards of purity for public water, irrespective of the nature or quality at its source or point of collection, this matter being reduced to the simple question of cost, or, shortly, the period required to obtain the standard of purification fixed upon. This is determined by a simple rule of capacity for a given period, and is entirely under control, the capacity of an apparatus being determined in its relation to the flow of liquid. For instance, the

flow of water required is say 1000 gallons per hour, and the standard of purification requires 5 hours say, then the apparatus requires to be in itself of not less than 5000 gallons capacity. Then the water of necessity is 5 hours in passing from the inlet to its outlet. From this simple rule it is seen that the system gives perfect control in this most important matter, as the flow may, in addition to the features given, be varied at pleasure by the connecting valves provided for the purpose. And I venture to think the general features of the system, as outlined, tend to show that the purification of water may, by the means proposed, be reduced to a practical science and give the geological chemist the means of fixing and maintaining standards of purity, and is, practically speaking, the artificial production of spring water using the same means.

The fourth section, for the preparation of water for trade purposes, is also a question of great importance to the industrial chemist and manufacturer. I do not propose to go into this matter further than describe the apparatus and to say it may be used alone or in conjunction with either or all of the other three. The principal feature of difference in the 4th section to those for purifying water, is the provision made for settling and accurately mixing with a flow of water any chemical or liquid for precipitation or giving the water an artificial chemical constituent. The provision consists of a shoot, provided with a hopper at its upper end to hold a supply of lime or other chemical which is delivered to the inflowing stream as it passes under the shoot by a pair of rollers, or, if a liquid, by a tap from a vessel which takes the place of the hopper, the effect being an accurate and automatic impregnation of the liquid at slight cost in comparison to the usual means. One feature of the section is, that after such impregnation and precipitation of mud has taken place, the effluent water may afterwards be filtered or otherwise treated as described for water for potable use. In addition to this is the feature that by using the second section it is in the power of the chemist to produce a neutral or soft water from impure sources—a water that is undoubtedly valuable for trade purposes and not readily procurable by other means; and it is not too much to expect that, given such water as this, corresponding to a great extent to natural rain water, the industrial chemist could produce results of great importance to several branches of manufacture.

I venture to hope that taken as a whole the system proposed opens up a wide field of practical science in the purification and treatment of water, in comparison to the novel and mechanical process in use, and does in effect transfer the purification of water from such admittedly inefficient condition into a system of geological and natural science.

The cost of purifying water by this system I estimate at about the following rates per 1000 gallons for medium and large quantities:—

For 100,000 gallons per day, constant work, about 1½d., including forced aëration, and all cost of upkeep and 5 per cent. interest on capital; on the same terms, with automatic aëration, ½d. per 1000 gallons would be sufficient for 500,000 gallons per day, including forced aëration and all costs and charges; the rate would be 3½¹/₂th of a penny per 1000 gallons. I do not advise a single apparatus of a larger capacity than half-a-million gallons daily, and as any number of the apparatus may be embodied in a system side by side, it fully meets the necessary condition of purifying water on the largest scale, with economy of space and cost.

The estimates given are for all three sections combined, or for purifying water for domestic use, while for filtering alone by the first the cost would be about

one-fourth that given. For filtering and agitating, and again filtering by a combination of the first and second, the cost per 1000 gallons would be about three-fourths that of water for potable use.

Space occupied by the whole system in comparison to filter beds:—The system: 100,000 gallons per diem, 729 feet; for filter beds, 3600 for constant work. The system: 500,000 gallons per diem, 3150 feet; for filter beds, 18,000 for constant work, with an average of 500 gallons per yard in 24 hours, or the best average work possible to the process under favourable circumstances—similar circumstances as to one reserve filter bed to allow of renewal, etc., to several others apply in both cases.

Having described the general features and process of the system, I would just indicate a few applications to which as a whole or in part it may be applied for liquid purification.

The first section may be used alone as a substitute for ordinary filter beds, and for purifying water from rivers for trade purposes and where ordinary filtered water is sufficient. A saving would be effected in labour and pumping, etc., as the filtered water would be obtained at the gravitation level of the stream supplying the impure liquid, and generally for all purposes of simple filtration the sections supersede sand filters with advantage in economy of space and cost.

Where a purer and softer class of water is required, the first and second sections may be combined, and in the case of manufacturers especially a forced pressure of air may in most cases be cheaply obtained, in which case the fall or gravitation level need not be much more than one foot as the difference between that at which the purified water is supplied and the level of the impure supply, and in any case would save both space and cost as between an ordinary filter bed.

The second and third sections without filtration may be used with advantage for revivifying and, practically speaking, transforming the nauseous and insipid, condensed, or stagnant water on board ship into natural spring water, using the same means.

The apparatus may be elevated over a contaminated well or other source of supply in country and isolated districts for villages, institutions, etc., and the water be pumped in. This would represent the extra labour, as pumping in, say a bucket of impure water, simply forces out by gravitation a similar quantity of purified water, which of course could be carried away, or in pipes would gravitate to any point required as a compensation for the extra labour in pumping. This form I think would also be very useful for farm premises, etc.

The same rules apply to a constant stream of water entering the apparatus by pumping, gravitation, or syphon, and either from the apparatus direct, or from a reservoir into which the apparatus or system would discharge the purified water; in this way it is possible to store and utilise water in districts and under circumstances not possible by the means in use, and also, if circumstances permit, accompanied by the convenience of having a gravitation water supply at slight cost. Of course, the pressure would depend upon exactly the same circumstances as those which apply at present by ordinary means.

The apparatus may be made small enough to suit a single house or a mansion, or may even be used in connection with a water cisterns, etc. A flush out at any time is obtained by turning a tap, and the filtering material, etc., is easily renewed. In relation to space, and for a given period, no other description of domestic filter would approach this in quantity or quality of water.

Lastly, in a modified form it admits of being made portable, and in that way used for filtering; and if two

apparatus were joined, also for agitating and aerating water for miners and for soldiers, especially in such countries as Egypt or India, where the water supply is generally bad. The apparatus, which resembles a cart on wheels, when not in use for its primary purpose would be useful for transport.

NOTES ON RIVER WATER PURIFICATION BY THE AGENCY OF ATMOSPHERIC OXYGEN.

BY J. J. COLEMAN, F.L.C., F.C.S.

PASTEUR and his school have assumed that some forms of organic matter, such as albumen and fibrin, are practically indestructible by any ordinary atmospheric agency, without a previous splitting up by bacterial life. Experiments have been made by Lister and others, which show that milk, urine, etc., will keep several years in contact with air deprived of micro-organisms. Some experiments have, however, seemed to me desirable with ozonised air, not only as regards its action upon dead organic matter, but upon micro-organisms themselves.

M. Davy (*Compt. Rendu*, lxxxii. 157) states that atmospheric air frequently contains one milligramme of ozone per 100cc., but assuming that M. Houzeau (*Ann. Chem. Phys.* [4] xxvii. 5) to be correct, then the atmosphere sometimes contains $\frac{1}{150000}$ of its weight, which would be equivalent to about 2 cwt. of ozone per acre of the earth's surface. Houzeau has, however, provided a well-known apparatus for obtaining a constant stream of atmospheric air more highly charged with ozone than is natural air.

The ozoniser I used for my experiments (see diagram) consisted of a tube about 500mm. long, the terminal wire of a Ruhmkorff coil, capable of giving sparks two or three centimeters long, being wound round the exterior of the tube, and the other terminal wire being made into a long spiral filling the inside of the tube. This arrangement was placed on a still wider tube, A, B, C, D, 50 millimetres diameter, through which a constant

stream of air was made to pass by means of an aspirator. A constant copper battery was used in order to maintain the silent discharge, and the ozonised air was first passed through the flask W, and then through the dry gas meter M, and finally discharged through the aspirator.

As the ozonised air acts rapidly on indiarubber, the glass tubes were fitted into the flask by paraffin wax cement, and the entrance tube and exit tube from the flask were plugged with cotton wool, the flask being capable of being detached from the rest of the apparatus by lifting two wide test tubes dipping into the water late V, V, V, V.

The flask W generally contained about 100cc. of the liquid being examined, and it was found that when the air was passed at the rate of 200 cubic

inches per hour, there was no inconvenient splashing of the liquid, and under such circumstances the quantity of iodine liberated per hour from potassic iodide solution equalled 0.068 of a gramme.

Several preliminary experiments were made with vegetable infusions, such as those of cauliflower, which under ordinary circumstances become opaque in a day or two from bacterial life. In all cases it was found that so long as the ozonised air was passing, the liquids remained pellucid, and even for several days afterwards, provided the cotton plugs remained intact, but that in every case opacity developed in a few days after ceasing to pass the ozonised air through, showing that whilst the mature organisms were killed the spores must have escaped destruction by the ozone.

It was then thought advisable to make the experiments with pure soluble albumen, and for this purpose a five per cent. solution of white of egg was employed, carefully filtered, and the ozonised air was passed through the flask, containing 100cc. of the liquid, for six hours. A similar solution outside the flask became opalescent in 48 hours, whilst the ozonised sample remained clear until the fifth day, when it then gradually increased in opacity notwithstanding the cotton plugs. Here again was evidence of the fact that it was easy to destroy micro-organisms, but very difficult to destroy spores.

These preliminary experiments demanded more minute attention in the final experiment. As before mentioned, the ozonised air liberated 0.068grm. of iodine per hour from iodide of potassium, and it was arranged to pass the air thus ozonised for 10 hours a day, three days consecutively, through 100cc. of a one per cent. solution of white of egg, which it will be noticed would bring the ozone into contact with about its own weight of dry albumen. The experiment was very successfully performed, great care being taken to stuff the entrance and exit tubes of the flask with $1\frac{1}{2}$ deep inch plugs of cotton wool, and the induction coil was carefully kept going by a man specially watching it. The aspirator was first stopped, and shortly afterwards the induction coil so as to be sure no *unozonised* air was drawn in. The whole was then left at perfect rest for six days, the liquid remaining pellucid and bright until the fifth day, when a slight cloudiness manifested itself. On opening the flask the liquid proved to be quite neutral, and yielded the usual precipitate with nitric acid (of unchanged albumen). On evaporation to dryness the proper percentage of albumen was obtained, and there was no evidence by the microscope of any crystallised product; the air after passing through the liquid acted strongly on indiarubber. Albumen, it has been shown by other chemists, also resists the action of a 20vol. solution of peroxide hydrogen. It is possible that both these active agents, when in a more concentrated form, may attack albumen, but these experiments are conclusive as to the *practical* indestructibility of albumen by any *atmospheric agency* whatever, without a previous splitting up by micro-organisms. It must, however, be borne in mind that atmospheric air acts as a natural purifier of water *indirectly*—namely, by increasing the activity of organisms, which, as soon as they have performed their functions of oxidation, disappear and die for want of food. Purification of water or sewage is, therefore, promoted by aëration—putrefaction, as Angus Smith surmised, being a necessary preliminary to oxidation and purification.

DISCUSSION.

Dr. WALLACE hardly thought that Mr. Hartland did justice to the system of sand filtration, as he had in his memory a series of sand filters which filtered

daily four million gallons of water. These filters were, therefore, worked upon a somewhat extensive scale, and during the winter months were used about six weeks each without renewal. It was quite true that in the summer—say in July and August—they were only in use about ten days, as Mr. Hartland stated; but it would certainly be unfair, in his opinion, to take that as the average duration of a sand filter; about three or four weeks would be a fairer average.

Mr. CURPHEY would have liked to have had a little more information as to the results which had been attained by this process. Many had been struck by the shortness of the time which would elapse between the aëration of water and its consumption. Five hours were not, in his opinion, too long a time for the removal of oxidised impurities, and measured results would certainly be very valuable in this case.

Mr. COLEMAN had omitted to say that the practical bearing of his paper was this, that—as Dr. Angus Smith had surmised—no water purification could take place without putrefaction—*i. e.*, before the matters which are in water, such as albumen, could be destroyed, there must be putrefaction. It was in fact a necessary preliminary to purification, and was, practically, promoted by aëration. This arose from the fact that the micro-organisms lived upon oxygen, and Mr. Hartland was quite correct in contending that to aërate water was to purify it. His experiments had been instituted rather with the view of ascertaining the possibility of purifying water—Thames water for example—by means of the ozone naturally contained in the atmosphere. He thought, however, that this could not be done.

Mr. E. C. C. STANFORD was not aware whether anyone present had had any experience with Pasteur's filter. He had used one for some time, and had found it very efficient. In construction, it was simply a long tube of biscuit porcelain, and while filtering very slowly was still very efficient. Although requiring cleaning very often, the simplicity of its construction enabled one to accomplish that very easily, as the outside of the tube required merely to be wiped and the tube screwed into the electro-plated case.

Professor MILLS: It had been conclusively proved both by Dr. Frankland, Dr. Percy Frankland and Mr. Coleman that mere oxygen did not act upon organic matter suspended in water. If they supposed the organic matter in water was, for the time being, a kind of sewage, the introduction of germs would facilitate the purifying action just as yeast is used to start the process of fermentation. The action would be hastened by the passage of air through the liquid. Touching on Mr. Hartland's suggestion that Loch Katrine water should be impregnated with chalk or limestone, this was, he said, really a very old notion. It was in the mind of Mr. Bateman when he constructed the waterworks, and there was to be seen at Mugdock Reservoir a breastwork constructed then in connection with the matter.

Mr. HARTLAND, in reply, said that in his opinion aëration was simply an incident in the process, just like filtration. He understood that Dr. Wallace in speaking of sand filtration, had referred to the Glasgow water supply, but he would ask if Dr. Wallace considered Manchester water to be on a par with Glasgow water, or that a similar quantity of the former would be passed through the same stratum of sand as the latter, with a similar purifying effect. His experiments had led him to hold that aëration, without violent agitation, was of little use, but that the passage of a current of air through a spray of falling water had the effect of developing soluble impurities, and had such an action on germ life as to render it amenable to the law of subsidence.

Professor MILLS at the close of the discussion exhibited some candles which were prepared with the view of preventing "guttering." The process was very simple, consisting in giving to ordinary paraffin candles a coating of a certain varnish. As the candle burns, the varnish forms a cup which holds the melted paraffin, and "guttering" seems to be very effectively prevented.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Apparatus for emptying Autoclaves by Automatic Means. Chem. Zeit. 10, 1273.

THE apparatus illustrated in the accompanying drawing is attached to autoclaves. It admits of the withdrawal of samples or the addition of liquor during the procedure of an operation, whilst after its completion the contents may be removed without disturbing the cover. When

the apparatus is at work, the three-way valve A is adjusted so as to prevent passage through the pipe c. In order to take a sample the three-way cock B is made to communicate with b and d, and the valve A turned with a jerk to connect c with b; the sample is then withdrawn at d. To completely remove the charge the valve A is

left open for some time. In working without pressure the air-cock C is opened and communication established between b and c and a and b. b and c are then filled with liquor identical in constitution with that contained in the apparatus, obtainable from a previous operation. The contents of the vessel are then removed by restoring the communication between c and b and b and d. To introduce liquor into the apparatus without removing the cover the air-cock C is opened and the funnel a' made to communicate with the pipe c by regulating the valve A. This apparatus is constructed for a pressure not exceeding fifty atmospheres, and is applicable to autoclaves of a maximum capacity of fifty litres.—D. B.

Improvements in the Manufacture of Thermometers. J. J. Hicks, London. Eng. Pat. 2027, Feb 13, 1885. 6d.

It is a well-known fact that thermometer tubes after filling undergo a contraction or shrinkage, which in time becomes so considerable that if the thermometer were graduated immediately after the manufacture and filling of the tube, the indications would soon show considerable inaccuracy, and in twelve months' time might amount to as much as one degree rise. To prevent this inaccuracy it has been customary to store the filled tubes for a year or more previous to graduation, but as this is not quite certain, and is certainly not economical, the inventor adopts the plan of gradually heating the filled tubes to a temperature about 100° F. higher than the highest point of the thermometer for a period of about sixteen days, and in order that the tubes may not burst from the expansion of their contents, an enlargement or chamber is blown at the upper end of the tube sufficiently large to allow for the maximum expansion. After gradual cooling the thermometers are graduated, the enlargement or chamber being either sealed off or retained.—W. D. B.

Improvements in Graduated Chemical, Medical and other Liquid Measures or Ganges of Capacity and Pressure, and in other Graduated Tubes, Bottles, Jars, Syringes, and Articles made of Glass. J. J. Hicks, London. Eng. Pat. 2347, Feb. 20, 1885. 8d.

ACCORDING to this invention, graduated chemical and other apparatus is made of glass with one or more longitudinal strips of white or coloured enamel or glass on the exterior or interior surface, or embedded in the body of the material, one or more spaces of clear glass being left between the widths or bands of opaque enamel to enable the height of the contents to be read off. The graduations are engraved, painted, or etched upon the opaque widths or bands, and extend right up to or even cross the transparent or clear widths.—W. D. B.

Improvements in Thermometric Apparatus. A. G. Brookes, London. From E. W. Upton, Peabody, Massachusetts, U.S.A. Eng. Pat. 4769, April 17, 1885. 8d.

THIS invention relates to the construction of thermometric apparatus in which a pointer is moved by the tension of a helical spring or coil composed of two metals of unequal expansibility. The improvements described consist of an arrangement by which the helical coil is brought parallel to the pointer and not at right angles as heretofore: of a holding device for the coil whereby the effective length of the coil may be adjusted, so that the sensitive helical coils of any number of instruments may be easily regulated to give the same amount of movement to the pointer, although the coils themselves are not exactly uniform in size; of an adjusting device for regulating the position of the helical coil in relation to other parts of the instrument, that the pointer may readily be set at any graduation on the dial for a given temperature. Provision is also made for registering maximum and minimum temperatures by means of free secondary pointers working upon a dial, preferably of smaller diameter than that which co-operates with the main pointer.—W. D. B.

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Lark, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8s.	4d.
Above 8s., and not exceeding 1s. 6d.	1d.
1s. 6d., ..	2s. 1d.
2s. 4d., ..	3s. 1d.
	2d.

Improvements in Arrangements for Use in Oxygenating Water contaminated with Organic Matter. W. F. B. Massey-Mainwaring and J. Edmunds, London. Eng. Pat. 14,807, Dec. 2, 1885. *Sd.*

THE water to be treated is introduced into a well divided in the centre by a partition, on one side of which the water enters and on the other side leaves the well by a suitable passage. Air is blown into the water at the deepest part of the incoming column of liquid, and under the pressure due to the head of water is dissolved, oxidising the impurities, the excess escaping at the surface of the outgoing column. The same thing may be effected by substituting for the open columns of water a stack of tortuous or coiled pipes, at the base of which the air is injected. In all cases the head of water should be from forty feet upwards.—C. C. H.

Improvements in Apparatus for Separating Dust or Solid Particles suspended in Air or other Gases. H. Simon, Manchester. Eng. Pat. 14,905, Dec. 4, 1885. *Sd.*

THE inventor effects the separation of dust or small solid particles from air, by causing the air to ascend slowly through a chamber, in which are arranged one above another, layers or rows of bars, grids, or channels, with

particles by means of subsidence, the rapidity of such subsidence depends directly upon the vertical depth of the liquid. The time taken for the separation being proportional to the depth, the shallower the depth the quicker the operation. In their invention advantage is taken of this rule by applying it to apparatus with extended shallow depositing surfaces provided within a limited space. The accompanying figures, which give three views of one arrangement of the apparatus, will make its action clear.

The tank A is shown raised from the ground, the end D forming a store chamber for the clarified liquid. The bottom of the tank is shaped hopper-like, into which the deposit sinks after separation, and it has a longitudinal opening below closed by a hollow cylindrical valve F, which can be turned by the hand wheel G and worm, for the periodical discharge of the deposit. Any other suitable discharging device may be used instead.

An inclined partition C is provided not far from one end of the tank, reaching from the top to near the bottom, and behind it is a series of inclined smooth plates H H, parallel to C and also kept clear of the bottom, but made water-tight at the sides. The inclination of the sides is such as to allow the deposit to slide down easily and to

FIG. 1.

FIG. 2.

FIG. 3.

small intermediate spaces between them for the passage of the air. The disposition is such as to allow the bare or passages to alternate in adjacent layers. The layers are by preference made higher in the middle of the chamber than at the sides, forming peaks along the centre, for the purpose of allowing the separated dust to slide down the inclined bars or channels, and collect in common receptacles at their ends, whence it may be removed in any convenient manner. The bars may receive a reciprocating movement in their longitudinal direction, or brushes may be made to travel over them with the view to accelerating the collection of the dust, which may be further assisted by the application of an exhaust at the delivery end of the channels. The specification describes some modifications.—B.

Improvements in Subsidence Apparatus. S. H. Johnson, and C. C. Hutchinson, Stratford, Essex. Eng. Pat. 15,713, Dec. 21, 1885. *Sd.*

THE inventors state that they have found, when treating torpid liquids for the separation of their suspended solid

reach the hopper without disturbance. The torpid water enters by the pipe B, sinks down behind the partition C, and slowly rises from below into the spaces between the inclined plates, its speed on rising being regulated to less than the rate of subsidence, which is easily ascertained for various liquids by trial. The cleared water falls finally over the last partition into the reservoir D, and is drawn off by the pipe E.—B.

II.—FUEL, GAS, AND LIGHT.

Experiments with Coal used for Gas Making. H. Bunte. Dingl. Polyt. J. 262, 141.

CONTRARY to the assumption that the elementary analysis of coal offers but little information concerning the value of coal for gas-making purposes, it is shown by experiment that the chemical composition of coal and the most essential factors which engage the attention of the gas maker, are intimately related to one another. As a characteristic constituent of gas coal, oxygen is mentioned, reference being made

to its influence on the quantity and quality of the gaseous and fluid products of distillation. That it is possible to form a definite or valuable judgment of the gas-making properties of a coal from the elementary analysis, is shown by the results of a series of experiments made by the Paris Gas Company at their La Villette testing works. From 1874 to 1884, 1012 experiments were made with 59 different kinds of coal. Each experiment involved the carbonisation of 36,000 kilos. of coal. In addition to the practical analysis, the coal and the products of distillation were subjected to chemical analysis. The constituent oxygen formed the criterion as to the value of each specimen of coal. The quantity varied from 5 to 12 per cent. in the different samples examined. The results arrived at fully confirm the author's views:—(1.) The greater the amount of oxygen present in coal the greater is the quantity of volatile matter, tar and ammonia. (2.) The yield of coke and gas decreases with an increase in the amount of oxygen. (3.) The quantity of hygroscopic water contained in the coal is dependent on the amount of oxygen present therein. With regard to the quantity of benzene contained in coal gas, the results of the Paris Company appear to show that the different varieties of coal yield a gas containing a fairly constant proportion of aromatic hydrocarbons (39grms. of hydrocarbons in 1 cubic metre of gas, of which 30grms. are benzene and 9grms. toluene and its homologues) amounting to 1.05 per cent. In addition to this quantity, the gas contains from 2.5 to 4.8 per cent. of propylene, acetylene and other heavy hydrocarbons. It is also shown that under normal conditions 94 per cent. of the valuable luminosity constituents remain in the gas whilst only about 6 per cent. are present in the tar, a circumstance which proves that the processes which aim at extracting the benzene from tar and restoring it to the gas are of but little practical value.—D. B.

Valuation of Petroleum. C. Engler. Chem. Zeit. 10, 1238—1239, and 1271.

THE author confirms the opinion expressed by Thoenner (this Journal, 1886, 371) that the best methods for determining the value of petroleum as an illuminating agent, are the flashing test and examination of the oil as to its temperature of distillation. For the latter purpose the use of the apparatus described by Thoenner is recommended; the author, however, prefers a glass distillation

9cm., whilst the delivery tube is 10cm. long, 0.6cm. wide, and passes into a copper condensing tube 45cm. long and 1cm. wide.

The ordinary method of distillation does not, however, give concordant results in the hands of different operators; the author therefore recommends the following modification: 100cc. of petroleum are distilled in the above-named apparatus. The distillate boiling up to 150° is allowed to come over at the rate of 2—2½cc. per minute, and when a temperature of 150° has been reached, the flame is removed and the temperature reduced by 20°, after which it is again raised to 150°, this operation of cooling to 130° and heating to 150° being repeated until it is no longer possible to measure the distillate. The fractions boiling up to 200°, 250° and 300° are distilled over in a similar manner. The author objects to limit the distillation to 25—30 minutes, as suggested by Thoenner, owing to the fact that the rate of distillation is dependent on the percentage of distillate obtainable at 300°. He does not approve of extending the limits of the fractionating temperature of normal petroleum (which boils between 150° and 300°) to from 140° to 310° as suggested, being moreover of opinion that the maximum temperature might be reduced to 270° with advantage, especially in the case of Caucasian petroleum, as it has been shown in a recent investigation (this Journal, 1886, 480) that the high boiling fractions have an injurious effect on the illuminating power of petroleum.—D. B.

Improvements in Machinery or Apparatus for the Manufacture of Gas for Illuminating and Heating Purposes. F. W. Clark, London. Eng. Pat. 6511. August 25, 1886. 8d.

GASOLINE or other suitable light hydrocarbon is passed into a heated retort, where it is partly decomposed. The vapour is conducted to a series of impinging points placed opposite to a corresponding series of short tubes, and, rushing through these, creates a partial vacuum whereby air is drawn in to mingle with the hydrocarbon gas. This air is heated on its way by passing in contact with the out-sides of the short tubes above mentioned. The mixed air and hydrocarbon vapour, which has become a practically fixed gas, is passed through horsehair or other scrubbing material placed in a water-cooled vessel.—A. R. D.

Improved Process for Manufacturing Illuminating Gas. A. M. Clark, London. From J. S. Leng, New York. Eng. Pat. 15,768, August 25, 1886. 8d.

HYDROGEN and carbonic acid are produced by the simultaneous action of dilute acid upon scrap iron and carbonate of lime. The mixed gases are carburetted by being passed through a chamber containing cotton wick saturated with petroleum or other suitable hydrocarbon.—A. R. D.

Improvements in Carburetting Compounds. P. M. Justice, London. From A. P. Rockwell, New York. Eng. Pat. 11,829, Sept. 17, 1886.

THE inventor dissolves 3lb. of gum camphor and 5lb. of vegetable wax in 25 gallons of "benzine" (petroleum spirit) and uses the compound in the same way as other carburetting compounds in any suitable carburetting apparatus. For illuminating gas, Japan-wax is preferred, but for heating purposes "Bay berry wax" is better.—A. R. D.

Improvements relating to the Utilisation of Fuel in a Comminuted Condition, and to Apparatus therefor. H. H. Lake, London. From H. K. Flagler, Boston, U.S.A. Eng. Pat. 15,780, Sept. 22, 1886. 8d.

THIS invention relates to an improvement in the process and apparatus for the utilisation of comminuted fuel referred to in the American patents 53,208 of 1866; 38,577 of 1870; 59,695 of 1866; 102,997, 103,695, 103,804, and 109,785 of 1870; and 111,705 of 1871. By this invention a storage bin is connected by a branch way with the passage whereby the fuel is conveyed from the commi-

flask to the copper distilling flask employed by Thoenner. In recommending the adoption of the conditions of distillation as suggested by Lunge (this Journal, 1884, 513 and 625), the author states that the top of the thermometer bulb should be in a line with the lower edge of the delivery tube, as illustrated in the accompanying drawing. The distance from the top of the charge in the flask (100cc.) to the lower edge of the delivery tube is

nutor to the furnace. By a suitable disposition of valves the comminutor may be made to work either into the furnace direct or into the bin. This latter is provided with a screw which feeds the contents into a shell or casing communicating with the passage to the furnace. Inside the shell works a blower which aids the delivery of the comminuted fuel. The mechanism of the screw-feeder in the bin is quite independent of the comminutor.

—A. R. D.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Some Notes on Gas Liquor and Ammonia Purification.

By Lewis T. Wright. *Journal of Gas Lighting*, 48, 280, 329, 373, and 511.

THIS is a review of what might be expected to take place in ammonia processes for the purification of coal-gas, and, for the purpose of illustrating the reactions involved, the author traces the history of the ammonia resulting from one ton of gas-coal through the various operations of its collection.

For the sake of convenience, the term "hydrogen equivalent" (H.E.) is borrowed from volumetric analysis, but it means, unless otherwise stated, not grammes per litre, but milligrammes simply of the bodies in question, thus—

1 hydrogen equivalent of NH_3 is 17 milligrammes.	
1 " " of CO_2 is 22 " "	
1 " " of H_2S is 17 " "	

And all analyses of liquor are in hydrogen equivalents per 100 cubic centimetres. To convert the hydrogen equivalents into percentages (assuming, for convenience, all the gas liquors to have a specific gravity equal to water), it will be only necessary to multiply them by the following numbers:—0.017 for NH_3 , 0.022 for CO_2 , and 0.017 for H_2S , to have grammes per 100 cubic centimetres, pounds per 10 gallons of the bodies in question, or percentages.

Thus a liquor stated to contain 44 H.E. (hydrogen equivalents) of NH_3 , 21.2 H.E. of CO_2 , and 10 H.E. of H_2S , will be found to contain—

$44 \times 0.017 = 0.748$ grammes. per 100cc., or lbs. per 10 gallons of NH_3 .
$21.2 \times 0.022 = 0.4664$ " " " " " " " " CO_2
$10 \times 0.017 = 0.1700$ " " " " " " " " H_2S

or 0.748, 0.4664, and 0.17 per cent., assuming the specific gravity of the liquor equal to that of water.

This method of stating analyses may appear to be complicated and recondite; but for such a discussion as this is will give a much clearer view of the quality of the liquor. For if it were said that in a certain liquor 0.748 per cent. of ammonia was found in combination with 0.4664 per cent. of carbonic acid, and 0.17 per cent. of sulphuretted hydrogen, no immediate mental picture of the relations of alkali and acids would be given; but if it were said that 44 H.E. of ammonia were found in connection with $21.2 + 10 = 31.2$ H.E. of acids, an immediate idea of its composition would be given, especially when we recollect that 1 H.E. of NH_3 combined with 1 H.E. of H_2CO_3 (or H_2S) gives $(\text{NH}_4)_2\text{CO}_3$ [or $(\text{NH}_4)_2\text{S}$], and 1 H.E. of NH_3 combined with 2 H.E. of H_2CO_3 (or H_2S) gives $(\text{NH}_4)\text{HCO}_3$ [or $(\text{NH}_4)\text{HS}$].

In scrubbing it would be desirable to get the compounds containing 2 H.E. of acid to 1 H.E. of ammonia only; but that, as will be evident later on, is not possible.

The author proceeds to trace the history of the ammonia resulting from the ordinary distillation of a ton of gas-coal for gas-making purposes. The gas liquor condensing between the retort and the condenser equals 13.3 gallons, containing 0.994 "free" ammonia, and having the following composition as regards this constituent, carbonic acid, and sulphuretted hydrogen:—

"Free" NH_3 H.E.	CO_2 H.E.	H.S. H.E.	Total Acids. H.E.	Dif- ference, H.E.	Difference per Cent.	Percentage of Acids as H.S.
44	21.2	10	31.2	-12.8	-29.1	32.05

By "difference" is meant either *plus* or *minus* the number of hydrogen equivalents of acids more or less

than the number of hydrogen equivalents of ammonia. By "difference per cent." is meant the number of hydrogen equivalents of acids more or less than 100 for every 100 H.E. of ammonia present. Thus in the case mentioned above, for every 100 H.E. of ammonia there are 70.9 H.E. of acids, or 29.1 H.E. less than the hydrogen equivalents of ammonia.

The "percentage of acids as sulphuretted hydrogen" will explain itself. Thus, in the case above, for every 100 H.E. of acids, 32.05 H.E. are sulphuretted hydrogen.

The gas, on being cooled in a condenser, deposits 4 gallons of liquor, having the following composition:—

"Free" NH_3 H.E.	CO_2 H.E.	H.S. H.E.	Total Acids. H.E.	Dif- ference, H.E.	Difference per Cent.	Percentage of Acids as H.S.
236.8	189.7	57	246.7	+9.9	+4.2	23.1

This liquor differs widely from the preceding one; but so do the circumstances attending its formation. The one is from hot gas; the other from cold. The variation in composition will become clearer later on. The next operation to which the gas is submitted is a copious washing with gas liquor, consisting of the two previous liquors and that resulting in a fourth washing process shortly to be mentioned, whereby a quantity of ammonia in the "free" condition, equal to 1.939 lb., is recovered. Finally, the gas is washed from any trace of ammonia in a "Standard" washer with clean water, whereby 5.7 gallons, containing 1.012 lb. of NH_3 , having the following composition, are produced:—

"Free" NH_3 H.E.	CO_2 H.E.	H.S. H.E.	Total Acids. H.E.	Dif- ference, H.E.	Difference per Cent.	Percentage of Acids as H.S.
10.4	100.8	26.1	126.9	+22.5	+21.55	20.57

On collecting the liquor at the end of the washing operations, 23 gallons of liquor are obtained, containing 5.553 lb. of "free" ammonia, and of the following composition:—

NH_3 H.E.	CO_2 H.E.	H.S. H.E.	Total Acids. H.E.	Dif- ference, H.E.	Difference per Cent.	Percentage of Acids as H.S.
142.0	136.8	35.5	172.3	+30.3	+21.3	20.6

Summarising the results and inserting the values for the "fixed" ammonia, we have—

	Free NH_3	Fixed NH_3	Free, Per Cent.	Fixed, Per Cent.
13.3 gallons of hydraulic main				
liquor	0.994	0.559	0.748	0.42
4.0 galls. condenser liquor	1.608	0.076	4.02	0.19
scrubber	1.939	0.555		
5.7 " washer	1.012	0.057	1.775	0.10
	5.553	1.247		

Or a total of 6.8 lb. of ammonia per ton of coals.

Continuing the investigation with regard to the carbonic acid and sulphuretted hydrogen removed from the gas by the liquor, and inserting (by difference) the work done by the foul scrubber in respect to these bodies, the results given in Table V. are arrived at.

It must not be understood that a condenser liquor, etc., will always have a composition similar to that stated. Really, the chemical forces regulating the composition are so delicate that apparently trifling differences of temperature and degree of concentration exert considerable influences on the character of a liquor. The same piece of apparatus is continually yielding different qualities of liquor with changes of circumstances; but yet these differences are within certain limits for the same works, because the operations therein conducted vary only within certain limits.

The author examines the composition of the liquor from each of the 10 chambers of the "Standard" washer, as thereby the "growth," so to speak, of gas liquor is capable of very simple illustration. (See Table I.)

Making allowance for experimental errors, it will be noticed that with the concentration of the liquor come: (1) a gradual falling off from 160.42 to 121.55 of hydrogen equivalents of acids per 100 hydrogen equivalents

* Free ammonia is a conventional expression for that portion of the ammonia of gas liquor combined with CO_2 and H_2S .

of ammonia; (2) a gradual falling off of the percentage of acids occurring as H_2S from 53.25 to 20.57 per cent.; and (3) a gradual rise in the fixed ammonia from nil to 6 H.E.

In reviewing these figures, it must be noted that there is one constant condition present—viz., temperature; for there was only 1° F. difference between the inlet and the outlet of the washer. They can be regarded as a case of the influence of concentration on the composition—perhaps a little complicated by variations in the composition of the gaseous mixture in contact; but it is hardly probable that this latter is more than insignificant.

It will be useful to compare the liquor in the fifth and sixth chambers with the liquor collected at the inlet of the condenser (hydraulic main liquor), which occupies a mediate position to them, as regards degree of concentration, and has a very low proportion of acids, and these results with some obtained at a different works

100cc., was heated to 65° C., and agitated, to assist in expulsion of the gases dissociated; then again heated to 80° C.; and, finally, to 85° C.—samples being drawn off at each stage, and submitted to careful analysis. The results are given in Table III.

It is a very common belief that, by prolonged contact of the gas liquor with the gas, the sulphuretted hydrogen can be "pushed out" in favour of the carbonic acid. With our present knowledge it is almost impossible to foretell, at least with any degree of sharpness, what will take place on washing crude gas with a certain sample of gas liquor. Sometimes the carbonic acid will be expelled in favour of sulphuretted hydrogen, and sometimes the reverse phenomenon will occur. It appears to be a question of the equilibrium between three bodies (CO_2 , NH_3 , and H_2S) *vis-à-vis* to four compounds formed by their union (NH_4HCO_3 , $[\text{NH}_4]\text{CO}_3$, NH_4HS , $[\text{NH}_4]\text{S}$)—a case of a base divided

NOTE.—The liquor in the tenth chamber was too weak for analysis.

from a washer taking the gas from the outlet of the condensers, and fed with clean water (there being no pumping over of gas liquor). (See Table II.)

With the exception of the seventh, eighth, and ninth chambers, these samples show a very regular and similar falling off of excess of acids and proportion of acids as H_2S . The three last chambers are to be regarded as approximate only, since the quantity taken for analysis being unfortunately small, experimental errors (impossible, under the circumstances, to avoid), would have very great influence. Thus only 0.2cc. of the standard acid was employed for titrating the ammonia in the ninth chamber liquor.

In order to further illustrate the influence of temperature on the composition of liquors, the following case is cited. It is interesting in regard to such proposals as that of Mr. F. C. Hills for the treatment of gas liquor for gas purification processes. Some of the liquor previously described, having 142 H.E. of ammonia per

between two acids complicated by the easy dissociability of the four resultant bodies.

As an instance of the pushing out of carbonic acid by sulphuretted hydrogen in the washing of gas by liquor, the following case is quoted:—One very hot day it became evident that the liquor circulating through a tower foul scrubber was not gaining in strength as regards ammonia. It could not be "got up." Repeated and most careful analyses were made of the liquor on the inlet and outlet of the scrubber, and these results were brought out:—

	"Free" NH_3 , H.E.	CO_2 , H.E.	H_2S , H.E.	Total Acids, H.E.	Difference, H.E.	Difference Per Cent.	Percentage of Acids as H_2S .

Out...	104.30	94.33	33.70	128.03	+23.73	+22.75	26.3

Temperature of scrubber, 60° Fahr.

With so low (for the degree of concentration) total acids, it was to be expected that the relative quantity of these to ammonia might be increased. The temperature was too high to admit of absorption of more ammonia; but the sulphuretted hydrogen increased, and this partly at the expense of the carbonic acid.

A fortnight later (the weather being much cooler in the meanwhile), the strength began to "get up;" and samples from the inlet and outlet gave the following results:—

	"Free" NH_3 H.E.	CO_2 H.E.	H_2S H.E.	Total Acids H.E.	Difference H.E.	Difference per Cent.	Percentage of Acids as H_2S .

The weather on the few days previously had been cooler even than on the day the sample was taken. Here there is an appreciable gain of ammonia, but a loss of acids. It would seem that gas-liquor is never in equilibrium, it being, as regards composition, in a continual state of unrest.

To illustrate the broad influence of seasons on the whole product of gas-liquor as sent from a gas-works,

larger proportionate washing surface in summer than in winter, the strongest liquor is procured when the weather is cold. This diagram emphasises the influence of temperature on the concentration of gas-liquor.

The value of each degree Twaddel in terms of the percentage of ammonia will be interesting to those who sell their gas-liquor on the hydrometer basis. This value (called the "factor") generally rises and falls with the

concentration of the liquor. It is too long a matter to go into the variations in the fixed ammonia. Enough has been said to suggest that though gas-liquor is a variable, sensitive sort of liquid, its variations are governed by laws, and is controlled by the action of chemical forces not so occult as to be undiscoverable. As it is often convenient to know the weights of quantities of H_2S , CO_2 , and NH_3 , when expressed in percentage by volume, Table IV. is inserted (page 657), calculated on the basis of 760mm. bar. and 15.5°C . These standards approximate so closely to the English ones

This is started with 23 gallons of gas-liquor, containing 5.553lb. of NH_3 combined with 6.922lb. of CO_2 and 1.388lb. of H_2S , and 1.247lb. of NH_3 combined with stronger acids, requiring for their liberation the assistance of a stronger base. It is assumed that the whole of these 6.8lb. of ammonia can be recovered in the caustic form; and by what means it can be so causticised is a matter of indifference at the moment, the commercial aspect of the question at this stage of the inquiry being purposely eliminated. It can be done by distillation with excess of lime. The gas-liquor is perfectly useless

DIAGRAM showing the Monthly Averages of Analyses of Ammoniacal Liquor delivered from Three Gas Works—A, B, and C.

(30in. bar. and 60°Fahr.) that it can be used with them.

The author refers to the past and present interest in ammonia purification processes, and declines to discuss either the Claus or Hammond process for want of sufficient information respecting these. The chances of ammonia purification are examined on theoretico-practical grounds, and the first case imagined will be the simplest expression we can give to such a method.

First Case.—The problem is to remove from the gas resulting from the distillation of one ton of gas-coal the whole of the carbonic acid and sulphuretted hydrogen,

in its ordinary form. With these 6.8lb. the coal-gas is to be washed at a stage immediately later than the ordinary scrubbing or washing that resulted in the production of the 23 gallons of gas-liquor. The liquor containing the causticised ammonia is called the "regenerated liquor," and would have 173.88 H.E. of caustic ammonia, or $173.88 \times 0.017 = 2.956\text{lb.}$ per 10 gallons. Since a liquor of this degree of ammonia concentration could probably not, in an ordinary way, combine with more than 110 H.E. of acids per 100 H.E. of ammonia, it is proposed to consider it as being diluted down so as to have a concentra-

tion of 142 H.E. This dilution can take place in the regeneration; and this because it is desired to retain a liquor of that degree of concentration as a type. The gas representing one ton of coals is supposed to contain 14.5 lb. of H_2S and 21.5 lb. of CO_2 at the commencement of the ammonia purification process.

Considering a hydrogen equivalent as equal to 0.0017 lb. of NH_3 , 0.0022 lb. of CO_2 , and 0.0017 lb. of H_2S , as it would be if the analyses were stated in pounds per gallon. We shall then have—

$$\begin{aligned} \frac{6.8}{0.0017} &= 4000 \text{ H.E. of } \text{NH}_3, & \frac{21.5}{0.0022} &= 9773 \text{ H.E. of } \text{CO}_2, \\ \frac{14.5}{0.0017} &= 8529 \text{ H.E. of } \text{H}_2\text{S}. \end{aligned}$$

or 4000 H.E. of ammonia and 18,302 H.E. of total acids. Further, assuming that the relation of 142 H.E. of ammonia to 172.3 H.E. of total acids will still be maintained through all the liquors obtained in the purification process, that the 4000 H.E. of ammonia can always be "regenerated" without loss, and that there will be no interference by the combination of some of the ammonia with bodies other than sulphuretted hydrogen and carbonic acid—in other words, that there will be no accumulation of fixed ammonia—the question is asked, *How many times will it be necessary to regenerate our 4000 H.E. of ammonia to remove from the gas 18,302 H.E. of acids?* The answer is 3.77 times; thus—

$$\frac{142 \times 18,302}{172.3 \times 4000} = 3.77 \text{ nearly.}$$

This purification is traced by steps in order to discover the composition of the gas as regards carbonic acid and sulphuretted hydrogen after each washing with the regenerated ammonia:—

Quantities of CO_2 and H_2S remaining in the Gas after each Washing with Regenerated Ammonia.

Before washing	21.5	lb. CO_2 ..	14.5	lb. H_2S .
After 1st washing	13.024	"	12.801	"
After 2nd washing	4.548	"	11.102	"
After 3rd washing	nil.	"	6.367	"
After 4th washing with 77 p.c. unregenerated ammonia	nil.	"	nil.	"

Thus arriving at the same result.

Since the causticisation of the gas-works ammonia by purely chemical methods (such as its replacement by some other alkali) is quite out of the question for an ammonia purification process, men have been led to consider other means of effecting this object—strictly mechanical means suggested by the property the compounds of ammonia with carbonic acid and sulphuretted hydrogen respectively have of being readily dissociated by heat. The weak chemical affinity possessed by these compounds, and the comparative ease with which the three bodies can be brought into a free gaseous condition, together with their varying solubilities in water, form the basis of a method for the separation of the alkali from the objectionable acids. The author thinks that Hills was the first to attempt the causticisation of the ammonia of gas-liquor for purification by the simple heating of the liquor, but is not aware that the behaviour of the liquor under these circumstances has been copiously studied; but a broad fact was recognised by Hills—namely, that the application of a certain degree of heat to gas-liquor resulted in the expulsion of comparatively more of the acids (CO_2 and H_2S) than the ammonia; and that, consequently, a liquor so treated contained less of these acids in proportion to its content of ammonia than it did before being submitted to this operation of heating.

Armed with these two generalisations—(1) that heat causes a dissociation of the principal ammonium compounds of gas-liquor into free NH_3 , CO_2 , and H_2S respectively; and (2) that ammonia gas is much more soluble in water than carbonic acid and sulphuretted hydrogen gases respectively—it is possible to conceive a method for the separation of the more readily soluble ammonia from the less soluble acid gases. Further, if (1), at a moderate temperature in the presence of water, the dissociation of the ammonium salts in question were complete, and (2), conversely, at the said moderate tem-

perature, it were only a question of the absorption coefficients of the ammonia, carbonic acid, and sulphuretted hydrogen in water, uncomplicated by the play of any chemical affinities (the dissociation in the presence of water being assumed as complete), the causticisation of the gas-works ammonia for practical purposes would be comparatively simple. But it unhappily occurs that no moderate heating short of boiling and consequent expulsion of the constituents of gas-liquor results in the complete dissociation of the compounds of ammonia with carbonic acid and sulphuretted hydrogen contained therein. That anything more than a very partial causticisation of the ammonia of gas-liquor is possible by Hills' process must be admitted.

It was previously shown that a liquor of the composition—

"Free" NH_3 H.E.	CO_2 H.E.	H.S. H.E.	Total Acids, H.E.	Differ- ence, H.E.	Differ- ence per cent.	Percentage of Acids as H.S.
142.0	126.8	35.5	172.3	+30.3	+21.3	20.6

on heating to 85° C., with agitation, was left with a composition of—

"Free" NH_3 H.E.	CO_2 H.E.	H.S. H.E.	Total Acids, H.E.	Differ- ence, H.E.	Differ- ence per cent.	Percentage of Acids as H.S.
126.5	83.8	25.1	108.9	-17.6	-13.9	23.0

This residual liquor would be of considerable value as a purificatory agent, as, with a difference per cent. of -13.9, it might, by contact with coal-gas, be readily brought up to a difference per cent. of +21.3. On this basis each gallon would be able to put on 44.6 H.E.; and as there are 18,302 H.E. of total acids in the crude coal-gas to be purified per ton of coal after the usual washing process, it would be necessary to treat the gas with—

$$\frac{18,302}{44.6} = 410 \text{ gallons (nearly)}$$

of this partially "regenerated" liquor for complete purification; or the 23 gallons would have to be submitted to Hills' process—

$$\frac{410}{23} = 17.8 \text{ (nearly)}$$

—say, about 18 times. This may sound a good many; but it would not be at all a serious matter to raise 410 gallons of gas-liquor to 85° C., and, after agitation, to cool it to normal temperature for every ton of coals carbonised; and it is difficult to think why Hills' process has not met with more success. In connection with a sulphate works, where the gases expelled on the heating of the liquor could be passed through an acid saturator for the manufacture of sulphate, the system would be simple. Agitation to assist expulsion of gases from the heated liquor would be a great feature in such a process.

For an argument of this kind, a higher temperature than 85° C. might have been selected, resulting in the production of a liquor containing, relatively to the ammonia present, a lesser proportion of total acids, and capable of removing per gallon a larger number of hydrogen equivalents of impurities from the gas to be purified. However, the instance cited will serve to illustrate one form of an ammonia purification process.

The author does not believe that any high degree of causticisation of gas-liquor by Hills' process is attainable. But until more definite information is forthcoming, it will be quite natural that great things should be expected of a method founded upon some system of fractional distillation, wherein the gases were expelled from the gas-liquor and the ammonia continuously washed back with as little as possible of the objectionable acids. But having obtained by any means a caustic liquor, it is in the highest degree improbable that any advantage can result by its final distillation, with a view of expelling its ammonia into the coal-gas to be purified in a gaseous condition, rather than using the caustic liquor direct for the treatment of the coal-gas. For all practical purposes of gas purification, when, by a process of fractionation, a caustic liquor can be secured, it will be sufficient to use it forthwith; for, that there are any magical results attending the application of a certain quantity of caustic ammonia to the coal-gas to be purified, simply

because it is in the gaseous condition, and not dissolved in water at the time of its introduction, the author does not believe.

The fractionation of the constituents of gas-liquor is a matter of great importance; but it is hard to call to mind a case of fractionation in every respect similar to the one at present under discussion.

Mallet's proposed process for the preparation of a concentrated oxygen from the atmosphere is referred to as an interesting case of the more or less perfect separation of the two constituents of atmospheric air.

The separation of the constituents of mixed liquids by fractional distillation, though in many instances a matter of ease, in other cases is impossible. Many mixtures of liquids—like a solution of hydrochloric acid, consisting of 79.8 per cent. of water and 20.2 per cent. of HCl—distil unchanged as a homogeneous liquid, and cannot be separated by fractional distillation. The disengagement of ammonia from carbonic acid and sulphuretted hydrogen is a case complicated by chemical affinities which come prominently into play at certain temperatures. Given a gaseous mixture of the three bodies in question, the differentiation of the ammonia from the other two is not an easy matter. Any attempt at separation by washing with water will result in a solution containing each of the three bodies. One cannot dissolve the ammonia without also dissolving some of the acids, with the formation of ammonium compounds. The first gases coming off a gas-liquor submitted to distillation are relatively to the liquor poor in ammonia and rich in acid gases; but as the distillation proceeds the gases become relatively richer and richer in ammonia.

By referring to the case of the liquor submitted to 85° C. with agitation (above-mentioned), the gases expelled had the constitution—

NH ₃ H.E.	CO ₂ H.E.	H ₂ S H.E.	Total Acids. H.E.	Difference H.E.	Difference per cent.	Percentage of Acids as H ₂ S.
15.5	53.0	10.4	63.4	+47.9	+309.0	16.4

In washing such a gas with water to arrest the ammonia a large quantity of acid gases must escape; but a caustic liquor is not thereby produced.

On pushing the liquor to distillation, and collecting successive portions of the distillate, liquors of the following composition were obtained:—

	NH ₃ H.E.	CO ₂ H.E.	H ₂ S H.E.	Total Acids, H.E.	Difference, H.E.	Difference per cent.	Percentage of Acids as H ₂ S.
First 10th of liquor over	577.0	622.0	118.2	740.2	+163.2	+28.3	15.5
Second do.	259.0	110.0	25.4	135.4	-123.6	-47.7	18.9
Third do.	84.5	7.0	10.1	17.1	-67.4	-80.0	59.0

Of 1420 H.E. of ammonia taken, 259 H.E., or 18.24 per cent., are recovered in connection with -47.7 difference per cent. of total acids, and 84.5, or 5.95 per cent., with -80 difference per cent. of total acids.

Now, if it were sought to secure a liquor containing only 20 H.E. of total acids per 100 H.E. of ammonia, it would be only possible to get on the first distillation—

$$\frac{84.5 \times 100}{1420} = 5.95 \text{ per cent.}$$

of the ammonia in the required condition; and the balance would have to be successively distilled and re-distilled till the whole of the ammonia was brought to the required degree of causticity. Of course, in a process of fractionation, these successive distillations would really form part of a continuous process.

Until further information is forthcoming, judgment as to the relative values of Hills' and Claus' methods of ammonia purification must be suspended.

On the Earth-Oil of Baku. Dingl. Polyt. J. 262, 47.

PROFESSOR D. J. MENDELEJEFF, who has been commissioned to study this industry on the spot, in a communication to the Russian *Zeitschrift Technik*, 1886, No. 109, says that the mode of working Baku oil is different from the method usually adopted in America, on account of the difference in composition. In his

experiments, he succeeds in obtaining 50 per cent. light oil, instead of the 30 per cent. hitherto obtained. It is known as "Bakuol," burns well, and compares favourably with the American product in every respect. The naphtha residues also now possess a higher value, and are not merely used for fuel as hitherto. The "Bakuol," mixed with 30 per cent. of tar-oil and other products, is known to the Petersburg Chemical Society as "Ragasin," and can be burnt in various lamps with the best results. He does not fear the exhaustion of the oil-springs in the near future, it being simply necessary to bore deeper for fresh supplies. In the neighbourhood of Baku, 5 parts of the sand contain 1 of naphtha. According to geological examination the naphtha-bearing layer has a thickness of several metres.—W. R.

IV.—COLOURING MATTERS AND DYES.

On Phenazine. A. Bernthsen. Chem. Zeit. 10, 1241.

THE author makes some interesting statements concerning the chromogenic character of the compound

which has been termed phenazine by Merz, who has also established its identity with the azophenylene described by Claus. It is shown that Witt's toluylene-red is *dimethyldiamidomethyl-phenazine*

By removing one amido group with N₂O₅, *dimethylamidomethyl-phenazine*

is obtained. This substance resembles erubidine in properties. It forms red prisms exhibiting a fine gold-coloured fluorescence in ethereal solution. The simplest toluylene-red obtained from metatolylenediamine and paraphenylenediamine proved to be *diamidomethyl-phenazine*

as by diazotising it the author obtained *methyl-phenazine*, a body which Merz had previously prepared by heating catechol with orthotolylene diamine.—D. B.

Improvements in the Manufacture of Colouring Matters for Dyeing and Printing. H. Hassenkamp and the "Farbenfabriken vorm. F. Bayer & Co.," Elberfeld, Germany. Eng. Pat. 15,337, Dec. 14, 1885. 6d.

THE object of this invention is to supply colours which can be used as cheap substitutes for certain indigo preparations. The materials employed are the nitroleuco-bases obtained by the condensation of metanitrobenzaldehyde with alkyl-derivatives of aniline (E. & O. Fischer, Ber. 12, 802) and the amidoleuco-bases obtained by their reduction. In the present process benzyl groups are introduced into these amidoleuco-bases, and the benzyl derivatives are converted into sulphonic acids, and the latter then oxidised to acid colouring matters of a bluish green shade. As examples of materials the authors mention the amidoleuco-bases obtained by reducing the condensation products of metanitrobenzaldehyde with mono- and dimethylaniline, mono- and diethylaniline, methyl- and ethylbenzylaniline, etc. It is stated that with these materials the benzyl groups contain the sulpho groups. The following illustration of the practical working of the process is given. The amidoleuco-base, NH₂.C₆H₄.CH : [C₆H₄.N(CH₃)₂]₂, from metanitrobenzaldehyde and dimethylaniline is first benzylised by being heated in an autoclave with the necessary quantity of benzyl chloride and caustic soda (115° C. for 4–6 hours), and the product is steam-distilled

and dried. The benzylised base is then sulphonated by treatment with five times its weight of fuming sulphuric acid (20–25 per cent. anhydride), the sulphonic acid oxidised by lead or manganese peroxide, and the colouring matter salted out.—R. M.

Improvements in the Manufacture of Colouring Matters. C. Rudolph, Höchst, and Oscar Gürke, Elberfeld, Germany. Eng. Pat. 15,716, Dec. 21, 1885. 6d.

THIS specification relates to the production of naphthalenetrisulphonic acid and naphtholdisulphonic acid, and the colours derived therefrom. Naphthalene is gradually introduced into eight times its weight of fuming sulphuric acid (24 per cent. anhydride), and the mixture kept at 180° C. for several hours, or six parts of acid containing 40 per cent. of anhydride can be used, keeping the temperature down to 80° during mixture, and then heating on a water-bath. The product is limed, and the calcium salt converted into one of sodium. Instead of naphthalene, its mono- or disulphonic acid may be employed, and sulphonation may also be effected by means of sulphonic chloride, sulphuric acid and sodium pyrosulphate, sulphuric and metaphosphoric acids, etc. The sodium salt, prepared as above, may be used directly, or it may, if required, be purified by fractional crystallisation from water, or by extraction with alcohol (80° Tralles). In order to convert the trisulphonic acid into naphtholdisulphonic acid, the sodium salt is heated in a closed vessel with half its weight of caustic soda, and a similar weight of water. The vessel is heated in an oil bath to 170–180° C. for several hours. The melt contains a mixture of naphtholdisulphonic acids which may be used without separation, or one of the isomerides may be separated in the form of an acid sodium salt, by adding hydrochloric acid and evaporating to the crystallising point. Another method of separation consists in neutralising the melt with hydrochloric acid, evaporating to dryness, and extracting with alcohol (80° Tralles). The inventors mention a number of characters in which their acid differs from the four known naphtholdisulphonic acids of previous patents. The azo-colours are prepared by combining various diazotised bases with the new acid in alkaline solution in the usual way.—R. M.

Improvements in the Production of Colouring Matters or Dyestuffs. C. D. Abel, London. From Carl Roth, Berlin, Germany. Eng. Pat. 43, Jan. 1, 1886. 6d.

THE colouring matters obtained by the oxidation of mixtures of aromatic monamines and paradiamines (Indamines) are well known to be very unstable, and have, therefore, but a limited application in dyeing and printing. According to the present invention, stable colouring matters are produced by oxidising the mixture in the presence of sodium hyposulphite or hypophosphite. Three examples of the mode of preparation of these dyes are given in the specification:—(1.) Dimethylaniline is converted into dimethylparaphenylene diamine, and the hydrochloride mixed with the necessary quantity of aniline hydrochloride, and afterwards zinc chloride and sodium hyposulphite are added. The solution is mixed in the cold with potassium chromate and heated for some time, dilute sulphuric acid and more chromate being added till the oxidation is complete. The colour is finally salted out by adding common salt, and is sent into the market in the form of a double zinc salt. (2.) Dimethylparaphenylene diamine is oxidised as before in the presence of dimethylaniline and sodium hyposulphite. The colour has a greenish blue shade, whereas that obtained in the first example has a reddish blue tint. (3.) "Dimethylphenylene green" is reduced to its leuco-base by means of zinc dust, and then oxidised in the presence of hyposulphite. The colour is identical with that obtained in the last example. Instead of the dialkyl-diamines the paranitroso derivatives of the tertiary amines may be employed. Thus the colouring matter of example 2 can also be obtained by heating a solution of nitrosodimethylaniline and dimethylaniline hydrochlorides with hyposulphite, and then oxidising with chromate as before.—R. M.

An Improved Process for Manufacturing Colour Sensitive (Isoschromatic or Orthochromatic) Photographic Emulsions or Plates by Dyeing the same with Dyes highly sensitive to Light. H. W. Vogel, Berlin, Germany. Eng. Pat. 7963, June 15, 1886. 6d.

THE object of this invention is to make gelatin or other photographic plates sensitive to yellow and red light by the addition of a small quantity of certain dyes. The dyes most suitable are such as are themselves readily decomposed by light. The following formula is suitable for many emulsions:—

2 to 4cc. of a solution of quinoline red in alcohol (1 to 500).
5 drops of a solution of cyanine (1 to 500).
100cc. of water.
1cc. of ammonia.

The plates are steeped in this solution for one minute, and then dried.—E. J. B.

Improvements in the Manufacture of Blue Dyestuffs or Colouring Matters, and in the Method of fixing the same. J. C. Jefferson, Leeds. From G. A. Dahl (Dahl & Co.), Barmen, Prussia. Eng. Pat. 10,134, Aug. 9, 1886. 6d.

THESE colouring matters are obtained by fusing paradiamines with amidoazo compounds or their sulphonic acids. They are soluble in water, and dye mordanted cotton blue which becomes darker on oxidation with potassium bichromate, and is then fast, both as to light and washing. The best results are given by paraphenylene diamine and amidoazobenzene and its homologues. The amidoazo compounds are used in the form of hydrochlorides, or else benzoic acid is added during the fusion. The method of oxidising the colour so as to fix it in the fibre consists simply in passing the dyed goods through a boiling bath containing the oxidising material.—R. M.

Manufacture of Resorcin Blue. O. Murray. From H. M. Baker, Brooklyn, U.S.A. Eng. Pat. 11,356, Sept. 7, 1886.

To prepare this colour, resorcinol is dissolved in excess of aqueous ammonia, and to the solution is added a solution of the double carbonate of ammonium and copper, equal in weight to that of the resorcinol. Into the mixed solutions a revolving copper plate is immersed; this plate or disc being partly in the solution and partly exposed to the air. The conversion into colouring matter takes place slowly at ordinary temperatures, ammonia being added from time to time to replace the loss by evaporation, and to keep the solution alkaline. When the whole of the resorcinol has been converted, the solution is acidulated and boiled, the colouring matter separating out on cooling. The product may be purified, if necessary, by redissolving in ammonia, and reprecipitating by acid. The colouring matter is said to have the formula $C_{14}H_{12}N_2O_6$; it is insoluble in water and dilute acids, but soluble in alkalis with a blue colour, and readily forms lakes. The methyl and ethyl derivatives have a great affinity for cotton. The inventor claims for this colour a value equal to that of the best qualities of indigo, for which, according to the specification, it can be used as a substitute.—R. M.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

Contributions to the Theory of Turkey-red Dyeing. P. Lukianoff. Dingl. Polyt. J. 262, 36–44.

EXPERIMENTS carried out to determine the rôle of the fatty substances in Turkey-red dyecol have hitherto led to two distinctly opposite views. Some experimenters attribute a chemical action to the fatty acids in the formation of the Turkey-red lake, others assume that the fatty substances in the form of undercomposed glycerides exercise a physical influence on the ingredients of the lake. These views are not new, they appeared even before the introduction of alizarin oil. The arguments

for these views are not satisfactory, so that at the present time not only is the composition of the Turkey-red lake undetermined, but the real action of the fatty substances in the dyeing process is also unexplained, and the composition of the so-called alizarin oil at present used in preparing the fibre for Turkey-red dyeing is still less known.

The following results may in some measure elucidate this question in its different forms; they show which particular fatty substances are able to assist in the formation of the Turkey-red lake, also what influence one or other of them exercises on the properties of the lake.

Liechti and Suida (see this Journal, vol. iii, p. 412), and other experimenters have shown that in the well-washed oil product obtained by sulphonating fatty substances (which on neutralising with ammonia gives alizarin oil), two different products exist, one soluble in water, the other insoluble, and although their exact composition is not yet known, still it is generally understood that the portion soluble in water contains sulpho-fatty acid compounds, whereas the portion insoluble in water contains no sulphur and consists of distinct acid bodies; indeed, according to Müller Jacobs, neutral fatty substances—i.e., glycerides—are also present, and that too in large quantity. It appears therefore very important to know what effect these two products of the action of sulphuric acid upon oil have upon the formation of the Turkey-red lake. To determine this the author treated the fibre with the soluble and insoluble portions of alizarin oil. The washed product obtained by sulphating castor oil is shaken up with four times its volume of water at the ordinary temperature and allowed to stand. The upper oily layer is decanted off, and on the addition of common salt to the lower aqueous solution an amber-yellow fatty substance is obtained; both products were neutralised with ammonia. The two alizarin oils thus produced are transparent, and give clear solutions on dilution with water, although the product insoluble in water is darker and thicker than the other. The product soluble in water contains four times as much sulphur as the insoluble portion, as shown by the following analysis:—

Alizarin Oil.	Water.	SO ₃ .	Fatty substances and Alkali.
From soluble portion	24.10	15.93	59.97
From insoluble portion	26.10	1.08	69.82

Comparative experiments showed that cotton prepared with the product soluble in water gave the purest and brightest reds, whilst that prepared with the product insoluble in water gave the deepest and most even colour, but it was not so pure, being of a dark-yellowish tone. Trials in which mixtures of the two were employed gave fuller but more yellowish colours, as the portion insoluble in water was increased, a difference no doubt due to the facility with which the product soluble in water is removed in the various operations, as proved by weighing the pieces both before and after the different operations, the piece prepared with the product soluble in water being much lighter than that prepared with the portion insoluble in water. The dyed pieces prepared with the portion insoluble in water withstood the action of soap, alkali acid, and chlorine solutions better than those prepared with the portion soluble in water. It is thus evident that the products have a very different action in the process of Turkey-red dyeing.

Since Müller-Jacobs maintains that the portion insoluble in water chiefly consists of unchanged glycerides, the author also examined the influence of this substance on the lake. The fibre was prepared with different mixtures of the portion soluble in water and castor oil. Similar results were observed as in the previous trial—viz., the increasing quantity of castor oil made the ultimate colour much fuller, but also yellower in tone; moreover the pieces felt more or less fatty. The dyed pieces prepared with the castor oil withstood the action of soap better than the others, in fact the colour was considerably improved by this means. Hence the presence of unchanged glyceride is not prejudicial to the formation of the Turkey-red lake, and it is not improbable that the portion insoluble in water may contain unchanged glycerides, as already expressed by Müller-

Jacobs. From various observations, however, the author concludes that the amount of unchanged glyceride in the product insoluble in water is not particularly important.

From the above trials it would be wrong to ascribe the influence of alizarin oils in Turkey-red dyeing entirely to the presence of unchanged glycerides, and that the portion soluble in water merely acts as a solvent suitable for the transfer of the glycerides to the fibre; on the contrary, the portion soluble in water has a much more important role, since it influences the purity and fire of the red colour. The presence of the unchanged glyceride in certain limited proportions is evidently useful in contributing to the fulness and fastness of the colour, but if present in larger quantity it affects the shade, and a strong clearing is required to restore the colour. This is confirmed by the fact that pieces prepared with alizarin oil made from free fatty acids compare favourably in colour with those prepared with alizarin oil made from glycerides.

The author explains that under the influence of heat the portion soluble in water is evidently changed into oxidised fatty acids, which combine chemically with the alumina, this compound again uniting with alizarin to form the Turkey-red lake. This triple compound is itself fast, but it is improved in fulness, lustre, and evenness by the presence of the neutral glycerides which act physically upon it, producing a lustrous fatty covering, thus preventing the loss of water of hydration, which, according to Müller-Jacobs, has a great influence on the beauty of the colour.

From the above it is not difficult to explain what takes place when preparing the fibre with “huile tournaute”—viz., that the glyceride is decomposed under the influence of alkalis, ferments, and heat, forming oxidised fatty acids. A similar relation exists, therefore, between the two methods of preparing cotton for Turkey-red dyeing, and that the fibre prepared by the older process should feel fatty, and require a more prolonged and stronger clearing, is easily understood. It may be urged against the purely physical theory, that if the oiling in Turkey-red dyeing be simply necessary to transfer the undecomposed glycerides to the fibre, this is attainable by a much simpler means than by the detailed and protracted process employed in the old mode of preparing.

—W. R.

An Improved Method of obtaining Baths of Chloride of Antimony for Use in Dyeing and Calico Printing. G. Watson, jun., Glasgow. Eng. Pat. 15,438, Dec. 15, 1885. 6d.

If antimony be taken in the form of trichloride, and water be added to it in order to obtain a bath of any required strength, basic compounds are formed, unless a sufficient quantity of free acid be present, or be added, and the bath is thereby rendered less efficient or useless. To avoid this, the inventor makes use of an addition of chloride of sodium, dissolved in the water used for dilution, in quantity sufficient to prevent the formation of basic compounds. In place of chloride of sodium, the chlorides of potassium or magnesium, or a mixture of any two or all of them, may be used.—J. H.

Improvements in Dyeing and Printing Aniline Black, and in the Solutions used therefor. B. F. Cresson, Philadelphia, U.S.A. Eng. Pat. 38, Jan. 1, 1886. 6d.

For dyeing aniline black the goods are twice padded in a colouring solution, then dried by running through ageing machine at 140° F., hung 24 hours at 85° F., passed through chrome at 6° Tw., washed and dyed in sumac. For printing aniline black a resist acid is used, the goods after drying being padded on the black machine with the colouring solution, after which they are immediately hung, and kept hanging, as in the process for plain aniline blacks, likewise chromed, well washed, and soaped three times to clear the whites, mangled and finished.

—J. H.

An Improved Method of and Apparatus for Dyeing.
S. Smithson, Bradford. Eng. Pat. 12,159, Oct. 13,
1885. 8d.

THIS invention relates to a method of extracting the colouring matter from dyewoods in such a way that the article to be dyed does not come in contact with the dyewood. The apparatus is shown in Fig. 1 (sectional elevation), and Fig. 2 (plan). The material to be dyed is placed in the vessel A, which also contains water. The water

as it rises above the level of the pipes M or L, returns to the dicing vessel A. The action thus becomes continuous.—E. J. B.

Improvements in Apparatus for Bleaching Light and Heavy Textile Fabrics and other Materials, by the "Thompson" and other Analogous Processes, which are also applicable for Dyeing Purposes. R. H. Ainsworth and E. B. Manby, London. Eng. Pat. 2051, Feb. 12, 1886. 11d.

FIG. 1.

FIG. 2

from A passes by the pipe C and rises in the tubes D in the cylinder B. Steam enters by the cock N (Fig. 2), surrounds the pipes D, and heats the water contained in them, which, rising above the level of the water in A, overflows into the dome E (Fig. 1) and passes by the pipe F into the vessel H, which contains the dyewood. The hot water extracts the colouring matter, and as soon

THIS apparatus is an improvement on the apparatus patented by Thompson, Eng. Pat. 595, Feb. 3, 1883, and Mather, Eng. Pat. 16,663, Dec. 19, 1884. It consists essentially of a "dash wheel," shown in sectional elevation, Fig. 1, and plan, Fig. 2. The wheel is charged with the material to be bleached by means of the doors E, which are provided with simple

means of being hermetically closed. Bleaching liquor is run in by means of the stationary pipe A, is set in motion by the bevel wheel D, so as to thoroughly saturate the material. The wheel is then stopped, and

FIG. 1.

FIG. 2.

fitted by means of a gland into the hollow spindle B, the excess of liquor allowed to accumulate at the bottom, passing into the wheel by the perforations C. The wheel from whence it is pumped through the pipe F, chamber G,

and pipe H. The pipe F is enclosed in the casing K, to protect it from the action of the bleach. The wheel is then filled with carbonic acid gas by the pipe A. The material can also be washed and scoured in the same apparatus. The wheel is provided with a back pressure valve L, and also with suitable arrangements, such as friction clutch, etc., for starting and stopping.—E. J. B.

Improvements in Printing on Calico and other similar Woven Fabrics. A. S. Young, Wm. Rumney & Co., Ramsbottom. Eng. Pat. 14,975, Dec. 7, 1885. 8d.

THE object of this invention is principally to print the same pattern upon both sides of a fabric at one time, and upon exactly the same spot, by means of the ordinary cylinder printing machine without the use of the additional cylinder printing machine and other apparatus usually employed for this purpose.

Two copper rollers are engraved, exactly alike, one for the face and one for the back. In the first instance a "bump" or grey cloth is printed, then the white cloth is entered past the rollers that have printed on the "bump" in front of a plain copper roller, which gives it a "nip" and takes an impression or transfer on to the back of the white cloth, which then passes on to be printed on the face side by the other rollers in the ordinary way. To print four colours one copper engraved roller and three surface rollers are taken; these print the transfer or back, while the face side is printed with four engraved copper rollers in the ordinary way, fitting the pattern exactly on top of the transfer, which, when finished, is equal in appearance to cloth printed on a double-cylinder printing machine. The essential novel feature of the invention is the transferring of the printed pattern from the grey or other material to the back of the cloth, then printing on the face on the top of the transfer, the same being performed by a single operation in a single-cylinder or common printing machine.

By another modification of this process the "bump" may be dispensed with, and at the same time a second piece of calico or other material may be printed. This is done by passing a piece of printing calico between the "bump" and the first printing roller, so that this piece of calico receives the first pattern instead of the "bump," and transfers it to the back of the cloth as in the first instance. This additional piece of calico transfers only a portion of the colour forming the pattern to the back of the other piece and retains the rest. By this means two pieces of calico are printed at once, one on both sides, and the other on one side only. In cases where the additional piece of calico or other fabric is of sufficient thickness it may be substituted for the "bump" entirely, and thus the latter may be dispensed with.—J. H.

An Apparatus for Oxidising Aniline Black on Woven Fabrics. T. R. Shillito, London. From the Zittauer Maschinenfabrik und Eisengiesserei of Zittau, Germany. Eng. Pat. 7083, May 26, 1886. 8d.

THIS invention has reference to an apparatus for oxidising aniline black on all kinds of woven fabrics. It is composed of several separate compartments, perfectly shut off from each other, except at narrow apertures provided for the passage of the fabric, which latter, however, nearly or quite closes up each compartment. Oxygen, air and steam are blown into these compartments during the passage of the fabric through the same, the fabric being carried over reels or drums driven by machinery fixed outside the apparatus. Air is supplied separately to each of the several compartments through adjustable apertures, parallel to the travel of the fabric, which is in this way operated upon equably, and the edges of the same protected. The temperature and degree of moisture of the entering air is separately regulated for each compartment. Each compartment is provided with an exhauster, which exhausts the vapours arising from the evaporation of the mordants and other matters. One or more of the several compartments, preferably the last, is supplied with air more highly heated, and more impregnated with steam than the other compartments, or is supplied with steam alone.—J. H.

Improvements in Bleaching Compounds. Charles Toppin, Salem, Massachusetts, U.S.A. Eng. Pat. 7663, June 8, 1886. 4d.

THE improved bleaching compound consists of a mixture of oil of mustard seed, solid paraffin, caustic soda, tallow, soap, and sulphate of soda.—E. J. B.

VII.—ACIDS, ALKALIS, AND SALTS.

Improvements in the Manufacture or Production of Sulphur and Sulphuric Acid. E. W. Parnell and J. Simpson, Liverpool. Eng. Pat. 14,364, October 24, 1885. 6d.

THEORETICALLY the action of sulphurous acid on sulphuretted hydrogen is thus: $\text{SO}_2 + 2\text{H}_2\text{S} = 2\text{H}_2\text{O} + 3\text{S}$. In practice, the theoretical quantity of sulphur is never obtained, the loss being generally attributed to the formation of pentathionic acid. It is now proposed to cause the reaction, mentioned above, to take place in the presence of sulphuric acid, of 15° to 20° Tw., whereby the greater part of the sulphur contained in the two gases is precipitated in the vitriol and may be separated by subsidence, while thionic acids accumulate in the vitriol. The latter is boiled from time to time till it is of a sufficient density, say 15° to 20° Tw., when the thionates will be decomposed with formation of sulphur, sulphuric acid, and sulphur dioxide, which latter may be employed to decompose fresh sulphuretted hydrogen. The vitriol can be used repeatedly. As a suitable apparatus, a leaden tower, filled with flints, is recommended, down which the vitriol is caused to flow, while the sulphurous acid and sulphuretted hydrogen are admitted near the bottom, and caused to ascend in the contrary direction to the vitriol.—S. H.

An Improved Process for Separating Substances from Phosphate of Lime. T. R. Shillito. From E. Haensch and M. Schroeder, Oberhausen, Germany. Eng. Pat. 15,664, Dec. 19, 1885. 11d.

THE process involved in this invention is based on the property of sulphurous acid of dissolving basic calcium phosphate in the cold state, when acid calcium phosphate and calcium bisulphite are produced. At boiling heat the phosphoric acid expels the sulphurous acid from the compound formed, the acid calcium phosphate being thereby reconverted into basic phosphate. By this means calcium phosphate may be separated from all those substances which are insoluble in sulphurous acid. But if calcium phosphate is accompanied by caustic lime, calcium carbonate, or similar compounds, as is the case in Thomas-slag, a special preliminary treatment is required. For this purpose the lime is converted into gypsum by adding to the pulverised material the quantity of sulphuric acid necessary for neutralising the excess of lime, an intimate mixture being obtained by stirring. The resulting mass is formed into blocks and heated to red heat, giving a porous material, which is broken into pieces, placed in vats, arranged on the contrary current principle, and supplied with a strong aqueous solution of sulphurous acid. The solution obtained is heated in lead pans to from 60° to 70° C., when basic calcium phosphate is precipitated, whilst sulphurous acid is evolved, which is absorbed in water or a weak solution of acid calcium phosphate. For the carrying out of the process, and a description of the apparatus required, the original specification should be consulted.—S. H.

Improvements in Lids applicable to Caustic Soda, Drum Heads, and to other purposes. G. H. Bolton and J. Leathwood, Widnes. Eng. Pat. 14,279, Nov. 21, 1885. 6d.

AN invention by means of which the lids of caustic soda drums can be most tightly screwed down, without however forcing the lid off, a collaterally induced compensating action preventing this.—S. H.

Improvements in Apparatus for Generating Carbonic Acid Gas. J. Chapman and R. Foote, Liverpool. Eng. Pat. 13,099, Oct. 30, 1885. 8d.

A is a gas generator of cast-iron, lined with lead. B is a store-vessel for whiting, or its equivalent. Both vessels are fitted with mechanical agitators, driven by the shaft *a*, and bevel wheels *a'* and K. The vessel B is connected with A by a passage through which a supply of whiting

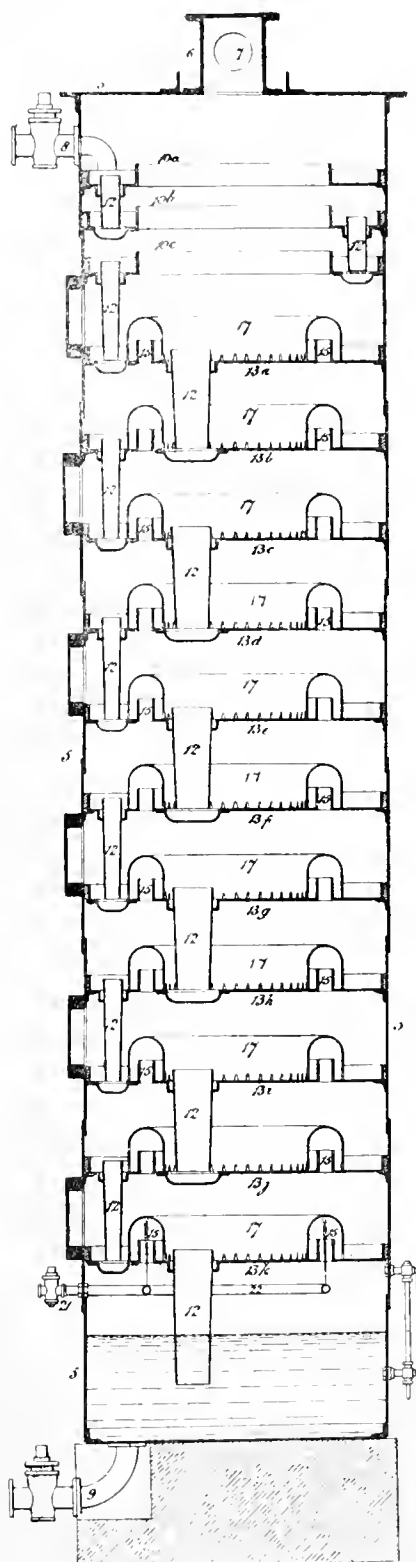

can be shot into the gas generator. The purifier C is made of glass, and connected by a pipe O with the top of the generator. The gas-escape pipe P enters through the bottom of the purifier, and passes upwards above the level of the water used for purifying the gas. D is a pipe for the supply of acid.—S. H.

Improvements in Apparatus for Distilling Ammonia. N. M. Henderson, Broxburn, N.B. Eng. Pat. 15,836, Dec. 24, 1885. 8d.

A VERTICAL CYLINDRICAL STILL is provided at the top with a pipe 8 (Fig. 1) for the admission of the ammoniacal liquor. The latter then passes into an annular open-topped channel 10^a, after travelling round which it descends successively into a second and a third similar channel 10^b and 10^c, and lastly upon the uppermost of a series of horizontal diaphragms 13^a and 13^k. Each diaphragm consists of an outer annular part 13 (Fig. 2), and a movable middle disk-shaped part 14, forming an annular opening 15 between them. The movable middle part rests on projections, so that it can be lifted out for cleaning purposes. A raised wall is formed round each edge of the opening 15, which is covered by an inverted channel-shaped piece 17, the sides of which are notched from the bottom to within half-an-inch of the working level of the liquid, and the steam or vapour passing up through each annular opening 15 finds its way through the notches amongst the liquid lying upon the diaphragm. At suitable points an overflow pipe 12 is fixed in each diaphragm and dips down into the liquid on the next one. The annular opening 15, with its cover 17, does not extend to a complete circle, a passage 19 (Figs. 2 and 3) being formed across it at one part, and a low partition

20 is placed so as to extend from the side of the still through the passage 19 across the disk of the diaphragm.

FIG. 1.

Owing to this partition the liquid descending from an upper diaphragm is made to pass first round the outside

of 15, and then round the inside on one diaphragm, next round the inside and lastly round the outside of the next lower diaphragm, and so on alternately, the overflow pipes 12 being alternately on the outer and inner sides of 15. The steam for heating the ammoniacal

FIG. 2.

liquor enters below the lowest diaphragm 13^k, the gases given off escape at the dome 7, whilst the exhausted liquid leaves at 9. It is claimed that the distilling and volatilising action of this apparatus is very effective and expeditious, owing to the liquid on the diaphragms

FIG. 3.

moving in currents round the outer and inner sides of the openings 15. The currents also prevent deposits on the diaphragms, so that the apparatus requires cleaning less frequently, the construction at the same time facilitating cleaning operations.—S. H.

An Improvement in the Production of Sulphuric Acid. H. J. P. Sprengel, London. Eng. Pat. 10,798, August 24, 1886. 8d.

THE patentee proposes to use the exhaust steam from steam-engines in the leaden chambers employed for the

other, the same work may be done by the same engine, if the pressure be kept at 40lb. per square inch on the one side of its piston and at 10lb. on the other. As, however, a pressure of 10lb. per square inch is ample for the steam entering the chambers, it is suggested, (1) to raise the pressure in the steam-boiler by 10lb. per square inch; (2) to drive the engine at this higher pressure; (3) to make the exhaust steam from the engine enter the chambers at a pressure of 10lb. per square inch; and (4) to supplement, when needed, any deficiency of steam in the chambers by steam of the same pressure from the same boiler. The annexed drawing, which will be readily understood without further explanation, shows a convenient arrangement.

—S. H.

Improvements in the Production of Pure Carbonic Acid Gas. E. W. Parnell and J. Simpson, Liverpool. Eng. Pat. 46, Jan. 2, 1886. 8d.

DILUTE or impure carbonic acid gas obtained from a lime-kiln or from any other source, is, after washing and cooling, brought into contact with a cold aqueous solution containing from 25 to 30 per cent. ammonium carbonate, taking care that the temperature never exceeds 70° F. Crystals of ammonium bicarbonate are formed, which are separated from the mother-liquor and heated to 165° F. in a closed vessel. Carbonic acid is evolved, carrying with it some ammonium carbonate and aqueous vapour. The gas, after passing through a cooling apparatus, which returns all the products of condensation to the heating vessel, is washed with acid, water, or brine to deprive it of any trace of ammonia, and is then ready for use. The liquor which remains in the heating vessel is cooled, when it deposits another crop of ammonium bicarbonate crystals, which are separated and heated as previously described, whereas the mother-liquor returns to the absorbing apparatus for carbonic acid.—S. H.

Improvements in the Manufacture of Carbonate of Soda with Production of Sulphuretted Hydrogen. E. W. Parnell and J. Simpson, Liverpool. Eng. Pat. 47, Jan. 2, 1886. 6d.

THE ammonium chloride produced in the ammonia soda process is decomposed by means of Leblanc waste, and the ammonium sulphide vapour given off is absorbed in water or in a weak ammoniacal solution until it contains from 8 to 10 per cent. of ammonia. This strong solution, after cooling, is subjected to the action of a current of carbonic acid gas until crystals of ammonium bicarbonate are formed and sulphuretted

manufacture of sulphuric acid in the following manner. Supposing the engine works with steam of 30lb. pressure per square inch on the one side of the piston and nil on the

hydrogen is evolved. The latter, after being washed to arrest any carbonic acid and ammonia, is conducted to a gas-holder for use. The ammonium bicarbonate

crystals, along with a portion of the mother-liquor, is removed from the carbonating apparatus, and after draining agitated in a solution of sodium chloride, when sodium bicarbonate is formed, which is converted into monocarbonate. The ammonium chloride remaining in the mother-liquor enters again the cycle of operations by being heated with vat-waste, and so forth. The ammonia which is removed in the form of bicarbonate and mother-liquor from the carbonating apparatus, is compensated for by the addition of ammonium sulphide, so that the strength of the ammoniacal liquor in the apparatus is maintained at the same degree. The mother-liquor from the carbonating apparatus is used for absorbing the ammonium sulphide given off in the first stage of the process. As the purity of the sulphuretted hydrogen evolved depends upon the purity of the carbonic acid gas employed, it is desirable to use the latter as pure as possible (see Eng. Pat. 46, 1886).—S. H.

Improvements in the Manufacture of Phosphoric Acid.

W. B. Giles and A. Shearer, London. Eng. Pat. 715, Jan. 16, 1886. 6d.

THE inventors have discovered that at an elevated temperature phosphoric acid distils freely in presence of a current of steam or hydrochloric acid. They make use of this property to obtain pure phosphoric acid from an impure acid, prepared in the usual manner from calcium phosphate and sulphuric acid and concentrated to a syrupy condition.—S. H.

VIII.—GLASS, POTTERY, AND EARTHENWARE

The Etching of Glass by means of Hydrofluoric Acid.

F. Reinitzer. Dingl. Polyt. J. 262, 322–329.

WOEHLER states, in his well-known translation of Berzelius' work on chemistry, that a dilute solution of hydrofluoric acid produces a transparent etching on glass, whereas the concentrated or gaseous hydrofluoric acid gives an opaque appearance to glass. The author's experiments do not correspond with the second part of this assertion. For the preparation of opaque etchings on glass, three processes are in use—viz., (1) the application of solutions of acid fluorides of the alkalis, (2) a mixture of fluorspar with sulphuric acid, or (3) hydrofluoric gas. As regards the first process, the solutions of the acid fluorides always contain more or less of uncombined hydrofluoric acid, as well as an indifferent salt, as shown in the following recipes of solutions:—

	I.	II.	III.
	Grms.		
Water	1000	100	1000
Acid Potassium Fluoride..	250	—	—
Sodium Fluoride	—	—	40
Ammonium Fluoride	—	—	—
Alkali Fluoride	—	8	—
Hydrochloric Acid	250	—	160 to 175
Sulphuric Acid	—	1	—
Glacial Acetic Acid	—	—	50
Potassium Sulphate	140	—	200
Ammonium Sulphate.....	—	—	—

The first recipe is recommended by Tessié du Mothay and Maréchal, the two under II. by Siegwart, the two under III. by J. B. Miller. In practice an acetic solution of sodium fluoride is much used, which is made by dissolving twenty-five parts of sodium carbonate crystals in five parts of fuming hydrofluoric acid, and adding to one litre of this solution, after clarifying, one litre of glacial acetic acid.

It is often necessary to etch glass in different shades of opacity; for instance, in etching landscapes on glass. For light shades a single application of hydrofluoric acid is sufficient, whereas a dark shade requires the repeated etching of the same spot. If an etched glass-plate be examined under the microscope, a uniform distribution of elevations and depressions is observed which have the shape of crystals. These become scarier near the edge, but their shape is more perfect there. Fig. 1 represents the edge of an etched plate. The crystals are hexagonal and agree with those of silicon-sodium-fluoride. There are also a few of a longish shape, which

FIG. 1.—Scale 450 : 1.

are very like those of silicon-calcium-fluoride. The crystals standing in relief on the glass plate, it is believed that alkali fluoride and hydrofluoric acid act on the glass, forming silicon-sodium-fluoride and silicon-calcium-fluoride, which are set free in a crystalline form, whereas hydrofluoric acid etches the spaces between the crystals. Silicon and calcium are derived from the glass, sodium partly from the etching-bath and partly from the glass. On etching potash glass, tesseral crystals of silicon-potassium-fluoride can be observed, and this suggests a simple method for the detection of potash glass. In connection with these

FIG. 2.—Scale 250 : 1.

observations, we can also determine the composition of any etching-bath according to the end which is desired. It is obvious that the etching will be the finer and the more delicate the smaller the crystals are, and *vice versa*. Small crystals are formed from concentrated solutions, consequently a concentrated bath gives a delicate etching. But, on the other hand, it is not immaterial whether a potassium, sodium, or ammonium fluoride be used. The first being the least soluble, produces the finest opacity. From the same cause ammonium compounds must be applied very concentrated, sodium compounds less, and potassium compounds still

less concentrated. The action of a bath being quicker, if the solution be concentrated, it follows that ammonium compounds will act quickest. The addition of indifferent salts and free hydrofluoric acid is, indeed, for the following purpose—viz., to modify the solubility of silicon fluorides and the rapidity of the crystallisation; the presence of indifferent salts diminishing the solvent power, the presence of free acid increasing the solvent power of fluorides. In using potassium or ammonium compounds, the etchings have a different appearance from those produced by sodium compounds. If a soda glass be etched with a potassium compound, the crystals

FIG. 3.—Scale 300 : 1.

of silicon-potassium-fluoride, silicon-sodium-fluoride, and silicon-calcium-fluoride can be observed under the microscope, either in the shape of a hexahedron or an octahedron, or a combination of either (Fig. 2). On etching a glass-plate with dilute hydrofluoric acid, crystals are formed in the first instance, but on a prolonged and repeated action of the acid, their shape widens, until it completely disappears, producing the appearance as shown in Fig. 3. Here the polygons are deepened, making the lines stand out in relief. The so-called etching inks by which opaque writing is produced on glass, belong to the same class of etching fluids, as they

FIG. 4.—Scale 300 : 1.

consist of alkali fluorides with an addition of gum or barium sulphate as a thickening. As to the proportion of the different constituents in an etching bath, definite statements can only be made with regard to a glass of a specific composition. Supposing the formula of glass to be $R_2Si_2O_7$, R being a monatomic metal—the reaction which represents the process of etching is represented by the following equation: $R_2Si_2O_7 + 4NaHF_2 + 10H_2F = SiF_6R_2 + 2SiF_6Na_2 + 7H_2O$. There must be present a large amount of free hydrofluoric acid in order to utilise all the sodium fluoride. This large amount of free hydrofluoric acid proves, however, injurious, and it is therefore preferable to bring about the neutralisation of

the bases by the addition of acetic acid, which does not decompose the acid alkali fluorides. The process is, then, thus: $R_2Si_2O_7 + 9NaHF_2 + 5C_2H_3O_2 = SiF_6R_2 + 2SiF_6Na_2 + 5C_2H_3Na + 7H_2O$. The proportion of sodium fluoride to acetic acid is 93 to 50, or 9 to 5 approximately. If the acid fluoride is replaced by neutral sodium fluoride, the proportion is 9 to 10, which nearly corresponds with Siegwart's recipe (8 to 10) previously mentioned. The application of gaseous hydrofluoric acid does not produce a uniform opacity, and is, therefore, not suitable for the production of opaque plates. A

FIG. 5.—Scale 200 : 1.

plate treated with gaseous hydrofluoric acid and examined under the microscope is represented in Figs. 4 and 5. There is an agglomeration of different crystals and a large number of small recesses. This is owing to the fact that in the beginning of the process numerous small drops of water condense on the glass, dissolving hydrofluoric acid and restricting the etching process locally. A good opaque etching can be produced by fluorspar and dilute sulphuric acid (1 : 4) at a temperature of 30° to 40° C. Fig. 6 shows a plate etched in this manner. The surface is covered with many minute depressions of different depth, between which there are elevations of no

FIG. 6.—Scale 450 : 1.

definite shape. These are due to an incomplete etching, caused by a piece of fluorspar covering that spot and thus protecting it from the action of the hydrofluoric acid. Near the edge the sulphuric acid can act on the fluorspar, forming hydrofluoric acid, which etches a groove round the protected spot. In conclusion, the author points out that chemical etchings are easily distinguished by the microscope from mechanical etchings produced by the sand-blast or grinding. The latter methods cause numerous fractures of various direction and size, all of which exhibit a characteristic 'conchoidal' appearance.—S. H.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Preservation of Timber by Means of Aluminium Chloride.
F. Filsinger. Chem. Zeit. 10, 1270—1271.

THE author has made a series of experiments on the preservation of oak and firwood after saturation with solu-

tions of aluminium chloride. The prepared specimens of timber were placed in damp garden mould rich in humus, and after about eighteen months' rest were removed and examined. The wood was found to be in good condition, whilst specimens of untreated wood, which had also been placed in the putrefying pit, were all rotten. It is not necessary to employ pure aluminium chloride, as it was found that the wood prepared with the crude salt containing iron was in most cases better preserved; the presence of free hydrochloric acid is, however, objectionable, owing to its destructive action on the woody fibre.

It is doubtful whether the present price of aluminium chloride would admit of its application to the preservation of railway sleepers; it is thought, however, that for other purposes where it is essential to use preserved timber, the use of this salt would compete favourably with other preserving agents.—D. B.

A New or Improved Combination of Materials for Making Cements, capable also of being used for other Useful and Ornamental Purposes. T. Smith, Sunbury. Eng. Pat. 13,328, Nov. 4, 1885. 6d.

THE debris of macadamised roads, broken china or porcelain, are washed, calcined and ground to a fine powder; 60 parts of the resulting powder are mixed with 40 parts of sulphur, and melted in a copper pan provided with an agitator. The heating is continued up to 250° C., after which the source of heat is withdrawn, and the stirring continued until the mass assumes a thin condition. It is then poured on to a slab or flat surface, and allowed to cool in a thin layer. It is again melted and cast into slabs, which are ready for use for a variety of purposes.—C. C. H.

Improvements in the Treatment and Utilisation of a certain kind of Clay. F. Candy, London. Eng. Pat. 15,948, Dec. 28, 1885. 6d.

THE carbonaceous clay found in Devon is ground, preferably wet, and incorporated with about 10 per cent. of chalk or limestone in a pug mill. It is then carbonised (ignited or roasted); or it may be first dried and afterwards carbonised. The product as thus prepared is reduced to a small state of division, dependent upon the purpose for which it is intended—*e.g.*, decolourising liquids in the purification of water or sewage. Carbonised after treatment as above described, without the addition of carbonate of lime, it may be ground with oil or silicate of soda, and used as a paint, or pressed into blocks or slabs suitable for carbon electrodes or for crayons and pencils.—C. C. H.

An Improved Material applicable as a Waterproof Covering for Roofs and other such like Purposes. A. Ford and J. A. Archer, London. Eng. Pat. 5993, May 15, 1885. Amended Oct. 11, 1886. 6d.

IRON WIRE GAUZE is successively dipped in linseed oil having the property of drying, and dried until the meshes are wholly closed and the wire covered. The result is a transparent, waterproof sheet, adaptable as a roof covering. Boiled oil should not be used; that found most suitable is prepared by first adding litharge to the oil and then subjecting to a blast of air in a closed tank.—C. C. H.

X.—METALLURGY, Etc.

Antimony Production in Banya. C. A. M. Balling. Chem. Zeit. 10, 1198–1199.

THE author having recently visited the new antimony works at Banya, now gives data as to the capabilities of the mines and works, and analytical details of the products and by-products. Lump ore is obtained in small proportions, and consists partly of antimonite, and partly of oxides. By far the largest amount of ore worked up here is that occurring in graphitic schist. At the present rate of working the annual production amounts to 200,000 kilos. of regulus, and 140,000 kilos. of crude antimony;

and experiments are now being made in connection with the manufacture of antimony red, and also of antimonious oxide. The lump and jigged ore are liquated in four reverberatory furnaces, each of which has 50 pots, holding 11 to 12 kilos. of charge. The ore subjected to this process has an average composition of Sb=50; Fe=12; SiO₂=9; CaCO₃=2; S=26 per cent. The crude antimony contains Sb=69.5; As=0.6; Fe=1.2; S=27.2; insoluble 0.7 per cent. The liquation residues also contain 21 to 25 per cent. of antimony, and these, together with flue-dust, collected at different stages, refinery slag, and the more impure crude metal, serve as material for the smelting process in the blast furnaces. These residues are first roasted on a bed of wood in kilns for six to seven weeks, and then subjected to the smelting process in the blast furnace with an admixture of 20 per cent. of fuel. The fuel as to proportion, usually consists of one-fourth by weight of coke in small porous lumps, and the remainder of wood charcoal. An analysis of the roasted residues gave the following figures:—Sb=32.06; Fe₂O₃=17.36; SiO₂=49.20; Al₂O₃=2.35; CaO=0.72; S=2.43 per cent. An analysis of the blast furnace slag gave—

	Before tapping.	After tapping.
SiO ₂	50.30	49.20
CaO	25.90	27.66
FeO)	20.25	19.17
Al ₂ O ₃)		
Sb	2.07	0.90

It may here be noted that the presence of 20 per cent. of iron in the slag is indicated by experience as being necessary for the most advantageous working of the blast furnace process. For the preparation of antimonious oxide only such ores as contain 40 per cent. and upwards of antimony are employed in these works.—W. D. B.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

Treatment of Mineral Oils with Arsenical Sulphuric Acid. Dr. Krey. Chem. Zeit. 10, 1272.

THE author is of opinion that sulphuric acid, containing arsenic, may be used without disadvantage for the purification of mineral oils, it being impossible to detect even traces of this substance in oils thus treated.—D. B.

Improvements in the Separation and Treatment of Fatty Matter from Compounds containing Wool Fat. C. D. Abel, London. From the Fabrik Chemischer Produkte Actien Gesellschaft, Berlin, Germany. Eng. Pat. 14,957, Dec. 5, 1885. 6d.

IN Glaser's patent (Eng. Pat. 4992 of 1882) are described processes for the production of "lanolin," the combination of neutral fatty matter from wool with water, which are subsequently separated by centrifugal action. The present patentee effects the separation mainly by largely diluting the liquid, or by adding to the solution soluble salts of the alkaline earths or of the heavy metals, or, in some cases, by simple subsidence, or by all three processes combined.—W. L. C.

Improvements in the Manufacture of Soap. R. Park and J. E. Park, Glasgow. Eng. Pat. 1113, Jan. 25, 1886. 6d.

KIESELGUHR, diatomite, or white peat powder, is incorporated with the soap paste before the latter solidifies. When a large percentage of kieselguhr is used, pipe-clay is added as well to prevent the mixture from being too friable.—W. L. C.

Improved Apparatus and Method of Treating Cotton Waste which has been used by Lithographic and Letterpress Printers, and obtaining Products therefrom. C. O'Neill, Manchester. Eng. Pat. 6762, May 20, 1886. 8d.

A VERTICAL BOILER of thin plate is filled with the waste, steam is blown in, and the mixed vapours of water and

turpentine are condensed in a worm, after which the two liquids are separated by the differences in their specific gravity.—W. L. C.

A Method and Apparatus for Extracting the Fat from Bones. T. Berliner, Ohlan, Silesia, Germany. Eng. Pat. 11,138, Sept. 1, 1886. 8d.

THIS patent contains the drawing of, and description for working, an apparatus in which superheated "benzine" vapour is made to act upon the bones in order both to dry them and to extract their fat simultaneously. The vapour employed is that arising from the evaporation of the solution produced in a previous operation, and the superheater is an iron vessel fed with superheated steam or air. The benzoline (petroleum spirit) vapour may be introduced either above or below the material to be extracted.—W. L. C.

XII.—PAINTS, VARNISHES, AND RESINS.

Lanolin. C. D. Abel. Eng. Pat. 14,957, Dec. 5, 1885. 6d.

THIS patent relates to some modifications upon the process described in a previous patent (Eng. Pat. 4992, 1882), for the preparation of "lanolin." Instead of separating the crude wool-fat by centrifugal action, the fat may be allowed to rise to the surface of the soapy liquid, and then be separated; the same result is effected by making a jet of water play upon the liquid, also by two other methods, involving the separation of the fat into fatty acids; and the applicant also claims for the use of other substances than the alkalis specified in the first patent. Notably he claims for the use of bicarbonates, silicates, borates, and all vegetable substances containing saponine, and for substances containing pancreatine, ether, or all of which, might be used for producing an emulsion of wool-fat.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

Improvements in Making Size or Dressing Material for Textile Materials and Fabrics, and to be used in Polishing Twine, String, or Cord. A. Hieronimus, Strassburg, Alsace. Eng. Pat. 15,953, Dec. 29, 1885. 6d.

THE improved size is made by boiling meal, which has been used with eggs for tawing skins, with four times its weight of water. An equal weight of scraps of kid or other skin is boiled in about six times its weight of water and the filtered solution thoroughly mixed with the meal paste. A little suitable antiseptic may be added.—B. H.

An Improved System of Tanning Hides and Skins by Continuous Application of Liquors, and New Mode of Suspending and Lifting Hides and Skins in "Shifting Frames" while in Process of Tanning. T. Brain, London. Eng. Pat. 7274, May 31, 1886. 11d.

THIS consists of a "round" of any suitable number of pits connected together so that liquor introduced into the first pit traverses the series. The fresh liquor flows from a raised cistern through a pipe ending in a circular chamber at the centre of the bottom of the pit, and issues into the pit through equidistant apertures round the sides of the chamber. A pipe connects the top of this pit with a similar arrangement in the next pit, and so on through the series. The hides are hung on swivel hooks attached to laths fixed in a frame. This frame rests on a groove round the top of the pit, and can be raised by suitable machinery with the hides and shifted from one pit to another. Perforated rods are suspended between the hides to keep them apart and allow free access of liquor. The rate of flow of the liquor through the series of pits can be regulated as found necessary.

—B. H.

XIV.—AGRICULTURE, MANURES, Etc.

Further Disintegration of Thomas-Phosphate Slag under the Influence of the Atmosphere. E. Jensch. Chem. Zeit. 10, 1271.

SINCE Wagner (Darmstadt) has shown that the solubility of the phosphoric acid in basic cinder from the Thomas process increases with the fineness of the slag, it has been stipulated by agriculturists to reduce the cinder by grinding to the finest possible condition. As this operation necessarily increases the price of the cinder the author made a series of experiments, the object being to save this extra expenditure. He found that coarsely-ground slag disintegrates still further under the influence of the atmosphere, so that by exposing it to the air for a few weeks the additional grinding operation may be abandoned.—D. B.

Use of Phosphoric Acid as Addition to Manure Liquors instead of Sulphuric Acid. K. H. Neuller. Chem. Zeit. 10, 1272.

FRESENIUS states that potassium phosphate is a highly active and valuable manure, a statement which is confirmed by H. and E. Albert, of Biebrich-on-the-Rhine, in a series of experiments with potassium phosphate extended to market gardens and vineyards. In a recent communication the author gave an account of some experiments made with ammonium phosphate, the results being very satisfactory. It is now shown that farmers can procure a considerable portion of the potassium and ammonium phosphate they need, by adding phosphoric acid to the manure liquors instead of sulphuric acid.—D. B.

Improvements in the Treatment of Phosphoretic Slag. A. Bobrownieki, London. Eng. Pat. 948, Jan. 21, 1886. 6d.

THE object of this invention is to reduce Thomas-slag to a state that will admit of its being used as a fertiliser. To this end, the powdered slag is moistened with water and treated with concentrated sulphuric acid, stirring the materials to produce an intimate mixture, while at the same time water is added for supplying the requisite water of combination and creating the heat necessary for the reaction. In place of sulphuric acid, soluble bisulphates may be used, neutral sulphates being thus formed, which are recovered by lixiviation.—S. H.

XV.—SUGAR, GUMS, STARCHES, Etc.

The Decomposition of Milk-sugar by Dilute Hydrochloric Acid. M. Conrad and M. Guthzeit. Ber. 19, 2575—2576.

MILK-SUGAR, when acted upon by dilute acid, has long been known to yield acetopropionic acid and formic acid. The authors have now determined the action quantitatively, in the same manner as in the preceding experiments (this Journal, vol. v. 36). Milk-sugar was heated with 9—10 per cent. hydrochloric acid for 17 hours with an inverted condenser in a salt bath. The results obtained are given in Table A on next page.

From former experiments on dextrose and galactose the authors obtained the following numbers:—

	Humin 8.1 auev.	Unchange- d.	Acetopropi- onic Acid.	Formic Acid.
Dextrose, 52.5grms.	1.76	14.32	15.53	6.51
Galactose, 52.5grms.	8.40	16.60	11.22	5.10
Milk-sugar, 105grms.	13.16	31.12	29.75	11.91

Whilst from the above results were calculated:—

Milk-sugar, 105grms.	18.03	27.70	31.20	12.13
---------------------------	-------	-------	-------	-------

The numbers for humin substances and unchanged sugar do not agree very closely, but those for acetopropionic acid and formic acid agree as well as can be expected from the method employed, and show clearly

The methods used for the determinations were exactly the same as in the above-quoted paper. The results with dilute sulphuric acid are given in Table I. These numbers calculated for 52.6 grms. of dextrose

TABLE A.

SUBSTANCES TAKEN (IN GRAMMES).				DECOMPOSITION PRODUCTS (IN GRAMMES).			
	Milk-sugar with Water of Crystallisation.	Water.	Hydrochloric Acid.	Humin Substances.	Unchanged Sugar.	Acetopropionic Acid.	Formic Acid.
1	21	50	4.87	3.68	5.54	6.29	2.39
2	21	50	5.00	3.94	not deter.	5.80	2.24
3	10.5	50	4.87	1.60	..	3.32	1.33

in what manner dextrose and galactose are formed by the decomposition of milk-sugar. The following numbers show the behaviour of equivalent amounts of different carbohydrates with 9–10 per cent. hydrochloric acid when heated for 17 hours:—

	Humin Substances.	Unchanged Sugar.	Acetopropionic Acid.	Formic Acid.
100 Cane-sugar yield	18.9	20.6	33.2	13.8
100 Milk-sugar (anhydrous) ..	18.0	27.7	31.2	12.1
105 Dextrose	9.5	29.0	31.1	13.1
105 Levulose	21.3	—	39.6	17.6
105 Galactose	16.8	33.2	28.4	10.8
105 Arabinose	43.0	—	12.4	4.2

—G. H. M.

Action of Dilute Acids on Dextrose and Levulose. M. Conrad and M. Guthzeit. Ber. 19, 2569–2574.

TOLLENS and GROTE have shown that when sucrose is decomposed with dilute sulphuric or hydrochloric acid, the greater portion of the acetopropionic acid formed comes from the levulose, since dextrose when decomposed with these acids only yields very slight traces of aceto-

and levulose—i.e., the quantities corresponding to 100 grms. cane-sugar, gave the following:—

	Humin Substances.	Dextrose.	Acetopropionic Acid.	Formic Acid.
{ Dextrose, 52.6 grms.	0.83	43.70	12.78	1.21
{ Levulose, 52.6 grms.	13.78	—	16.78	6.46

= Cane-sugar, 100 grms. 11.61 43.70 19.56 7.67

These numbers agree very closely with those found in the former experiments with cane-sugar. The mean of five experiments was:—

	Humin Substances.	Dextrose.	Acetopropionic Acid.	Formic Acid.
Cane-sugar, 100 grms.	16.6	43.3	17.5	8.

It is thus seen that the greater part (94 per cent.) of the humin substances and acetopropionic acid (85 per cent.) formed by the decomposition of cane-sugar with dilute sulphuric acid proceeds from the levulose which completely disappears, whilst about 83 per cent. of the dextrose formed by the inversion remains untouched.

The action of dilute hydrochloric acid was examined in the same way. The results are given in Table II. on next page. These numbers calculated for 52.6 grms. of dextrose and levulose gave the following results,

TABLE I.

SUBSTANCES TAKEN (IN GRAMMES).				DECOMPOSITION PRODUCTS (IN GRAMMES).			
	Sugar.	Water.	Sulphuric Acid.	Humin Substances.	Unchanged Sugar.	Acetopropionic Acid.	Formic Acid.
Dextrose..... {	10.5	50	3.50	0.13	8.54	0.51	0.25
	10.5	25	1.75	0.20	8.87	0.56	0.23
Levulose..... {	10.5	25	1.81	2.60	trace	3.50	1.33
	10.5	20	1.71	2.90	..	3.20	1.25

propionic acid. They also found that there is a relationship between the formation of this acid and the separation of humin substances. The authors confirmed this in their experiments on cane sugar (Ber 18, 439), in which they found a large percentage of dextrose remained unacted upon. In order to again confirm this action, the authors acted upon quantities of dextrose and levulose corresponding to 20 grms. cane sugar for 17 hours with the same quantities of acid and water as before. Levulose could only be indirectly used, since it is most difficult to obtain pure. Inulin, which is completely converted into levulose by the action of dilute acids, was employed.

which agree closely with those formerly found for cane-sugar:—

	Humin Substances.	Unchanged Dextrose.	Acetopropionic Acid.	Formic Acid.
{ Dextrose, 52.6 grms.	4.76	11.52	15.53	6.51
{ Levulose, 52.6 grms.	10.65	—	16.28	8.73
= Cane-sugar, 100 grms.	15.11	11.52	31.81	15.29

Dextrose gives with 8–10 per cent. of hydrochloric acid nearly as much acetopropionic acid as levulose, whilst with 7–8 per cent. of sulphuric acid it is almost untouched. The proportion between acetopropionic and formic acids is nearly the same in all the decompositions—viz., 1:2.35. The amount of humin substances formed by acting upon 100grms. cane-sugar, with sulphuric and hydrochloric acids respectively, is almost the same, but with the former acid only 5.7 and with the latter acid 30.8 of the total amount is formed from dextrose. 10.5grms. of dextrose heated with 50cc. concentrated hydrochloric acid yielded 4.5grms. humin

XVI.—BREWING, WINES, SPIRITS, Etc.

An Improved Method of Aerating and Attenuating Worts and other Liquors, and securing a pure germless Atmosphere wherein to carry on Fermentation. T. P. Chittenden, London. Eng. Pat. 14,868, Dec. 3, 1885. 8d.

A FULL description with drawings of an apparatus for cooling and fermenting beers, worts, and other liquids in closed vessels supplied with germless filtered air; also for aerating and attenuating worts with germ-

TABLE II.

SUBSTANCES TAKEN (IN GRAMMES).				DECOMPOSITION PRODUCTS (IN GRAMMES).			
	Sugar.	Water.	HCl.	Humin Substances.	Unchanged Sugar.	Acetopropionic Acid.	Formic Acid.
Dextrose.....	10.5	50	4.42	0.9	3.07	3.10	1.24
	10.5	50	4.78	1.0	2.73	3.10	1.35
Levulose.....	10.5	50	4.31	2.12	—	3.57	1.72
	10.5	100	5.00	2.12	—	3.84	1.75
	10.5	50	4.87	2.12	—	4.09	1.73

substances, but no acetopropionic acid or any other acid was found. This is contrary to Tollens' experience, who found small quantities of the former acid. Concentrated hydrochloric acid thus acts very differently to dilute acid upon dextrose and other carbohydrates. The duration of the action of heat is also important in determining the nature of the decomposition products, as Soxhlet has already shown. It is important in the preparation of glucose from starch by means of acid, that the acid should not be above 2 per cent. in order to prevent the formation of acetopropionic acid and consequent loss of the carbohydrate.—G. H. M.

free air. The original must be consulted for details of the process and apparatus employed.—G. H. M.

Improvements in the Manufacture of Finings for Sour Beer, Brewers' Waste and Returns. A. W. Gillman and S. Spencer, Southwark. Eng. Pat. 15,063, Dec. 8, 1885. 6d.

THE patentee claims the use of a solution of eutch (catechu) either in water or dilute acids for fining, returns, etc.—G. H. M.

A Combined Eliminator and Filter for Treating Sugar-cane Juice and other Liquids. A. C. Ewing, Glasgow. Eng. Pat. 13,792, Nov. 12, 1885. 8d.

IN the evaporation of sugar-cane juice it is usual to raise the whole of the liquor to a state of ebullition and to filter through filter-bags before allowing it to enter the vacuum pan. To shorten this process a vessel is used in which all the liquor is heated as before to boiling, but only the top part of the liquor containing the scum is allowed to pass over to the filter-bags, the main portion of the clear liquor being drawn off from the bottom of the "blow up." This liquor mixes with the filtrate from the bags, and the whole is then taken into the vacuum pan. Diagrams and description of special plant required are given.—A. J. K.

The Improved Utilisation of Lime and other Calcareous Material Impregnated with Saccharine Matter. A. G. Wass, Bermondsey. Eng. Pat. 9992, Aug. 4, 1886. 6d.

LIME and calcareous matter which has been used in the filtration of sugar gradually becomes unfit for use, and forms a waste product which it is the object of this patent to utilise. The calcareous material impregnated with sugar and other organic impurities is heated in a closed kiln until all the organic matter is carbonised. The mass is then allowed to cool in the absence of air, and the resulting black material is found to be useful for various purposes, such as forming the body of blacking, paint, or ink; also as a disinfectant and as a fertiliser or manure. A convenient temperature for obtaining a good black is found to be about 900° F. By using a lower temperature, or by admission of a little air, amber and grey colours are respectively obtained.—A. J. K.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

Improvements in a Method of Preserving Animal and Vegetable Food and Liquids. B. H. Thwaite, Liverpool. Eng. Pat. 14,552, Nov. 27, 1885. 6d.

IN this specification reference is made to Eng. Pat. 16,565, 1884, certain modifications having been introduced by the inventor.—E. G. C.

Improvements in the Preservation of Alimentary Substances, and in Apparatus therefor. V. Tribouillet and E. Husson, Paris. Eng. Pat. 15,599, Dec. 18, 1885. 8d.

VESSELS containing the alimentary substances to be preserved are heated by means of injected steam or heated gas.—E. G. C.

(B) SANITARY CHEMISTRY.

Improved Means and Appliances connected with the Separation of Liquids from Sewage and like Matters, in what are termed Filter-presses. J. A. Drake and R. Muirhead, Maidstone. Eng. Pat. 15,402, Dec. 15, 1885. 6d.

THE filtering medium described in Eng. Pat. 10,143, Aug. 27, 1885, by the same authors, and which consisted of cocoa-nut fibre, coir or bass, is rendered more adapted to the purpose by being coated or incorporated with a porous material—e.g., sand, burnt clay, powdered bricks, or charcoal. This may be retained within the filtering mat by coating the plates with tar, or adhesive substances, by scouring their surfaces or providing projections thereon.—C. C. H.

Improvements in the Method of Treating Sewage and other Polluted Waters. J. Bannehr, Devon. Eng. Pat. 8874, July 7, 1886. 8d.

THE coarser matter is first separated from the sewage by a fixed screen, the more finely-divided suspended matter being afterwards separated by a sloping screen, the meshes of which are kept free by a reciprocating frame of triangular bars. The sludge falls therefrom into a receiving well, from which it is pushed by a scraper into a dewatering chamber provided with mechanical rakes, where it is dried by a current of hot air passing over the surface and steam heat from below. The partially clarified sewage is filtered through cells, the walls of which are formed of carbonised sawdust.

—C. C. H.

Improvements in the Manufacture of Filtering Media for use in the Purification of Liquids and Gases. F. Candy, Middlesex. Eng. Pat. 1793, Feb. 6, 1886. 6d.

IRONSTONE having combined carbon in its constitution is heated in a suitable vessel, kiln or chamber, air not being allowed free access to the interior thereof. When vapour ceases to pass off, and the gases have been nearly or quite driven off, the chamber and contents are allowed to cool, and the carbonised ironstone is now disintegrated, if necessary. —E. G. C.

Improvements in the Manufacture of Filtering Materials and Precipitants. Frank Candy, Middlesex. Eng. Pat. 2517, Feb. 20, 1886. 6d.

THE filtering material is manufactured by granulating carbonised natural mixtures of clay and carbonaceous matter, removing iron and alumina therefrom by boiling the granules in mineral acid, separating them from the acid, and rinsing and boiling them with water, in order to remove any absorbed acid and salts produced. The precipitant consists of a powder made by mixing together the pulverised "carbonised material" and an acid liquor containing iron and alumina, and boiling the mixture to dryness. —E. G. C.

Improvements in the Utilisation of Blood from Slaughter Houses in and for the Preparation of Food and Drink for Man and Cattle, and other Animals. H. P. Madsen, Middlesex. Eng. Pat. 10,995, Aug. 28, 1886. 4d.

THE blood fresh from the animal is treated with salt and saltpetre, with or without ginger, while stirring, and then filtered. In the preparations of food from blood, the cleansed blood, mixed with albumen or not, is exposed to heat for the purpose of producing blood-meat. Various improved foods can be made from the cleansed blood and blood-meat, here referred to. —E. G. C.

Improvements in Machines for Drying and Powdering Blood, Town Sewage, or other Material. A. Forest and W. Welsh, Manchester. Eng. Pat. 11,409, Sept. 8, 1886. 6d.

THE improvements consist of flexible springs attached to the revolving arms of cylindrical drying machines with scrapers attached. —E. G. C.

The Application and Use of Carbon in the Compression of Sewage Sludge. G. H. Leane, Westminster. Eng. Pat. 11,820, Sept. 17, 1886. 4d.

THE patentee proposes to substitute porous carbon, such as is manufactured from Kimmeridge shale, for the caustic lime at present used to render sewage sludge pressable. From 2 to 4 cwt. of carbon is sufficient to treat one ton of compressed sludge. —C. C. H.

A Treatment of Excreta and Sewage Sludge for Production of Manure. J. H. Barry, Clapton. Eng. Pat. 11,883, Sept. 18, 1886. 4d.

THE liquid part of the sludge is first separated by filtration in a tall tank having a porous bottom, or by means

of a centrifugal machine; it is then distilled to separate the ammoniacal products. The liquid residue from distillation is treated with lime, and the precipitated matters settled out; the effluent is purified by filtration through charcoal or earth. The solid matter separated from the sludge is then incorporated with the ammoniacal stillate and the precipitate from the lime treatment, and the whole finally dried by exposure on large surfaces to a current of hot air. —C. C. H.

XVIII.—ELECTRO-CHEMISTRY.

A New or Improved Process and Apparatus for Separating Compounds of Metals by Electrolysis. L. Elmore, New York. U.S.A. Eng. Pat. 1565, March 27, 1883. 2d.

THIS invention consists in the use of a hollow conducting anode to contain the compound to be operated upon. Thus, if copper, silver and gold are to be separated, the copper and silver will be dissolved, pass through the anode, if porous, and be deposited or precipitated in the outer cell. If the anode is not porous, the dissolved copper and silver are withdrawn by suitable means and separated in any of the ordinary ways. —E. T.

An Improved Method of and Apparatus for the Working of Metals and Metalloids by the Direct Application of Electric Currents. N. de Benardos and S. Olzowski, St. Petersburg. Eng. Pat. 12,984, Oct. 28, 1885. 1s. 3d.

THIS invention consists in methods of applying the heat of the voltaic arc to various mechanical operations. Thus, if a bar of metal is to be divided, an arc is formed between the metal and a movable carbon pencil; the metal is melted in the path of the pencil, and the bar eventually divided. Methods are described for joining together, riveting, and forging substances; also for coating bodies with different metals and producing metallic inscriptions by the introduction of the desired substance into the arc. —E. T.

A New or Improved Galvanic Battery with Apparatus for Automatically supplying Liquids thereto. W. A. Barlow. From M. Sappey, Paris. Eng. Pat. 13,422, Nov. 5, 1885. 1s. 1d.

THIS invention consists of apparatus, automatically regulated by a system of electro-magnets, for supplying exciting and depolarising liquids to a specially constructed galvanic battery. —B. T.

Improvements in Voltaic Batteries. J. P. Rees and T. D. C. Parker, London. Eng. Pat. 13,694, Nov. 10, 1885. 8d.

TO counteract the effects of endosmose, porous pots provided with overflow spouts are used, the superfluous liquid flowing away by means of these spouts into a suitable receptacle. The porous pots and zinc plates are so supported as to be capable of being lifted out of the exciting liquid when the battery is not working. —B. T.

An Improvement in Manganese Voltaic Batteries. B. Pell, London. Eng. Pat. 15,285, Dec. 12, 1885. 4d.

IN manganese cells as at present constructed, agglomerated blocks present only a small surface, while porous cells are apt to break or become clogged. The inventor therefore confines granules of carbon and manganese in a vessel pierced with small holes or slits, which allow free passage of the liquid only. —E. T.

Improvements in Cells for Generating Electricity by means of Hydrogen. J. A. Kendall, Middlesborough. Eng. Pat. 15,105, Dec. 9, 1885. 8d.

INSIDE the electrodes or metallic tubes is placed a core of porous material which will resist the heat at which

the battery is worked. Cores may be constructed from almost any fire-resisting earthy matter not reducible by hydrogen at the temperature employed.—B. T.

Improvements in Primary Electric Batteries. G. F. Rose, London. Eng. Pat. 7028, May 25, 1886. 6d.

IN this battery, which is a double-fluid one, the outer cell contains one or more carbon electrodes in a solution of bichromate of potash and sulphuric acid, and the porous cell the zinc electrode in neutral or acidulated water. The zincs are attached by cords to a roller provided with a handle, which, when turned, withdraws them from the liquid; the roller is retained in position by a ratchet and pawl. A layer of mercury is sometimes added in the porous cell.—E. T.

Improvements in Primary and Secondary Batteries. P. Bailly, Ermont, France. Eng. Pat. 11,823, Sept. 17, 1886. 8d.

ELECTRODES are formed of masses of lead wool bound together by strips of lead cut at the sides to produce fringes. The latter lessen the internal resistance, and avoid the necessity for numerous soldered joints where several electrodes are used. To prevent the straps being eaten through at the surface of the liquid, they are in some cases brought out at the sides. When zinc electrodes are employed, they are in the shape of a stiff amalgam dipping into a little mercury. The electrodes may be used in various positions and, if required, separated by various porous bodies. The containing cell consists of one vessel inside another, from which it is separated by a material not acted upon by acids.—E. T.

A New and Useful Composition of Matter to be used as an Electric Battery Excitant. E. D. Kendall, Brooklyn, U.S.A. Eng. Pat. 10,536, Aug. 17, 1886. 4d.

THIS composition, termed "Solid Battery Excitant," consists of a bi-sulphate or bi-sulphates of an alkali or alkalis, or sulphuric acid, or both, in combination with chromic acid. The composition may be conveniently prepared by mixing together bichromate of potash and sulphuric acid.—B. T.

XIX.—PAPER, PASTEBOARD, Etc.

Improvements in the Construction of Boilers or other Vessels used in the Conversion of Woody or other Fibres into Pulp for the Manufacture of Paper or other Articles prepared from Pulped Fibres. A. McDougall, Penrith. Eng. Pat. 4569, April 14, 1885. 6d.

To obviate the inconveniences, by the use of lead-lined iron or steel boilers, in consequence of the unequal expansion and contraction of the two metals by alternate heating and cooling, the boilers are constructed, according to this invention, with a packing of felt or other elastic and compressible material between the interior leaden vessel and exterior iron or steel jacket. When the interior leaden vessel is expanded by heat and steam pressure the compressible packing yields to such expansion. Also, in the cooling, the packing prevents rupture of the lead. The compressible packing may be composed of caoutchouc, felt, flocks, coir, cork, asbestos, etc. Another improvement consists in the construction of the outer iron or steel vessel in flanged sections, drawn together and fixed in position over the packing surrounding the leaden vessel by screw bolts or other suitable means.—W. D. B.

Improvements in the Manufacture of Pulp or "Half-Stuff," utilising Waste or Refuse Materials. F. G. Morton and N. Salamon, London. Eng. Pat. 13,022, Oct. 29, 1885. 6d.

THIS invention relates to a method of preparing pulp by boiling waste vegetable fibres such as jute, gunny, etc.,

previously leased out by any suitable machinery, in weak alkaline lyes at atmospheric pressure, and subsequently bleaching with calcium hypochlorite.

—E. J. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Preparation of Vanillin from Metachloroparanitrobenzaldehyde. L. Landsberg. Dingl. Polyt. J. 262, 139.

IT is proposed to convert metachloroparanitrotoluene into chloronitrobenzyl chloride or bromide, and treat the latter with lead or copper nitrate in order to obtain metachloroparanitrobenzaldehyde. On treating this aldehyde with an alkaline methylate or hydroxide dissolved in methyl alcohol, the chlorine is replaced by the methoxyl group, with formation of metamethoxyparanitrobenzaldehyde. The same compound is obtained when the chlorine in metachloroparanitrobenzaldehyde is replaced by hydroxyl, and the resultant hydroxynitrobenzaldehyde is converted into its methyl ether. Metamethoxyparanitrobenzaldehyde crystallises from boiling water in white needles, melting at 62°, and is converted into vanillin according to the known methods. When treated with acetic anhydride or sodium acetate, it is resolved into metamethoxyparanitrocinnamic acid, melting at 218°.—D. B.

Some Derivatives of Kairin. C. A. Kohn. Inaug. Dissert. Erlangen, 1886.

THE ammonium iodide addition product of hydroxyhydroxymethylquinoline gives, on treatment with solid caustic potash, methoxyhydroxymethylquinoline. The action of the caustic alkali is, in the first place, to form the potassium salt of hydroxyhydroxymethylquinoline, which then undergoes an atomic displacement, when potassium iodide is removed, and the added methyl group replaces the potassium in the hydroxyl, forming the methyl ether of the original compound. Similarly hydroxyhydroxymethylquinoline ethiodide yields ethoxyhydroxymethylquinoline previously obtained by Otto Fischer. Both the above compounds combine readily with alkyl iodides, forming crystalline bodies, which, when treated with moist silver oxide, yield the corresponding ammonium bases. These behave quite normally on heating.

Benzyl chloride also forms an addition product with kairin, which is decomposed by caustic potash, with the formation of a substance which was proved, by treating hydroxyhydroxymethylquinoline with benzylchloride, to be the benzyl ether of kairin; thus proving that by the action of caustic alkali on the kairin ammonium iodides it is actually the added group that undergoes displacement.

Kairin treated with sodium acetate and acetic anhydride yields acethydroxyhydroxymethylquinoline (acetyl kairin), a body possessed of feebly basic properties, on which account it was of no value as an antipyretic. The physiological properties of benzoyl kairin were not investigated, for a similar reason. Hydroxyhydroxymethylquinoline heated with ethylene bromide in closed tubes gives hydroxyhydroxymethylquinoline, a body in which two quinoline groups are linked together by the bivalent residue—CH₂—CH₂—. It is a white crystalline substance, both the acid and basic properties of which are weak. The physiological action of this body, owing to its constitution approaching that of the quinine alkaloids somewhat more closely than that of kairin does, is of interest. It acts as a febrifuge, but its action is far weaker than that of kairin—a fact due, in all probability, to its feebler basic properties. It appears that the relative activity of these febrifuges bears a due proportion to their basicity.

Of many kairin derivatives prepared since the discovery of this body by O. Fischer (1881), none have proved of greater efficiency as antipyretics than kairin itself. Kairin has been applied with success as a febrifuge, and is still employed as such. The introduction of antipyrin has, however, greatly restricted its use. The advantage to be claimed for kairin is that it reduces the temperature

of the body more rapidly than antipyrin, and, therefore, is of special value in extreme cases in which the latter would be of less avail.—C. A. K.

Some Substances contained in the Root of Hydrastis Canadensis. M. Freund and W. Will. Ber. 19, 2797—2803.

PERRINS described an alkaloid which he found together with berberine in the root of *Hydrastis canadensis*, and named *hydrastine*. The authors prepared this substance by extracting the finely-powdered root with ether, evaporating off the ether, and dissolving the residue in hot alcohol. On cooling, the alcoholic filtrate deposits hydrastine in a pure state. Hydrastine forms crystals belonging to the rhombic system, melting at 132°. On analysis it gave numbers agreeing with the formula $C_{22}H_{23}NO_6$.

Hydrastine acted upon by methyl iodide yields a crystalline compound, melting at 208°, and having the composition $(C_{22}H_{23}NO_6)CHI_3$. Decomposed with moist silver oxide, it gives a body crystallising in small brilliant crystals, melting at 236—238°.

On oxidation with an acid solution of potassium permanganate, hydrastine yields an acid agreeing in all respects with opianic acid.

When heated with nitric acid of 1.3 sp. gr., hydrastine yields a mixture of opianic acid, and a base which greatly resembles cotarnine in its properties. The authors consider, from the behaviour of hydrastine with various reagents, that it is closely related to narcotine.

By treating the residue remaining after separation of berberine and hydrastine with sulphuric acid, and then with ether, a neutral substance, not containing nitrogen, was obtained, which crystallises in fine needles, melting at about 100°.—G. H. M.

Manufacture of Salol. By Dr. Hugo Eckenroth. Arch. der Pharm.

IN a recent number of the *Pharm. Zeit.*, a process for the manufacture of salol was described by Mr. B. Fischer. In studying that process it occurred to the author that phosgene (carbonylchloride, $COCl_2$) would be a much better medium for the preparation of salol. This body is a gas at ordinary temperatures, and may be prepared in various ways, but most practically by passing carbonic oxide through a boiling solution of antimony or phosphorus pentachloride.

Phosgene readily parts with its chlorine; for example, in the preparation of ethylene chloride from aldehyde:— $C_2H_4O + COCl_2 = C_2H_4Cl_2 + CO_2$. Another phase of its action is seen in the decomposition which acetate of sodium undergoes when a stream of the gas is passed through it. Here the acid is reduced to the anhydrous state, as will be seen from the following equation:— $2NaC_2H_3O_2 + COCl_2 = 2NaCl + (C_2H_3O_2)_2O$.

Similarly alcohols are reduced to ethers by phosgene; for example, ethyl alcohol reacts as follows, yielding ethyl chlorocarbonate:— $C_2H_5OH + COCl_2 = C_2H_5OCOC_2H_5 + HCl$; while phenol is decomposed by liquid phosgene into phenyl carbonate, thus:— $2C_6H_5OH + COCl_2 = C_6H_5O.CO.OC_6H_5 + 2HCl$. The application of phosgene to the preparation of salol is based upon the following reaction, which takes place when the gas is passed through a mixture of salicylate and phenate of soda:— $C_6H_4 \begin{smallmatrix} OH \\ COONa \end{smallmatrix} + C_6H_5ONa + COCl_2 = HIO.$

$C_6H_4.CO.OC_6H_5 + 2NaCl + CO_2$. In practice molecular proportions of salicylate and phenate of soda are intimately mixed and placed in a flask provided with a well-fitting indiarubber stopper with two holes in it—one for a tube through which phosgene may be conveyed, the other for an exit tube about seven feet long. The gas being slowly passed in, the beginning of the reaction is manifested by a considerable rise in temperature, which, however, falls speedily; and it is necessary, in concluding the operation, to heat the contents of the flask on a water-bath. The completion of

the reaction is known when a small portion of the contents shows, on testing, freedom from phenol. After this the contents of the flask are further heated on the water-bath for twelve hours; then washed free from sodium chloride by means of water, the salol being purified by repeated crystallisation from alcohol, whereby it is obtained in tabular crystals, melting at 40°. When boiled with a caustic alkali it yields abundance of salicylic acid after the resulting solution is acidified.

Bromine water precipitates the salol from alcoholic solution in the form of long needles, which the author determined to be those of a bromo-derivative. He dissolved salol in five times its volume of absolute alcohol, and added to the solution bromine in small quantities at a time, each portion being allowed to combine before another was added, until a yellow tint—which did not disappear in a short time—was imparted to the liquid. After ten hours, crystals of a bromo-derivative, $C_{11}H_9O_3Br$, were obtained and purified by crystallisation from alcohol. Thus the compound was obtained in beautiful white silky needles, melting at 98.5° C. (uncorr.). The body is insoluble in water, difficultly soluble in cold, but easily soluble in boiling alcohol and ether. The author continues his study of the bromo-derivatives of salol, as well as the action of phosgene in the production of other "salols."

Improvements in the Manufacture of Lactic Acid and Lactates. A. G. Brookes, London. From F. S. Nowell, Boston, U.S.A. Eng. Pat. 14,001, Nov. 17, 1885. 6d.

THE invention has for its object the production of a lactic ferment and crude lactates practically pure from other ferments, and consists in cultivating lactic ferments in media specially favourable to the growth of lactic ferment, but less favourable to the growth of other ferments, such as butyric, alcoholic, etc.

A medium favourable in the highest degree for lactic fermentation is composed of 1000 parts starch sugar, dextrin or glucose or milk sugar, 6000 parts of water, 500 parts carbonate of lime, and 100 parts vegetable nitrogenous matter kept at 95 to 113° F.—T.

New Compounds of Organic Alkaloids and Saccharine and Method of producing the same. C. Fahlberg and A. List. Eng. Pat. 596, Jan. 14, 1886. 6d.

THE object of the process covered by this patent is to render certain alkaloids of objectionable taste—such as quinine, strychnine, and morphine—more palatable. This is effected by making an aqueous or alcoholic solution of saccharine (benzoyl sulphonic imide, Eng. Pat. 6626, 1885), and neutralising the solution by the addition of the alkaloid of which a compound is desired. The solution so formed yields the compound in an amorphous or crystalline condition on evaporation; but if an excess of saccharine is used, an easily crystallisable acid-salt of the alkaloid is produced, which possesses in a still less degree the characteristic taste of the alkaloid.

XXI.—EXPLOSIVES, MATCHES, Etc.

The Analysis of Explosives. G. Lunge. Chem. Ind. 1886, 273.

THIS paper commences with a brief review of the various methods which have recently been proposed for the estimation of nitrogen in organic nitro-compound explosives; and the author points out that whilst the original form of his nitrometer was perfectly applicable to the analysis of liquid nitro-compounds, or to nitrates and nitrogen oxides in solution, it could not be conveniently employed for the nitrogen assay of solid bodies, such as gun-cotton or kieselguhr dynamite, especially when such contained carbonates, as in this case the nitric oxide would be contaminated with carbonic acid. The author now proposes

a simple modification (see illustration), which renders the nitrometer capable of application to the analysis of solid nitro-compound explosives, even when they contain carbonates in admixture. The mouth of the nitrometer cup is closed with a perforated caoutchouc stopper, through which passes a small thistle-headed funnel, bent twice upon itself. The end of the funnel tube projects a short distance into the cup, and is ground obliquely. For the actual performance of the analysis, the weighed quantity of substance is introduced into the cup, the caoutchouc stopper inserted, and 2 to 3cc. of concentrated sulphuric acid passed in through the funnel. By this procedure,

a few drops of acid naturally remain in the bend of the funnel, and retain any nitrous fumes which might be evolved. When solution of the substance is effected, the liquid in the cup is drawn into the nitrometer in the usual way, the cup is once washed out by passing a small quantity of acid through the bent funnel, the stopper then removed, and the rinsing of the cup completed in the usual manner. The analysis is then proceeded with in the usual way. Working under such conditions, it is clear that the presence of carbonic acid can have no vitiating effect upon the results. Tested according to this plan, a sample of collodion cotton yielded the following figures:—

I.	12.09	per cent.	Nitrogen.
II.	12.07	"	"
III.	12.05	"	"

In I. the whole of the acid for solution and for washing was introduced through the funnel; in II. and III. the small portions of substance, resting on the sides of the cup, were washed down with acid. The cup then closed, and the main portion of acid introduced through the funnel. The rinsing out of the cup was effected whilst the cup was open. The results show that the simpler manipulation adopted in II. and III. gives as accurate results as that in I.—W. D. B.

Improvements in the Treatment of Explosive Compounds.

H. E. Newton, London. From Alfred Nobel, Paris. Eng. Pat. 5852, April 28, 1885. 4d.

THE object of this invention is to render nitro-glycerine comparatively safe and inexplosive while it is stored. For this purpose methylic alcohol was employed, but owing to the volatility of that liquid, the protection obtained was not sufficient. The present improvement consists in diluting nitro-glycerine with solvents, which are non-volatile or only slightly volatile, whereby a practically inexplosive mixture is obtained. Of such solvents common tar oil, that distilling above 200° C., is employed by preference, the mixture being made in the proportions of 100 parts of nitro-glycerine to 50 parts of the tar oil. When it is required to restore to the nitro-glycerine its explosive properties, about 100 parts by weight of oleic acid are added to the above mixture, and the whole well shaken. Or in place of oleic acid, petroleum, carbon bisulphide or other liquid, in which tar oil is soluble, and nitro-glycerine insoluble, may be used. The nitro-glycerine is precipitated, together with a small percentage of tar oil, which it retains, but which for many purposes is not detrimental, as it lessens the sensitiveness to concussion of the nitro-glycerin.—W. D. B.

Improvements relating to the Manufacture of Explosive Compounds. H. S. Maxim, London. Eng. Pat. 6926, June 8, 1885. 6d.

THE object of this invention is the preparation of an explosive mixture less liable than ordinary gunpowder to be affected by moisture, and capable of being compressed or moulded into prisms or blocks, having a more regular density throughout than is the case with compressed forms of ordinary gunpowder. A mixture of the following ingredients, in or about the proportions specified—viz., 78.18 parts of potassium nitrate, 11.42 parts of paraffin wax, and 10.40 parts of sulphur, is prepared by first incorporating the potassium nitrate and sulphur in the usual manner, and then adding the paraffin in the molten condition. The resulting mixture may be employed alone, or better in conjunction with gunpowder or gun-cotton. By incorporating one part of the mixture with three parts of gunpowder, a compound is obtained which can be readily moulded under pressure, since it flows in the press like wax, and which yields forms or prisms less liable than gunpowder to be injuriously affected by rough handling or moisture.

—W. D. B.

Improvements in the Manufacture of Explosives. D. Johnson, London. Eng. Pat. 8951, July 24, 1885. 8d.

NITRO-CELLULOSE explosives in the granular or compressed form are treated with camphor in solution. The solvents employed are such as boil below 100° C., such, for example, as petroleum ether. The explosive is saturated with the camphor solution, the solvent volatilised at as low a temperature as practicable, and the grains, cylinders, prisms, or other forms of the explosive, now containing finely-divided camphor, disseminated through their mass, are subjected in a closed, though not necessarily an air-tight vessel, to a temperature not exceeding 100° C. Between 50° and 100° C. the camphor exerts a remarkable gelatinising action upon the nitro-cellulose, and the grains or other forms become hard and tough. The camphor having effected the requisite amount of hardening, may either be driven from the explosive by heat and condensed for repeated use, or it may be washed out by any appropriate solvent. In proportion to the amount of camphor employed, the nature of the explosive may be regulated at will, this not being due to the presence of camphor in large or small amounts in the finished products, but to the gelatinising action of the camphor upon the nitro-cellulose at the temperatures stated. The camphor treatment provides a means whereby the grains or other forms of the nitro-cellulose explosive are hardened uniformly throughout their mass and not simply at the surface, so that as regards burning or explosion the action is uniform throughout. Moreover, the grains still retain at the surface their microscopically fibrous structure, whereby a number of minute points is presented to the flash of the cap, and free ignition thus brought about. The invention may be employed in the preparation of explosives for use in sporting and military small arms and in ordnance.—W. D. B.

An Improved Explosive Compound for Guns or Firearms and Blasting Purposes. C. D. Abel. From F. Gaens, Hamburg, Germany. Eng. Pat. 14,412, Nov. 24, 1885. 6d.

“THIS invention relates to an improved explosive compound for guns or firearms and blasting purposes, similar to ordinary gunpowder, in which, in place of the sulphur, an ammonium salt is employed in combination with saltpetre in such proportions that on ignition a compound of potassium, nitrogen and hydrogen, termed potass-amide, is formed, which is volatile at high temperatures and which increases the useful effect of the explosive and burns without residue. The composition and action of this explosive, which is termed ‘Amide powder,’ is expressed, for example, in the application of nitrate of ammonia, by the formula $\text{KNO}_3 + \text{H}_2\text{N}(\text{NO}_2) + 3\text{C} = \text{KH}_2\text{N} + \text{H}_2\text{O} + \text{CO} + 2(\text{CNO}_2)$. The amide KH_2N is potassium nitride combined with ammonia for $3\text{KH}_2\text{N} = \text{K}_3\text{N} + 2\text{H}_3\text{N}$.”

The manufacture of this powder is the same as that of ordinary gunpowder, and where deemed advisable other nitrates may be substituted for that mentioned, and salts of ammonia other than the nitrate may be employed, so long as the composition is such that amide compounds are produced in the process of combustion.

—W. D. B.

Improvements in the Manufacture of Gunpowder and similar Explosives. E. Schultze, Germany. Eng. Pat. 15,129, Dec. 9, 1885. 6d.

THE inventor prepares a sporting powder by mixing 12 parts of nitrified tar, colophony, turpentine or turpentine oil, or mixtures of same, with 60—80 parts of pyroxylin, 60—80 parts of barium nitrate, 8—10 parts of potassium nitrate, granulating as usual. The grains of the finished powder may be coated with paraffin, resin, or collodion.

A rifle powder is prepared by mixing 10 parts of nitrified tar, colophony, turpentine or turpentine oil, or mixtures of same, with 280—300 parts of pyroxylin, 100—120 parts of barium nitrate, 40—50 parts of potassium nitrate, and 10 parts of sulphur. Explosives for blasting purposes are prepared by increasing the amount of pyroxylin. The claims are for the use of nitrified "hydrocarburets," such as nitrified tar, colophony turpentine or turpentine oil in conjunction with pyroxylin, nitrates, and sulphur in the preparation of explosives for propelling and rending purposes.—W. D. B.

A New Explosive, Processes of Preparing and Using the same, Primings therefor and Shell charged therewith. A. M. Clark. From E. Turpin, Paris. Eng. Pat. 15,089, Dec. 8, 1885. 8d.

THE inventor claims as novel the employment of picric acid alone, without any admixture of oxidising agents, moulded by compression or heat into compact blocks or masses.—W. D. B.

Improvements in Fuses for Explosive Shells and Torpedoes. E. L. Zalinski, Washington, U.S.A. Eng. Pat. 6340, May 11, 1886. 8d.

THIS is an improvement upon Eng. Pat. 2826, March 3, 1885, and consists in the arrangement of an electric battery in a shell or torpedo by which the charge is exploded; in the mechanism by which the electric battery is held out of action until the desired time for firing, and in the method in which the same is brought into play either on impact or as a time fuse. Arrangements are also described by which the shell or torpedo explodes when in contact with water or immersed therein, the battery contained in the shell or torpedo being put up in the dry and inert state and remaining inactive until the ingress of water has taken place.

—W. D. B.

Improvements in Explosive Compounds. Hermann Scheneweg, Dudweiler, Germany. Eng. Pat. 6664, May 18, 1886. 4d.

To prepare a mixture which can only be exploded by a very powerful initial detonation the inventor compounds 218 parts of di-nitronaphthalene with 720 parts of ammonium nitrate. For use with less powerful detonators, there may be substituted for the di-nitronaphthalene two parts of dinitrobenzene mixed with five parts of ammonium nitrate. The claims are as follows:—

1. The production of explosive compounds consisting of mixtures of di- or tri-nitrobenzene, or di- or tri-nitronaphthalene with ammonium nitrate.

2. The mode of regulating the action of the explosive compound referred to in the preceding claim by mixing together two or more of the compounds, consisting of ammonium nitrate with one or other of the nitro-derivatives there enumerated.

3. The use, in combination with the explosive compounds referred to in the preceding claims, of nitrated resin for the purpose of protecting them against moisture and increasing their durability.—W. D. B.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

Congo-red as an Alkalimetric Indicator. P. Julius. Chem. Ind. 9, 109.

CONGO-RED dissolves in water and alcohol with a red colour, changing into blue by acids, and which is again turned to red by alkalis. The author recommends its use for the titration of aniline and its homologues, especially for the mixture of aniline and toluidine, known as the "échappés" of aniline colour works. The échappés is completely dissolved in water, a few drops of an alcoholic Congo-red solution added, normal hydrochloric or sulphuric acid being used for the titration, until the red colour changes into a bluish-violet, which point can be clearly distinguished. Commercial "aniline-oil for blue" was used for the following experiments. In Nos. 1 to 4 the water added was not sufficient for dissolving all the aniline; in Nos. 5 to 8 all the aniline was dissolved in water:—

No.	Amount of Aniline used.	cc. of Normal HCl used.	Amount of Aniline found.	Difference.
1	0.9242	9.9	0.9207	-0.0035
2	1.7656	19.0	1.7670	+0.0014
3	1.0680	11.5	1.0694	+0.0014
4	1.1510	12.4	1.1532	+0.0022
5	3.5894	38.5	3.5805	-0.0089
6	2.6512	28.6	2.6598	+0.0086
7	3.6906	39.8	3.7011	+0.0105
8	2.6799	28.8	2.6784	-0.0015

—S. H.

Detection of Small Amounts of Hydrocyanic Acid. G. Portmann. Monatsh. f. Chem. 7, 416.

THE reaction depends upon the formation of sodium nitroprusside by the action of a nitrite in acid solution on potassium cyanide and a ferric salt (Playfair). The process is carried out as follows: The liquid to be tested for hydrocyanic acid is treated with some drops of a potassium nitrate solution, from two to four drops ferrous sulphate solution and so much dilute sulphuric acid, until the yellow-brown colour of the basic ferric salt formed is just changed into a light yellow. The liquid is then heated to a boil and afterwards allowed to cool. The iron in excess is precipitated with a few drops of ammonia, filtered, and the filtrate tested with one or two drops of dilute colourless ammonium sulphide. If hydrocyanic acid was present in the original solution, the liquid at once assumes a violet colour, which changes in a few minutes into blue, then green, and finally into yellow. Very minute traces of hydrocyanic acid produce a bluish-green colour, which soon changes into greenish-yellow. 0.000032 grms. hydrocyanic acid in 10cc. of water can still be thus detected.—S. H.

The Titration of Soda in the presence of Alumina, and of Vanadic and Tungstic Acids. E. B. Zeits. Anal. Chem. 25, 186.

A COMMERCIAL CARBONATE of soda which contains alumina, on titration with acid, using dimethyl-orange as indicator, will be shown to contain too much sodium carbonate when the titration is carried slowly to the point of permanent redness, the error amounting to 53 of sodium carbonate for every 17 of alumina. For example, a rather impure soda, especially Leblanc-soda, containing one per cent. of substances insoluble in water, of which one-half is alumina, 1.5 per cent. too much soda will be found, if, as is generally the case, the insoluble matters be not removed.

Sodium carbonate containing vanadium, when treated as above, gives a brown colouration; the red colour does not appear until there is a considerable excess of acid. Litmus paper must be used in this case. Tungstic acid acts similarly, but such varieties of soda very seldom occur in commerce.—W. S.

Automatic Washing Apparatus. R. Lucien. *Chem. Zeit.* 10, 1272.

THE essential part of the apparatus is a hydraulic, radiating cross α , suspended by a thread above the funnel, through which the water passes before it reaches the funnel. The cross is fed with water by the aid of a

lever b , with intermittent action, the water being supplied from a Mariotte's bottle c . The accompanying drawing illustrates the apparatus. The flow of water is said to be easily regulated.—D. B.

ERRATUM.—In the November number of this Journal, page 618, second column, article on the *Determination of Phenol in Crude Carbolic Acid*, in the 5th line from end of abstract, for "10cc. iodine solution is added," read "10cc. of potassium iodide solution are added."

New Books.

MANUAL OF PRACTICAL PHARMACEUTICAL ASSAYING, including Details of the Simplest and Best Methods of Determining the Strength of Crude Drugs, and of Galenical Preparations. Designed especially for the use of the Student and of the Practical Pharmacist. By A. B. LYONS, A.M., M.D. Detroit: D. O. Haynes & Co., Publishers. 1886. London: H. Grevel & Co., Foreign Booksellers, 33, King Street, Covent Garden.

SMALL 8VO VOLUME bound in cloth, containing Preface, Table of Contents, 146 pages of subject-matter, and an Appendix of 5 pages, with tabulated results of considerable value of assays of some of the more important vegetable drugs. The work contains eleven excellent woodcuts, and taken in detail it treats of the apparatus needed in the process described; the reagents; general methods for the assay of crude drugs; methods of extracting alkaloids from crude drugs; general assay processes; the use of Mayer's reagent; gravimetric estimation of alkaloids; assay of Galenical preparations; special methods of separating alkaloids in a state of purity; separation of alkaloids from one another by solvents; Parson's scheme of proximate analysis; estimation of alcohol in fluid extracts, etc.; estimation of glycerine in fluid extracts, etc.; aconite and its pre-

parations; assay of commercial aconitine; belladonna and stramonium and their preparations; cinchona bark and its preparations; assay of cinchona alkaloids; estimation of quinine in mixed alkaloids from cinchona bark; coca and its preparations; colchicum and its preparations; conium and its preparations; digitalis and its preparations; elaterium; gelsemium and its preparations; guarana, coffee and tea, and their preparations; hydrastis and its preparations; hyoseynus and its preparations; ipecacuanha and its preparations; nux vomica and Ignatia bean and their preparations; opium, physostigma, pilocarpus, podophyllum, Quebracho bark and their preparations; rhubarb; tobacco; veratrum virides; amyl nitrite; ethyl nitrite; peptone and pepsin.

A TREATISE ON CHEMISTRY. By Sir H. E. ROSCOE F.R.S., and C. SCHORLEMMER, F.R.S., Professors of Chemistry in the Victoria University, Owens College, Manchester. Vol. III.: The Chemistry of the Hydrocarbons and their Derivatives; or, Organic Chemistry. Part III. London and New York: Macmillan & Co. 1886.

8VO VOLUME, bound in cloth, containing 372 pages of subject-matter, and an alphabetical index covering nearly 14 pages. As stated in the Preface, "This part of the work commences the consideration of the complicated but most important series of bodies known as the aromatic compounds. It contains, after an introduction, a description of the mode of formation, and of the properties of the aromatic hydrocarbons and their derivatives, together with an historical discussion of their isomeric modifications. The constitution of benzene, and the characteristic reactions of its di-substitution products, are then fully explained. Next follows a review of all the important benzene derivatives, so that the part now published forms a complete chapter of the ever-increasing volume of aromatic chemistry." Besides being a work specially designed for the theoretical chemist, its text is sufficiently comprehensive to satisfy the wants of the technologist who seeks for points of departure in the various directions of applicability to the wants of pharmacists, colour chemists, etc. The text is embellished by 14 wood engravings.

The German counterpart of the above volume has also recently appeared under the following title:—"Ausführliches Lehrbuch der Chemie." Vierter Band. Die Kohlenwasserstoffe und ihre Derivate oder Organische Chemie. Zweiter Theil. Erste Abtheilung. Braunschweig. Druck und Verlag von Friedrich Vieweg & Sohn. 1886.

TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the "Board of Trade" and other Journals.)

CLASSIFICATION OF ARTICLES IN TARIFFS.

RUSSIA.—(Rouble=3s. 2d. Pound=36lb.) Carbonic acid lime, chemically pure, such as purified chalk, section 108, part 2, duty 6 copecks per pound.

SWITZERLAND.—(Quintal=2204lb.) Nitrate of baryta, Category 16, duty 20 centimes per quintal. Ultra-marine (blue for washing) without distinction of package, Category 36, duty 3frs. 50c. per quintal.

MODIFICATIONS IN TARIFFS.

NETHERLANDS.—A law received the royal sanction on the 1st November last, exempting from excise duty foreign varnishes made with methylated spirit.

GREECE.—The duty on cotton tissues, bleached, not classified, will in future be at the rate of 40 per cent. above the duty on unbleached cotton tissues, instead of 25 per cent. as formerly. The duty on dyed and printed cotton tissues will in future be at the rate of 80 per cent. above the duty on unbleached cotton tissues, instead of 60 per cent. as formerly. All the import duties of the revised tariff are payable in gold, or with an increase of 15 per cent. if paid in paper.

ITALY.—It is expected that a duty will be placed on pig iron, now admitted free.

ROUMANIA.—The duty on cement, natural and prepared, to be 60 centimes per 100 kilos.

ECUADOR.—To pay 2d. per kilo:—Common soap, refined table salt, and writing ink. To pay 5d. per kilo:—Olive, castor, and almond oil, varnish, vinegar, matches, paint in powder, and candles.

MEXICAN CUSTOMS TARIFF (Mexican Dollar=4s. 2d.).

No. in Tariff.	ARTICLES.	Kilos.	Dollars.
	Chemicals, Drugs, and Medicines:		
507	Acetates of copper and lead, legal weight*	0	08
508	Acetates of all kinds, not specified, legal weight*	0	15
510	Acids, gaseous or liquid, not specified, legal weight*	0	25
511	Acids in crystal or powder, not specified, legal weight*	1	10
515	Albumen, net weight*	0	30

SUGAR BOUNTIES IN RUSSIA.—A telegram, dated the 3rd December last, has been received from Sir R. B. D. Morier, Her Majesty's Ambassador at St. Petersburg, to the effect that the payment of bounties closed on the 1st July last on all sugar, except that exported to Central Asia. This year's crop will therefore receive no bounty.

CUBAN SUGAR CROP OF 1886-87. The following information, respecting the prospective sugar crop in Cuba, is extracted from a report by Her Majesty's Consul-General at Havana, dated the 30th October last:—

"Accounts received from the sugar-producing districts in all parts of the island tend to the conclusion that the sugar crop of 1886-1887 will be one of the largest hitherto gathered, and the probable result of the grinding is confidently expected to produce at least 800,000 tons, a figure not hitherto reached in the sugar annals of Cuba.

"This calculation is necessarily subject to climatic disturbances, and should prices at New Year not rise somewhat, or even maintain themselves at their present level, this abundance will hardly enable planters to recover from the effects of previous bad years."

GERMANY—CONDITION OF SUGAR INDUSTRIES.—"The sugar manufactories are mostly in the hands of companies which control large amounts of capital, and only a few establishments are in possession of agricultural associations. Up to the present date the Government has refunded to the manufacturers the entire duties collected on export sugar, and for this reason their dividends have been large; but farmers who produce the beets do not seem to have been benefited by this liberal measure, as the price of sugar beets has been trending steadily downward.

"Farmers are, however, growing wise by experience, for they have learned that the conversion of their sugar-beet crops into beef, by feeding them to cattle, is a much more profitable transaction than selling them for sugar purposes at present prices, and the result will be probably an advance in the price of sugar during the next two or three years."

PETROLEUM INDUSTRIES OF RUSSIA.—The *Moniteur des Intérêts Matériels* of the 31st October last has an article on the petroleum industry on the shores of the Caspian Sea. It states that there are now no less than 200 refineries of petroleum in the neighbourhood of Baku, the principal port of this district, and that the exportation of mineral oil is increasing regularly and with great rapidity. The amount of petroleum exported from Baku in 1876 was 50,000 tons; in 1885, 993,000 tons were exported. When the difficulty of bringing the oil to the sea has been completely surmounted, the trade of Baku is likely to attain very vast proportions. Large sums have been voted by the Russian Government for the improvement of the chief ports of the Black Sea, and there is every reason to expect that in a short time we shall see the mineral oils of the Caucasus drive the American oils out of a great part of the European market.

TRADE STATISTICS FOR NOVEMBER, 1886.

The Board of Trade Returns for November show the following figures:—

	Nov. 1885.	Nov. 1886.
Imports: Total value.....	£29,713,768	£33,050,955
Exports: ".....	16,464,250	17,569,692
Foreign and Colonial produce (partly estimated).....	3,918,589	3,869,976

Nitre (nitrate of potash).....	cwt. 2,135	5,719	389
Nitre (nitrate of potash).....	value £ 1,923	4,646	318

PRUSSIAN MINERAL STATISTICS FOR THE YEAR 1885.—The year 1885 seems, by the reports just printed of the mineral production, to have been a very favourable one throughout. With the exception of iron ores, iron pyrites, and salt, there has been an increased production of nearly all minerals and ores over the amount produced in 1884. The decrease in iron ores is considerable, amounting to 260,000 tons. The production of manganese ores, however, was nearly double the yield of 1884, and nearly quadruple that of 1883 and 1882. While the iron ores mined during the year were less than in 1884, the amount of pig iron produced shows an increase of 46,000 tons, having, however, a value of nearly nine million marks less than the total product of 1884.

All the other metals produced show considerable decline in values for the year. While there is a total increase of production equal to nearly 43,000 tons, there is a decrease in the total value of metals produced amounting to over fourteen million marks.

The number of hands employed during the year in the Prussian mines, above and below ground, amounted to 292,713. The number of fatal accidents was 841, or 2·873 per thousand, as against 2·419 per thousand in 1884. This is also a considerable increase in the death rate by accidents over the average of the last eighteen years, which was 2·5 per thousand.

Production of Minerals and Ores in the Kingdom of Prussia for the year 1885:—

	No. of mines worked.	Production.	
		Tons.	Kilos.
I. Mineral coals and bitumen:			
Stone coal.....	388	65,879,004	..
Lignite.....	428	12,387,284	..
Asphalt.....	4	19,401	..
Petroleum.....	8	2,695	..
II. Mineral salts:			
Rock salt.....	5	205,492	13 ³
Kainit.....	1	195,391	423
Other potash salts.....	1	520,339	261
Kieserit and Glauber's salt.....	..	27	..
Boracite.....	..	121	65
III. Ores:			
Iron ores.....	573	3,925,783	375
Zinc ores.....	64	679,787	713
Lead ores.....	107	110,336	782
Copper ores.....	18	611,336	713

Sulphate of zinc	12	683	430	..
Others	12	161	..	85

* Kilograms. † Per kilogram.

PROGRESS OF THE BASIC OR THOMAS-GILCHRIST PROCESS FOR THE TWELVE MONTHS ENDING OCTOBER 31, 1886.—The total make of steel and ingot-iron from phosphoric pig during this period amounts to 1,313,631 tons, being an increase over the make for the previous twelve months of about 368,314 tons. It is noticeable that of this make no fewer than 927,281 tons were ingot iron containing under 0.17 per cent. of carbon. The makes of the various countries for the 12 months ending September 30, 1885, and October 31, 1886, respectively, are as follows:—

	1885.		1886.	
	Total.	With under 0.18 p. cent. Carbon.	Total.	With under 0.17 p. cent. Carbon.
England	Tons. 115,707	Tons. 70,813	Tons. 258,166	Tons. 161,908
Germany, Luxemburg, and Austria	617,514	424,862	883,859	651,523
France	130,582	62,350	122,711	77,111
Belgium and other countries.	51,514	42,118	48,595	36,712
Totals	945,317	600,183	1,313,631	927,284

It is noteworthy that these 1,313,631 tons of steel represent about 394,000 tons of slag, containing from 30 per cent. to 35 per cent. of phosphate of lime. Nearly all the basic slag made in Germany is very finely ground, and used in place of super-phosphates.

COPPER PRODUCTION IN RUSSIA.—Since the discovery of copper in Chili, Australia, and America, the production of copper in Russia has gradually fallen off. Thus, in 1856, Russia supplied the Continent with 2570 tons of copper, and imported only some 50 tons. Now, of every 100kilos, used in Russia 75 per cent. is of foreign production. At present the metal is chiefly raised in the Elizabethopol district of Transcaucasia. There are two works there, owned by the Brothers Siemens, and they get their ore from six shafts in Mount Misdag. The ore varies in richness from 2 to 20 per cent. In the period from 1876 to 1881 these two works produced from 18,070 tons of ore 3209 tons of copper. The workmen number 1500, and they are paid at from 30 to 40 copeks per day. Owing to the results obtained being regarded as satisfactory, a spur has been given to the development of production in the Government of Tiflis. Ore exists in some districts there yielding metal of an average value of 16 per cent.—*European Mail*.

Monthly Patent List.

1.—GENERAL PLANT, APPARATUS, AND MACHINERY.
APPLICATIONS.

- 15215 H. J. Allison, London.—From J. H. Blessing, United States. Improvements in apparatus for purifying water. Complete specification. November 23
- 15216 H. J. Allison.—From J. H. Blessing. Water purifying apparatus. Complete specification. November 23
- 15218 W. W. Beaumont, London. Supplying fresh feed water to steam boilers of surface condensing engines. November 23
- 15220 S. Harrison, Ripon. Regulating outlets of reaction turbines. November 23
- 15208 A. J. Boulton, London.—From N. Carvalho, United States. Improvements in apparatus for heating air, steam, or the like. Complete specification. November 23
- 15292 G. Westinghouse, jun., and F. Moore, London. Improvements in thermostats. Complete specification. November 23
- 15293 G. A. Godillot, London. Improvements in revolving fire grates for furnaces. November 23
- 15350 H. Bamford, London. Valves for controlling the flow of water, steam, compressed air, or other fluids or gases through pipes. November 21
- 15104 H. W. Cole and A. F. Cole, London. Improvements in or relating to gas and other fluid pressure controlling apparatus. November 25
- 15410 T. S. Marriage, London. Metallic vessels for holding liquids. November 26
- 15479 M. Vining, London. Apparatus for facilitating the use of compressed air or other gases or vapours for imparting pressure to water for extinguishing fires and for other purposes. November 26
- 15456 J. Henderson, Wakefield. Improved furnace or grate bars. November 27
- 15520 W. J. Clark, London. An apparatus for automatically regulating the supply of air to furnaces under forced draught. November 27
- 15550 F. J. Ricarde—Seaver, London. Linings for furnaces, retorts, crucibles, and the like. November 29
- 15558 R. Fraser and J. B. Edmiston, Liverpool. Improvements in or appertaining to forced draught apparatus for furnaces. November 29
- 15505 D. B. Morison, Hartlepool. Artificial air supply to boiler furnaces. November 30
- 15536 W. H. Mirfin, London. Improvements in or applicable to steam boiler or other furnaces. November 30
- 15604 A. J. Boulton, London.—From J. L. W. Oesen, Denmark. Apparatus for indicating the level in steam boilers and the like. Complete specification. November 30
- 15715 J. Joly and J. Bochon, London. Machinery or apparatus for granulating or disintegrating coke and other materials. Complete specification. December 1
- 15751 J. B. Fenby, Sutton Coldfield. Cocks and valves for controlling the flow of liquids. December 2
- 15757 R. Fraser and J. B. Edmiston, Liverpool. Improvements in or appertaining to forced draught apparatus for furnaces. December 2
- 15768 O. J. Ellis, London. Air refrigerating machines. December 2
- 15787 H. Wilson, Stockton-on-Tees. Apparatus for creating forced draught and forced combustion, for injecting fuel into furnaces and the like, applicable to steam-boiler and other furnaces. Complete specification. December 3
- 15812 A. Blechynden, London. Centrifugal fans for extracting or forcing air. December 3
- 15861 H. C. Simpson and E. W. Astle, Derby. Construction of boilers for heating purposes. December 4
- 15872 W. W. L. Lishman, J. T. Lishman, and W. R. Bootland, Liverpool. Condensers used in the analysis of chemicals. December 4
- 16029 C. Marquis de Montgrand, London. Process and apparatus for the production of heat and cold. December 7
- 16067 A. A. Rickaby, London. System of promoting circulation of water in steam boilers, and preventing the deposit of scale on furnaces or other parts exposed to heat. December 8
- 16135 E. Kaselowsky, London. Apparatus for pumping and compressing air. Complete specification. December 9
- 16227 F. J. Browne, London. An improved smoke consumer. December 11
- 16263 W. R. Dennis, London. Improvements in heating apparatus. Complete specification. December 11
- 16277 E. Seger, London. Improvements in centrifugal apparatus. Complete specification. December 11
- 16290 J. B. Hannay, Glasgow. Apparatus for condensing, absorbing, or washing gases or fumes, and for similar purposes. December 13
- 16375 G. S. Follansbee, London. Improvements in fluid meters. Complete specification. December 14
- 16401 G. P. Bradford, Haney. The prevention of sulphurous fumes from the use of coke for firing on tramway or other engines and in the manufacture of iron. December 14
- 16411 W. W. Popplewell, London.—From J. Trueb, United States. Thermometric regulators for heating apparatus. Complete specification. December 14
- 16433 D. Rylands and R. Potter, Barnsley. Construction of port mouths of regenerative gas furnaces. Complete specification. December 15

- 16325 F. W. Bond, London. Apparatus for heating liquid by steam. December 16
 16332 H. P. Miller, London. Gas heating apparatus. December 16
 16333 W. Richardson and J. Fidler, Manchester. Machines or apparatus known as "Steel tape condensers." December 16
 16317 J. Atkinson, London. Improvements in refrigerating apparatus. December 17
 16389 E. L. Marsden and P. H. S. Nicklin, London. Improvement in steam blast apparatus. December 17
 16392 T. Milburn, C. W. Haydon, and E. Mundy, Manchester. Furnace grates having movable bars. December 17
 16393 S. Bennett, London. Apparatus for purifying water for boilers. December 17
 16611 B. J. Davenport, Birmingham. Gauge for indicating the depth of water or other liquid in an elevated tank or other receptacle. December 18
 16618 C. Vaughan, Shetfield. Clacks or valves for pumps and appliances for raising water and other liquids. Complete specification. December 18
 16721 T. S. Webb, London. Apparatus for heating water and other liquids. December 20

COMPLETE SPECIFICATIONS ACCEPTED.*

1886.

- 682 J. C. Brentnall. Steam generator and other furnaces. December 17
 1210 H. J. H. King. Mercurial gauges. November 30
 1213 A. Fould and P. Genéan. Refractory bricks, tiles, tubes, crucibles, furnace linings, etc., to be subjected to high temperatures. November 30
 1391 H. Mans. Apparatus for feeding furnaces without admitting air. November 30
 1439 J. Atkinson. Pumps for compressing or exhausting air or other gases. December 3
 1990 J. Maclear—From J. Kolb. Raising liquids and apparatus therefor. December 7
 2075 A. Sweet. Water heating apparatus. December 17
 2086 P. A. Maignen. Purifying and softening liquids, and apparatus therefor. December 11
 2176 J. Dewrance. Duplex water ganges for boilers. December 17
 2962 J. A. Muller. Apparatus for measuring and registering currents of fluids or gases. December 17
 8375 W. C. Nickels. Filtering funnels. December 17
 13116 J. McEwen. Signal employed in carbonic acid gas generators. November 26
 13671 D. McColey Weston. Centrifugal machines. November 26
 14162 H. T. Varyan. Vacuum distillation apparatus. December 3
 161616 W. E. Gedge—From J. E. Carroll. Apparatus for heating and purifying feed water for boilers. December 11
 161690 A. M. Clark—From C. S. Wilcox. Means for effecting consumption of smoke in furnace. December 11
 11887 D. George. Creating a draught in boiler flues or chimneys. December 17

H.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

- 15227 G. Pettigrew and G. Harper, Sligo. An improved system of injecting and regulating the flow of tar, oil, or other liquid fuels into furnaces for heating gas retorts, steam boilers, and other purposes. November 23
 15287 J. S. Sellon, London. Improvements in apparatus to be employed in lighting and heating. Nov. 23
 15301 W. Wells, Glasgow. Improvements in apparatus for obtaining light from hydrocarbons. November 21
 15328 R. Wallwork, London. Improvements in burners for generating gas from oils or combustible liquids, and burning the same to produce light and heat, and in apparatus connected therewith. November 21
 15456 C. Appleby, London. Heating chambers or closets. November 26
 15478 F. Lux, London. The purification of illuminating gas and other liquids, and apparatus therefor. Complete specification. November 26
 15481 J. Horrocks, Southport. Improvements in gas and electric light lamp pillar, and other illuminating pillars, and the means of effecting the same. November 27
 15560 J. Schweizer and P. E. Huber, London. Apparatus for lighting and heating with petroleum or other substance. November 29
 15621 B. H. Thwaite, Liverpool. Improvements in methods of generating gaseous fuel, and in apparatus therefor. November 30
 15716 S. Cutler, London. Apparatus for the distribution of liquid in gas scrubbers. December 1
 15728 F. J. Jones, London. Method of and apparatus for producing or manufacturing gas for illuminating and other purposes. December 1

- 15742 D. Ballardie, Glasgow. Burners for lamps to burn solid paraffin, naphthalene, or such oils or hydrocarbons as freeze or solidify at a low temperature. December 2
 15771 G. T. Budd, Plymouth. Lighting or resuscitating fires (domestic or otherwise), by employing gas instead of paper and wood or other quick combustible. December 2
 15839 T. Fletcher and A. Clare, Manchester. Improvements in and connected with gas fires and gas stoves. December 1
 15902 H. H. Lake, London—From J. J. Johnston, United States. Manufacture of gas for lighting and heating purposes. December 1
 15974 A. McDougall, Penrith. Treating coal or coke to improve its qualities for heating, smelting, or gas making, also to diminish the smoke evolved in the combustion of coal. December 7
 15991 C. J. Sandahl, J. Birchall, and J. Musson, Liverpool. Process of manufacturing gas, and apparatus employed therein. December 7
 16029 C. Marquis de Montgrand. See Class I.
 16018 A. Thomas, West Cowes. An improved means for straining gas-tar to be used as fuel in gas and other works. December 8
 16053 B. H. Thwaite, Liverpool. Methods of producing combustible gases from liquid hydrocarbons, and in apparatus therefor. December 8
 16112 F. B. Fowler, London. Improvements in the mode of and means or appliances for making oil-gas. Complete specification. December 9
 16380 T. W. Bayes, London. Apparatus for drying washed coal, or coal partially prepared for the manufacture of artificial fuel, applicable also to drying other materials. December 11
 16431 W. Wilkie, Glasgow. Improvements in preventing smoke by increasing the draught in chimneys, the said improvements being also applicable for supplying or discharging heated air into rooms or other apartments for heating and ventilating purposes, as well as for disinfecting the same. December 15
 16531 H. Arch, Leeds. Preparing smithy coke. December 17
 16581 A. Paget, Loughborough. The use and construction of "mantles" for incandescent gas lighting. December 17
 16657 W. Defries, London. Improved means of distributing light by reflection. December 18
 16727 W. Boggett, London. Obtaining heat and light, and apparatus employed therefor. December 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 15291 J. Butterfield. Means for increasing the temperature of furnace gases and air heated thereby. November 30
 15331 A. Kinnear and E. Fahrig. Apparatus for carburetting and increasing illuminating power of gas. December 10
 16052 W. Young. Purification of coal-gas, and apparatus therefor; in part applicable for preparation of caustic ammonia solutions. December 7

1886.

- 603 S. Banner. Manufacture, blending, and treatment of certain mineral hydrocarbons or compounds thereof. December 11
 1226 J. West. Apparatus for charging and drawing gas retorts. November 26
 1459 J. L. Balfour and J. Lane. Manufacture of illuminating gas and volatile liquid hydrocarbons. November 26
 1891 J. W. Brewster. Apparatus for regulating the temperature of, and supplying heating or cooling media to rooms, etc. December 10
 2299 H. Fournier. Stop valves for regulating admission of gas, etc., to burners of illuminating apparatus. December 17
 2307 H. Barclay and R. Simpson. Manufacture of coke for metallurgical purposes. November 30
 2411 A. Kempster. Centre valves for working purifiers, etc., used in the manufacture of coal-gas. December 17
 2892 H. Bowater. Purification of coal-gas. December 10
 11691 G. R. Cottrell. Method and apparatus for carburetting and mixing gas and air. December 7
 13227 W. H. Hawkes. Compound for treating coal and other fuel. December 2
 11795 J. F. Wright and G. E. Wright. Waste heat extractors for gas fires. December 17

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

APPLICATION.

- 15772 R. B. Tement, Glasgow. Destructive distillation of shale and other minerals, and retorts therefor. December 2

COMPLETE SPECIFICATION ACCEPTED.

1886.

- 8191 R. Tervet. Apparatus for distilling or refining mineral oils. December 17

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

- 15576 C. Collin and L. Errani, London. Black liquid prepared from aniline, nitro-benzene, and from their derivatives, for dyeing, printing, painting, and varnishing on all kinds of materials. November 30
 15651 H. Hirsch and J. Dawson, London. A process for obtaining chloride and bromide of amidodimethylaniline, and producing dyes therefrom. November 30
 16258 W. P. Thompson, Liverpool—From Ewer and Pick, Germany. Manufacture of aromatic diamines, and of azo-dyes, and derivatives therefrom. December 11

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

- 2213 C. A. Martins. Production of mixed azo-colours. December 3
 2878 A. M. Clark—From A. Müller-Jacobs. Manufacture of colouring matters, and vehicle therefor. December 14
 3890 T. Carnelley. Preparation of para-amido-diphenyl-sulphonic acid. December 10
 13780 C. D. Abel—From the Actiengesellschaft für Anilin-Fabrication. Production of azo-colours from orthosulpho or orthocarbo acid of benzidine. December 3

V.—TEXTILES: COTTON, WOOL, SILK, ETC.

APPLICATIONS.

- 15283 T. Zebrowski. See Class VI.
 15313 W. Mather, London. Apparatus for treating textile materials with liquids, gases, or vapours. November 24
 15399 J. B. Whiteley and W. Whiteley, Halifax. Machinery for drying wool and other fibre. November 30
 15600 J. B. Whiteley and W. Whiteley. Machinery for washing and scouring wool and other fibrous substances. November 30
 15669 G. Jagenburg, London. Machine for washing cotton and other textile materials. Complete specification. November 30
 15714 W. Pfirsch and B. Kirchner. See Class XIX.
 16066 A. Morel, Liverpool. Apparatus for treating wool and other fibrous materials for the removal of burrs therefrom. Complete specification. December 8
 16078 E. Casper, London. Treating the barks of ilea or China-grass, and like plants; and apparatus therefor. December 8
 16116 H. H. Lake, London—From H. R. Randall, United States. Improvements relating to the treatment of silk and other fibres. Complete specification. December 14
 16714 G. S. Patullo, Glasgow. Treating or preserving jute and other similar fibres. December 20

COMPLETE SPECIFICATION ACCEPTED.

1886.

- 1939 H. H. Doty. See Class XIX.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

- 15273 H. H. Leigh, London—From J. G. Watmough, United States. Improvements in apparatus for dyeing. November 26
 15283 T. Zebrowski, London. Improvements in the method of, and apparatus for, washing, scouring, and bleaching wool. November 23
 15355 T. O. Arnfield, Manchester. Improved apparatus to be employed in soaping, scouring, and cleansing printed and dyed fabrics. November 25
 15363 D. Stewart, Glasgow. Preparing and applying grey and black colouring matters to textile fabrics and materials. November 25
 15122 E. Edwards, London—From L. Gevaert, Belgium. Process for dyeing blue by means of alizarin. November 26
 15435 R. Holt, Halifax. Method and apparatus for dyeing warps of Turkey red, alizarin red, and other fancy colours. November 26
 15611 C. Gaydet, London. Apparatus for printing colours on hanks, yarns, or pieces of textile material. November 30
 15824 J. B. Alliot and J. Wade, London. Method of fixing colour upon printed yarns or other material, and in the apparatus employed therefor; parts of the improved apparatus being also applicable to other purposes. December 3
 16112 L. Weldon, London. Improvements in dyeing apparatus. Complete specification. December 14
 16143 E. Sutcliffe and G. E. Sutcliffe, Halifax. An improved means or method of drying dyed slivers of fibre. December 15
 16596 C. Carron, London. Machine for dyeing hanks or skeins of textile materials. Complete specification. December 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

- 211 J. C. Munn. Production of piece-dyed goods. December 3
 1465 H. Horner—From C. C. Sabin. Blueing water for laundry and other purposes, and apparatus therefor. December 3
 1482 J. Conlter. Hawking machines for indigo dyeing. December 3
 1750 W. G. White. Dyeing fabrics, and apparatus therefor.
 15388 J. Fletcher. Dyeing tissue and other papers, and apparatus therefor. December 7

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

- 15286 J. J. Hood and A. G. Solomon, London. Improvements in the manufacture of manganese sulphate. November 23
 15352 W. Burns, Leith. Manufacture of bicarbonate and carbonate of soda by the ammonia process, and construction and use of apparatus for that purpose. November 25
 15391 A. A. Croll, London. The distillation of ammoniacal liquors, the concentration of liquids and salts in solutions, and means or apparatus employed therein. November 25
 15436 H. Byk, London. Process for manufacturing tannic acid in bright, semi-transparent or translucent crystals or grains. Complete specification. November 26
 15488 W. Burns, Leith. Manufacture of sulphate of soda and bleach in one operation under high pressure, and in the construction and use of apparatus for that purpose. November 27
 15498 W. Branley and W. P. Cochrane, Redcar. Treating solutions of chloride of calcium so as to obtain chloride of magnesium and other products. November 27
 15793 J. S. Rigby, Holywell. Treatment for utilising a residue from the manufacture of caustic soda or caustic potash, commonly termed lime-mud. December 3
 15897 W. P. Thompson, Liverpool—From H. Reimann, Germany. Production of chlorine from chlorides of the alkalis and alkaline earths, and treatment of pyrites residues for the extraction of copper and other metals therefrom. December 7
 16022 G. Eschellmann and K. Markel, Liverpool. Manufacture of caustic soda or caustic potash and carbonic acid from carbonate, sesqui carbonate, or bicarbonate of soda, or carbonate or bicarbonate of potash. December 7
 16118 H. Kenyon, Manchester. Production of sulphide of zinc and chloride of ammonium. December 9
 16191 J. M. Walton, Manchester. Manufacture of sulphurous acids and other sulphur compounds, and apparatus employed in such manufacture. Complete specification. December 16
 16199 W. B. Giles and A. Shearer, Stratford. Manufacture of phosphoric acid. December 16
 16362 G. L. Wigg, M. Steele, W. J. Wigg and W. Towns, Liverpool. Treatment of sulphate of soda to obtain alkali, and apparatus therefor. December 17
 16363 G. L. Wigg, M. Steele, and W. J. Wigg, Liverpool. Treatment of certain residual liquors obtained in copper works for the production of sulphate of iron. December 17
 16399 The Tyne Alkali Company, Limited, and T. Gibb, London. Manufacture of hydrate of baryta and strontia and salts of barium and strontium. December 17
 16600 T. Scott, Glasgow. Evaporating saline solutions, and apparatus therefor. December 17
 16712 R. McCowan Service, Glasgow. Treatment of spent liquor or alkali waste from paper mills and other works, and recovery of caustic soda therefrom. December 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 16052 W. Young. See Class H.

1886.

- 1939 J. Maclear. Preparing soda for sale and distribution. December 10
 16022 J. Whitley. Apparatus for manufacture of acids and distillation and condensation of corrosive liquid and gaseous substances. December 10
 13116 J. McEwen. See Class I.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

- 15310 W. H. Turner, London. Machines for printing designs upon paper or other material, especially applicable to the decorating of earthenware, china, glass, tiles, granite, and the like. November 21
 15579 H. J. Allison, London—From C. C. Gilman, United States. Manufacture of porous earthenware. Complete specification. November 30
 15988 H. P. Dunnill and F. R. Smith, Iron Bridge, Salop. Method or means of manufacturing or producing constructions in tiles or any other similar articles. December 7

- 16009 G. F. Chance, London. New or improved machinery for rolling glass. December 7
 16229 E. Lee, Leeds. An improved process, mode, or means of ornamenting and utilising glass or other hard substances by sand blasting. December 11
 16268 J. Armstrong, London. Blowing and moulding glass, opal, etc., and machinery and appliances therefor. Dec. 11
 16365 A. D. Brogan, Glasgow. Improvements in kilns for annealing glass. December 11
 16366 A. D. Brogan and A. M. Malloch, Glasgow. Improvements in the manufacture of rippled glass, and in apparatus therefor. December 11
 16500 J. P. Guy, Longport. Improvements in machinery for making potters' seggars. December 16
 16555 H. Sulley, Nottingham. Improvement in the manufacture of pavement lights, and an improved method of fixing glass in metal frames. December 17
 16613 J. Northwood, London. Method of treating the glass cullet, known as "blacks." December 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

- 801 J. Scott, Manufacture of rolled plate glass, and apparatus therefor. December 17
 2073 G. Lazenby. Kilns for bending glass, firing stained glass, tiles, pottery-ware, etc. December 7
 11330 W. Boulton. Manufacture of articles of pottery having straight parallel sides. December 7

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

- 15211 G. Weston, Sheffield. An improved composition for preventing disintegration of roads and footpaths. Nov. 23
 15317 L. Schlenheim, London. An improved method of making ornamental granite marble mosaic. November 25
 15473 J. Winkler, London. A drop press for moulding building blocks. November 26
 15965 C. J. Dobbs, London. An improved construction of paving with moulded slag blocks. December 6
 16180 W. Joy, London. Improvements in and connected with the manufacture of Portland cement and natural cement, or hydraulic lime and other lime, and in apparatus therefor. December 15

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11619 T. C. Fawcett and J. D. Fawcett. Machinery for pressing bricks, tiles, etc. November 26

1886.

- 2399 H. Faija. Apparatus for mixing concrete. Dec. 17
 2171 E. W. Collier. Drying slurry, etc., and apparatus therefor. November 30
 10829 C. J. Dobbs. Manufacture of scoria paving blocks. November 30
 11131 G. Howard. Decorating wood. December 11

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

- 15216 F. B. Felt, London. Improvements in the manufacture of iron bars, plates, and similar articles. Complete specification. November 23
 15270 F. A. Herbertz, London. Improvements in cupola smelting furnaces. Complete specification. November 23
 15308 C. W. Crossley, London. Improved apparatus for the separation, extraction, and amalgamation of metals. Nov. 24
 15320 H. A. Stuart and C. R. Binney, London. Improvements in machinery for coating metallic sheets or plates with other metal alloys. November 24
 15322 E. C. Kleiner-Fiertz, London. Improvements in and connected with the manufacture of aluminium and other light metals. November 24
 15357 J. T. King, Liverpool—From D. Brose, United States. Improvements in making steel. Complete specification. November 25
 15403 A. J. Boulton, London—From La Société Anonyme de Metallisation Artistiques des Animaux, Vegetaux, ou Autres Corps, France. Preparation of organic matter for metallisation by galvanic deposit
 15476 A. Wilson, London. Manufacture of compound armour-plates. November 26
 15477 E. Morewood, Llanelly. Coating with tin, or other coating metal, sheets, plates or pieces of iron or other metals. November 26
 15515 C. Appleby, London. Machinery or apparatus for reducing to powder mineral ores or other hard substances. November 27
 15534 A. E. Tucker and F. W. Harbord, Smetbwick. Improvements in materials used in the construction of metallurgical furnaces and converters. November 29
 15535 R. Dixon, Stockton-on-Tees. Apparatus for purifying coal or the like material by the washing process. November 29

- 15550 F. J. Riearde-Seaver, London. Linings for furnaces, crucibles, retorts, and the like. November 29
 15591 W. Hlawdon, Middlesbrough. Apparatus for removing and disposing of the slag of blast furnaces. November 30
 15710 L. R. Forbes, London. Construction of armour for ships and other vessels, fortifications, and defences. Dec. 1
 15740 J. Platt, Birmingham. Manufacture of nuts, and process for making iron from which to manufacture nuts. Dec. 2
 15788 T. Cossar and J. Bryce, Glasgow. Enamelling of dairy utensils made of iron or other metal with porcelain, enamel, ground glass, silica of soda, sand, and chloride of sodium. December 3
 15790 W. G. Copestake and C. Jones, Derby. Converting or reconverting old steel, iron, and other kinds of metal into compounds known generally as the different kinds of steel. December 3
 15797 G. Quick, Chipping Campden. Improvements in steel armour-plates. December 3
 15798 G. Quick. Steel armour-plates. December 3
 15804 G. W. Elliott, Sheffield. Appliances for boring and mining rock, coal, and other minerals. December 3
 15831 F. E. Elmore. See Class XVIII.
 15836 J. W. Hall, London—From F. H. Durell, United States. Improvements in ordnance. December 3
 15854 R. Scott, Newcastle-on-Tyne. Miners' safety lamps. December 4
 15879 H. F. Elkington & H. T. Fellows, jun., London. An improvement or improvements in decorating gold, silver, electro-plate, and other metal wares. December 4
 15916 C. Payen, London. Crystallisation of metals by a general method, with variable porosity, and preserving in every instance the crystalline aggregation. December 6
 15946 J. Clark, London. Obtaining alloys of aluminium with certain other metals. December 6
 15965 C. J. Dobbs. See Class IX.
 15978 E. H. Cowles, The Cowles Electric Smelting and Aluminium Co., London. Manufacture of compound armour-plates of aluminium alloys and other metals. December 7
 15987 W. P. Thompson—From H. Reimann. See Class VIII.
 16004 J. Nicholas and H. H. Fanshawe, London. Process for procuring the precious metals from their ores. December 7
 16038 K. M. Deeley, jun., Derby. Process for casting metals. December 8
 16047 G. Ashworth and E. Ashworth, Manchester. Apparatus for hardening and tempering steel wire and tape. Dec. 8
 16065 R. B. Thomas, London. Improvements in cleaning metal plates or sheets. December 8
 16109 S. F. Walker, Cardiff. Electric miners' safety lamps. December 9
 16128 E. de Pass, London—From La Société Anonyme des Mines de Fer de l'Anjou et des Forges de Saint Nazaire, France. A process of converting old steel rails into metallic sleepers for railways, tramways, and the like. December 9
 16224 E. Morewood, Llanelly. Improvements in coating with tin,terne, or other coating metal, sheets, plates, or pieces of iron or other metal. December 10
 16242 C. W. Thompson, Dulwich. Improvement in rock drills. December 11
 16271 T. Lockerbie, London. Construction of regenerative furnaces for melting iron, steel, and other metals or minerals. December 11
 16386 H. E. Newton, London—From J. J. Crooke and R. Crooke, United States. An improved process for treating and desilverising copper matte and copper ores analogous to copper matte. Complete specification. December 11
 16400 J. H. Lancaster, London. Crushing ore and rock. December 11
 16401 G. P. Bradford. See Class I.
 16419 W. A. Bariow, London—From J. Bulliat, France. New or improved means for the manufacture of fine steel from coarse grain steel (Bessemer and such like), and for the regeneration of burnt steel. December 11
 16523 J. E. Bott, S. J. Hackney, and W. Craven, London. Improvements in and apparatus for the production of steel castings, also applicable for melting copper, tin, and other metals. Complete specification. December 16
 16546 H. W. Buddicom, London. Apparatus for tinning plates. December 16
 16563 G. L. Wigg, M. Steele, and W. J. Wigg. See Class VII.
 16574 G. H. Lloyd, Sutton Coldfield, A. L. Lloyd, Leamington, and H. Bewlay, Moseley. Welding and heating, and apparatus connected therewith. December 17
 16608 D. G. Fitzgerald, London. The production of coherent masses of peroxide of lead for use as voltaic battery elements, and for use in electrolytical and metallurgical operations. December 17
 16627 J. W. Noad, P. Higgs, and J. Hobart, London. Production of aluminium. December 18
 16631 C. M. Pielsticker, London. Production of compressed metal castings. December 18
 16658 W. Elmore, F. E. Elmore, and A. S. Elmore, London. Treatment of tin scrap and the like in the obtainment therefrom of oxide of iron and oxide of tin. December 18
 16682 S. Adams, Middlesbrough. Universal mill for rolling iron and steel plates, etc. December 20

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

- 566 R. Hadfield. Production and treatment of steel. Dec. 11
 1359 J. R. Turnock. Apparatus for annealing, pickling, coating, and cleaning metal plates or sheets. December 7
 1796 T. Twynam. Purification of iron and of phosphatic ferruginous slags. December 7

1885 M. Evrard. Machinery for washing coal and other minerals. December 10
 2062 G. F. Simonds. Dies, etc., for use in the production of rolled metal articles. December 14
 2102 H. H. Lake—From Verein Chemischer Fabriken. Recovery of tin from scraps of tinned plate. December 17
 13686 J. Laidler. Miners' safety lamps. November 26
 11238 A. Schmöle. Separating the injurious ferruginous alloys of tin contained in baths for tinning iron. December 7
 14927 J. R. Whitney. "Chills" employed in casting metals. December 17

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

15995 R. Wharry and G. Dyson, London. Making an odourless antiseptic soap. December 7
 16516 W. Boggett, London. Oxidising oils, and apparatus therefor. December 16

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2178 J. Dewrance. Lubricants for steam cylinders. December 17
 11069 A. H. Allen and B. Nickels. Treatment of spent soap leys, crude glycerine, etc., for removal of impurities and recovery of glycerine and other products. December 7

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

15561 W. Carter, London. Anti-fouling composition for ships' bottoms. Complete specification. November 29
 16429 F. W. Hayward, Norwich. Improvements in varnish. December 15

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1086 F. Wendling. Manufacture of paint. November 26
 2310 D. Swan. Improvements in obtaining pigments. December 14

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

15158 J. Pujos, London. A process of treating membranous or interval parts of animals for the manufacture of leather therefrom. November 26
 15632 T. Palmer and L. Palmer, London. Tawing, or treating leather which has been stuffed or dressed with oleaginous substances, and apparatus employed therein. November 30
 15884 C. R. Bonne, London—From P. F. Reinsch, Bavaria. Treatment and tanning of skins, and the manufacture of a new material for tanning and other purposes. December 4
 16647 A. Bedu, London. Manufacture of novel substances suitable for tanning and for other purposes. December 18

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1280 B. Wright. Apparatus for adjusting machines used in splitting leather, hides, and skins. November 30
 1503 J. Hall and A. Hall. Machinery for skiving, bevelling, etc., in the manufacture of leather. December 3
 2052 W. R. Earp. Manufacture of leather. December 10
 14916 E. A. Brydges. Treating and preserving hides and skins. December 17

XIV.—AGRICULTURE, MANURES, ETC.

APPLICATIONS.

15566 H. Fuchs, London. Preparation and application of a material for destroying insects that infest vines. November 29
 16039 W. H. Hartland. See Class XVII., B.
 16244 T. B. Wilson. See Class XVII., B.

XV.—SUGAR, GUMS, STARCHES, ETC.

APPLICATIONS.

15240 O. Bowen and J. Cobeldick. See Class XVII., B.
 16016 F. Scheibler, London. Moulding sugar, and apparatus employed therein. Complete specification. December 7
 16126 J. Frankenbnrg, Manchester. Manufacture of india-rubber for boot and shoe soles, belting, and similar purposes. December 15
 16142 J. Frankenbnrg. Manufacture of india-rubber for boot and shoe soles, belting, and similar purposes, and in apparatus therefor. December 15

16603 A. J. Boulton, London—From J. De Rubio y Daza, Spain. Machines for cutting sugar-canes and the like. December 17
 16615 J. Kelly, London. Making and preparing boiled-sugar goods or sweets. December 17

XVI.—BREWING, WINES, SPIRITS, ETC.

APPLICATIONS.

15528 T. F. Wiley, Bradford—From A. Frolich and Captain Fischer, Denmark. Apparatus for charging beer and analogous liquids with carbonic acid gas, and simultaneously withdrawing such liquids from the reservoirs containing the same. November 29
 15896 W. P. Thompson, Liverpool—From S. Bensande, France. The manufacture of alcohol from manioc, or improvements relating thereto. December 4

COMPLETE SPECIFICATION ACCEPTED.

1886.

13738 H. H. Lake—From J. W. Free. Manufacture of malt, and apparatus therefor.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

APPLICATIONS.

A.—CHEMISTRY OF FOODS.

15161 F. Krietsch, sen., London. Treating leguminous seeds after removal from their pods, to prevent their deterioration. November 26
 15594 W. H. Rhodes, Manchester. An improved means of preserving fruit. November 30
 16270 C. D. Abel, London—From C. Linde, Germany. A process and apparatus for making clear ice. December 11
 16320 F. Edwards, London. The preservation of fish, flesh, fowl, fruit, vegetables, syrups, cider and fruit juices, and other perishable articles of food. December 13
 16691 V. St. Lawrence Symonds, Lewdown. Preserving perishable goods while in transit. December 20

B.—SANITARY CHEMISTRY.

15222 W. Burns, Leith. Improvements in purifying sewage and other foul liquids, and in making oil, alkali, and cement from sewage precipitate, and in apparatus for that purpose. November 23
 15210 O. Bowen and J. Cobeldick, London. An improved decolorising, decolorising, and filtering medium. Nov. 23
 15341 J. Mayer, London. Improvements relating to the treatment of sewage and to apparatus therefor. November 24
 15887 W. F. Nast, London. Treatment of manure and other organic matters, and production therefrom of ammonia and residual products free from ammonia. December 4
 16039 W. H. Hartland, Glasgow. Treating sewage for the recovery and manufacture therefrom of manurial and other products, and in means or apparatus therefor. December 8
 16244 T. B. Wilson, Manchester. Treatment and purification of sewage and other impure liquids, and obtainment of fertilisers therefrom. December 11
 16181 F. D. Brown, London—From A. Howatson, Belgium. An improved method of treating sewage, and apparatus for the purpose. December 15
 16669 B. Haigh, London. Apparatus for disinfecting and decolorising closets, urinals, and the like. December 18

COMPLETE SPECIFICATIONS ACCEPTED.

A.—CHEMISTRY OF FOODS.

1886.

2501 D. Johnson and H. G. R. Davies. Means and apparatus for preserving vegetable matters to be used as food. December 7
 13742 H. H. Lake—From P. B. Rose. Manufacture of an article of food. December 3
 13758 J. Marshall and T. A. Marshall. Preparing a nutrient or digestive and medicinal substance from malt. December 3
 14472 S. Pitt—From J. M. Hughes. Mixture of salt and phosphate of lime for table use. December 11

B.—SANITARY CHEMISTRY.

1886.

10 V. L. E. Miller. Drying of sewage. November 30
 1259 S. D. Cox and J. Cox. Treatment of sewage. November 30

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

15162 N. J. Raffard, London. Method and apparatus for desiccating the insulating coverings of electrical apparatus. Complete specification. November 26

15515 R. Dick and R. Kennedy, Glasgow. Improvements in and relating to the transformation and distribution of electric energy, and appliances therefor. November 29

15533 W. H. Cannon, Merton—From A. M. Richardson, United States. An improved magnetic galvanic battery. December 29

15553 H. H. Lake, London—From E. Shaw, United States. Manufacture of blocks, plates, or rods of carbon for electrical or other purposes. Complete specification. November 30

15733 R. A. Parrish, London. Method and apparatus for producing and utilising electricity. Complete specification. December 1

15762 M. Immisch, London. Electro-magnetic accessories to maritime warfare. December 2

15831 F. E. Elmore, London. Improvements in or connected with means and apparatus for the deposition or obtainment of metals by electrolysis. December 3

15837 J. A. Kingdon, London. Dynamo-electric machinery. December 3

15961 H. H. Lake, London—From Count R. de Montgela, United States. Improvements in electric batteries. Complete specification. December 6

16049 S. F. Walker, Cardiff. Improvements in galvanic batteries. December 8

16050 S. F. Walker. Improvements in dynamo-electric machines. December 8

16085 E. Jones, London. Construction of armatures for dynamo-electric machines. December 8

16110 J. C. Lemmens and H. G. Cottrell, Liverpool. Improvements in primary electric batteries. December 9

16151 W. Webster, jun., London. Improvements in primary voltaic batteries and in the preparation of the elements and solutions employed therein. December 9

16200 F. C. Phillips and H. E. Harrison, Westminster. Dynamo-electric generators and motors. December 10

16201 R. Dick and R. Kennedy, Glasgow. Improvements in and relating to the transformation and distribution of electric energy and appliances therefor. December 10

16210 J. D. F. Andrews, London. Commutating apparatus for transmitting electrical currents to and from inductors, and in commutator brushes. December 10

16211 J. D. F. Andrews. Apparatus for regulating electrical currents. December 10

16215 Sir W. Vavasour, London. Improvements in galvanic batteries. December 10

16237 L. Hendle and J. N. Moerath, London. An improvement of a primary balancing electric battery. December 11

16326 R. Dick and R. Kennedy, Glasgow. Improvements in and relating to the transformation and distribution of electric energy. December 13

16405 A. J. Boulton, London—From P. J. R. Dujardin, France. Improvements in or relating to electric accumulators. December 14

16510 M. Immisch, London. Controlling electric currents at varying speeds of a generating dynamo. December 16

16608 D. G. Fitzgerald. See Class X.

16633 J. Ryan, Newport, Monmouthshire. An instrument for use in the testing of dynamo-electric machines, electro-motors, and the like. December 18

16660 T. Mace and H. Edmunds, London. Apparatus to be employed in the manufacture or treatment of materials suitable for the filaments or incandescing media of electric lamps or for other purposes. December 18

16675 N. G. Thompson, London. Improved primary battery. December 20

16678 G. Hookham, Birmingham. Improvements in dynamo-electric machines with slotted armatures. December 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

15251 S. Z. de Ferranti. Means for distributing electric energy. December 11

16009 R. D. Smillie. Apparatus for measuring electric currents. November 26

1886.

12 C. D. Abel—From Siemens and Halske. Volta inductors. November 26

1610 G. E. Dorman. Secondary or storage batteries. November 30

13151 J. Roper. Cover for the ends of the revolving armatures of dynamo-electric machines. December 10

13159 H. J. Haddon—From F. V. y Graells. Apparatus for regulating automatically the intensity of electric currents. December 11

15251 S. Z. de Ferranti. Means for distributing electric energy. December 11

XIX.—PAPER, PASTEBOARD, ETC.

APPLICATIONS.

15714 W. Pörsch and B. Kirchner, London. Process for the treatment of wood and other vegetable fibres. December 1

15739 H. Harford and C. F. Sutcliffe, South Shields. Improved apparatus for drying paper and other materials. December 2

15823 S. H. Hodges, London. Manufacture of paper and paper board, and apparatus to be used for this purpose. December 3

15856 H. Blackman, London. Disintegrating fibrous substances and manufacturing paper pulp, and apparatus employed therein. December 4

15898 A. E. Symonds and T. Humphrey, London. Manufacture of a solution for treating paper. December 4

16001 O. Melachrin, London. Treatment and preparation of cigarette tubes or papers. December 7

16113 J. M. Walton, Manchester. Construction of boilers for treating wood and other fibre in the manufacture of paper and other pulp. Complete specification. December 9

16538 H. Harford and C. F. Sutcliffe, South Shields. An improved apparatus for drying and finishing paper or other material. December 17

16618 W. H. Wiles, London. A preparation for the use of paper makers to prevent frothing, also stickiness on the press roll, and in which oil will assimilate. December 17

16712 R. McCowan Service. See Class VII.

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1795 J. T. McDougall and J. McDougall. Extracting moisture from wood and other pulp. December 10

1859 H. H. Doty. Waxing paper and textile fabrics, and treating same for antiseptic purposes. December 16

2221 T. Rowland. Apparatus for pulping fibres for the manufacture of paper. December 17

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

15136 H. Byk, London. Process for manufacturing tannin acid in bright semi-transparent or translucent crystals or grains. Complete specification. November 26

15500 H. V. Knaggs, London. Preparations for treating skin diseases. November 27

COMPLETE SPECIFICATION ACCEPTED.

1886.

1551 O. Imray—From J. G. Smith. Manufacture from green ginger of ground ginger, ginger paste, essential oil of ginger essence of ginger, etc. December 3

XXI.—EXPLOSIVES, MATCHES, ETC.

APPLICATIONS.

15521 J. J. Masters, London. Manufacture of wax vesta matches and vesuvians, and flaming fuses with wax vesta stems. November 27

15912 C. Kellner, London. Process for the manufacture of cellulose. December 6

16081 D. Campbell and G. L. Schultz, London. Improvements in and connected with submarine mines. December 8

16196 J. Lauer, London. Improvements relating to the firing of blasting charges in mining and other operations, and to means therefor. December 10

16535 W. H. Noble, London. Manufacture of gunpowder and of gunpowder charges for guns. December 17

16622 F. J. Shand, Glasgow. Fuses for blasting and analogous operations. December 18

16656 H. E. Newton, London—From A. Nobel, France. Improvements in explosions and in the use of explosives especially in shells and torpedoes. December 18

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1955 F. Bolton. Manufacture of explosive compound and preparation of cartridges therefrom. December 11

13011 O. Imray—From G. M. Mowbray. Process and apparatus for manufacturing pyroxyline. December 7

11623 C. E. Bichel. Manufacture of explosive compounds. December 17
